Part I Introduction to Applied Mathematics			
I.1 What Is Applied Mathematics?	1	II.25 Markov Chains	116
I.2 The Language of Applied Mathematics	8	II.26 Model Reduction	117
I.3 Methods of Solution	27	II.27 Multiscale Modeling	119
I.4 Algorithms	40	II.28 Nonlinear Equations and Newton's Method	120
I.5 Goals of Applied Mathematical Research	48	II.29 Orthogonal Polynomials	122
I.6 The History of Applied Mathematics	55	II.30 Shocks	122
		II.31 Singularities	124
		II.32 The Singular Value Decomposition	126
		II.33 Tensors and Manifolds	127
		II.34 Uncertainty Quantification	131
		II.35 Variational Principle	134
		II.36 Wave Phenomena	134
<hr/>			
Part II Concepts			
II.1 Asymptotics	81		
II.2 Boundary Layer	82	III.1 Benford's Law	135
II.3 Chaos and Ergodicity	82	III.2 Bessel Functions	137
II.4 Complex Systems	83	III.3 The Black-Scholes Equation	137
II.5 Conformal Mapping	84	III.4 The Burgers Equation	138
II.6 Conservation Laws	86	III.5 The Cahn-Hilliard Equation	138
II.7 Control	88	III.6 The Cauchy-Riemann Equations	139
II.8 Convexity	89	III.7 The Delta Function and Generalized Functions	139
II.9 Dimensional Analysis and Scaling	90	III.8 The Diffusion Equation	142
II.10 The Fast Fourier Transform	94	III.9 The Dirac Equation	142
II.11 Finite Differences	95	III.10 Einstein's Field Equations	144
II.12 The Finite-Element Method	96	III.11 The Euler Equations	146
II.13 Floating-Point Arithmetic	96	III.12 The Euler-Lagrange Equations	147
II.14 Functions of Matrices	97	III.13 The Gamma Function	148
II.15 Function Spaces	99	III.14 The Ginzburg-Landau Equation	148
II.16 Graph Theory	101	III.15 Hooke's Law	149
II.17 Homogenization	103	III.16 The Korteweg-de Vries Equation	150
II.18 Hybrid Systems	103	III.17 The Lambert W Function	151
II.19 Integral Transforms and Convolution	104	III.18 Laplace's Equation	155
II.20 Interval Analysis	105	III.19 The Logistic Equation	156
II.21 Invariants and Conservation Laws	106	III.20 The Lorenz Equations	158
II.22 The Jordan Canonical Form	112	III.21 Mathieu Functions	159
II.23 Krylov Subspaces	113	III.22 Maxwell's Equations	160
II.24 The Level Set Method	114		

III.23	The Navier-Stokes Equations	162	IV.36	Information Theory	545
III.24	The Painlevé Equations	163	IV.37	Applied Combinatorics and Graph Theory	552
III.25	The Riccati Equation	165	IV.38	Combinatorial Optimization	564
III.26	Schrödinger's Equation	167	IV.39	Algebraic Geometry	570
III.27	The Shallow-Water Equations	167	IV.40	General Relativity and Cosmology	579

Part IV Areas of Applied Mathematics

IV.1	Complex Analysis	173	V.1	The Mathematics of Adaptation (Or the Ten Avatars of Vishnu)	591
IV.2	Ordinary Differential Equations	181	V.2	Sport	598
IV.3	Partial Differential Equations	190	V.3	Inerters	604
IV.4	Integral Equations	200	V.4	Mathematical Biomechanics	609
IV.5	Perturbation Theory and Asymptotics	208	V.5	Mathematical Physiology	616
IV.6	Calculus of Variations	218	V.6	Cardiac Modeling	623
IV.7	Special Functions	227	V.7	Chemical Reactions	627
IV.8	Spectral Theory	236	V.8	Divergent Series: Taming the Tails	634
IV.9	Approximation Theory	248	V.9	Financial Mathematics	640
IV.10	Numerical Linear Algebra and Matrix Analysis	263	V.10	Portfolio Theory	648
IV.11	Continuous Optimization (Nonlinear and Linear Programming)	281	V.11	Bayesian Inference in Applied Mathematics	658
IV.12	Numerical Solution of Ordinary Differential Equations	293	V.12	A Symmetric Framework with Many Applications	661
IV.13	Numerical Solution of Partial Differential Equations	306	V.13	Granular Flows	665
IV.14	Applications of Stochastic Analysis	319	V.14	Modern Optics	673
IV.15	Inverse Problems	327	V.15	Numerical Relativity	680
IV.16	Computational Science	335	V.16	The Spread of Infectious Diseases	687
IV.17	Data Mining and Analysis	350	V.17	The Mathematics of Sea Ice	694

Preface

1 What Is *The Companion*?

The Princeton Companion to Applied Mathematics describes what applied mathematics is about, why it is important, its connections with other disciplines, and some of the main areas of current research. It also explains what applied mathematicians do, which includes not only studying the subject itself but also writing about mathematics, teaching it, and influencing policy makers.

The Companion differs from an encyclopedia in that it is not an exhaustive treatment of the subject, and it differs from a handbook in that it does not cover all relevant methods and techniques. Instead, the aim is to offer a broad but selective coverage that conveys the excitement of modern applied mathematics while also giving an appreciation of its history and the outstanding challenges. *The Companion* focuses on topics felt by the editors to be of enduring interest, and so it should remain relevant for many years to come.

With online sources of information about mathematics growing ever more extensive, one might ask what role a printed volume such as this has. Certainly, one can use Google to search for almost any topic in the book and find relevant material, perhaps on Wikipedia. What distinguishes *The Companion* is that it is a self-contained, structured reference work giving a consistent treatment of the subject. The content has been curated by an editorial board of applied mathematicians with a wide range of interests and experience, the articles have been written by leading experts and have been rigorously edited and copyedited, and the whole volume is thoroughly cross-referenced and indexed.

Within each article, the authors and editors have tried hard to convey the motivation for each topic or concept and the basic ideas behind it, while avoiding unnecessary detail. It is hoped that *The Companion* will be seen as a friendly and inspiring reference, containing both standard material and more unusual, novel, or unexpected topics.

2 Scope

It is difficult to give a precise definition of applied mathematics, as discussed in WHAT IS APPLIED MATHEMATICS? [I.1] and, from a historical perspective, in THE HISTORY OF APPLIED MATHEMATICS [I.6]. *The Companion* treats applied mathematics in a broad sense, and it cannot cover all aspects in equal depth. Some parts of mathematical physics are included, though a full treatment of modern fundamental theories is not given. Statistics and probability are not explicitly included, although a number of articles make use of ideas from these subjects, and in particular the burgeoning area of UNCERTAINTY QUANTIFICATION [II.34] brings together many ideas from applied mathematics and statistics. Applied mathematics increasingly makes use of algorithms and computation, and a number of aspects at the interface with computer science are included. Some parts of discrete and combinatorial mathematics are also covered.

3 Audience

The target audience for *The Companion* is mathematicians at undergraduate level or above; students, researchers, and professionals in other subjects who use mathematics; and mathematically interested lay readers. Some articles will also be accessible to students studying mathematics at pre-university level.

Prospective research students might use the book to obtain some idea of the different areas of applied mathematics that they could work in. Researchers who regularly attend seminars in areas outside their own specialities should find that the articles provide a gentle introduction to some of these areas, making good pre- or post-seminar reading.

In soliciting and editing the articles the editors aimed to maximize accessibility by keeping discussions at the lowest practical level. A good question is how much of the book a reader should expect to understand. Of course “understanding” is an imprecisely defined

concept. It is one thing to read along with an argument and find it plausible, or even convincing, but another to reproduce it on a blank piece of paper, as every undergraduate discovers at exam time. The very wide range of topics covered means that it would take a reader with an unusually broad knowledge to understand everything, but every reader from undergraduate level upward should find a substantial portion of the book accessible.

4 Organization

The Companion is organized in eight parts, which are designed to cut across applied mathematics in different ways.

Part I, “Introduction to Applied Mathematics,” begins by discussing what applied mathematics is and giving examples of the use of applied mathematics in everyday life. THE LANGUAGE OF APPLIED MATHEMATICS [I.2] then presents basic definitions, notation, and concepts that are needed frequently in other parts of the book, essentially giving a brief overview of some key parts of undergraduate mathematics. This article is not meant to be a complete survey, and many later articles provide other introductory material themselves. METHODS OF SOLUTION [I.3] describes some general solution techniques used in applied mathematics. ALGORITHMS [I.4] explains the concept of an algorithm, giving some important examples and discussing complexity issues. The presence of this article in part I reflects the increasing importance of algorithms in all areas of applied mathematics. GOALS OF APPLIED MATHEMATICAL RESEARCH [I.5] describes the kinds of questions and issues that research in applied mathematics addresses and discusses some strategic aspects of carrying out research. Finally, THE HISTORY OF APPLIED MATHEMATICS [I.6] describes the history of the subject from ancient times up until the late twentieth century.

Part II, “Concepts,” comprises short articles that explain specific concepts and their significance. These are mainly concepts that cut across different models and areas and provide connections to other parts of the book. This part is not meant to be comprehensive, and many other concepts are well described in later articles (and discoverable via the index).

Part III, “Equations, Laws, and Functions of Applied Mathematics,” treats important examples of what its title describes. The choice of what to include was based on a mix of importance, accessibility, and interest. Many equations, laws, and functions not contained in this part are included in other articles.

Part IV, “Areas of Applied Mathematics,” contains longer articles giving an overview of the whole subject and how it is organized, arranged by research area. The aim of this part is to convey the breadth, depth, and diversity of applied mathematics research. The coverage is not comprehensive, but areas that do not appear as or in article titles may nevertheless be present in other articles. For example, there is no article on geoscience, yet EARTH SYSTEM DYNAMICS [IV.30], INVERSE PROBLEMS [IV.15], and IMAGING THE EARTH USING GREEN’S THEOREM [VII.16] all cover specific aspects of this area. Nor is there a part IV article on numerical analysis, but this area is represented by APPROXIMATION THEORY [IV.9], NUMERICAL LINEAR ALGEBRA AND MATRIX ANALYSIS [IV.10], CONTINUOUS OPTIMIZATION (NONLINEAR AND LINEAR PROGRAMMING) [IV.11], NUMERICAL SOLUTION OF ORDINARY DIFFERENTIAL EQUATIONS [IV.12], and NUMERICAL SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS [IV.13].

Part V, “Modeling,” gives a selection of mathematical models, explaining how the models are derived and how they are solved.

Part VI, “Example Problems,” contains short articles covering a variety of interesting applied mathematics problems.

Part VII, “Application Areas,” comprises articles on connections between applied mathematics and other disciplines, including such diverse topics as integrated circuit (chip) design, medical imaging, and the screening of luggage in airports.

Part VIII, “Final Perspectives,” contains essays on broader aspects, including reading, writing, and typesetting mathematics; teaching applied mathematics; and how to influence government as a mathematician.

The articles within a given part vary significantly in length. This should not be taken as an indication of the importance of the corresponding topic, as it is partly due to the number of pages that could be allocated to each article, as well as to how authors responded to their given page limit.

The ordering of articles within a part is alphabetical for parts II and III. For part IV some attempt was made to place related articles together and to place one article before another if there is a natural order in which to read the two articles. The ordering is nevertheless somewhat arbitrary, and the reader should feel free to read the articles in any order. The articles within parts V–VIII are arranged only loosely by theme.

The editors made an effort to encourage illustrations and diagrams. Due to the cost of reproduction, color has been used only where necessary and is restricted to the color plates following page 364.

Despite the careful organization, the editors expect that many readers will flick through the book to find something interesting, start reading, and by following cross-references navigate the book in an unpredictable fashion. This approach is perfectly reasonable, as is starting from a page found via the table of contents or the index. Whatever the reading strategy, we hope the book will be hard to put down!

5 Relation to *The Princeton Companion to Mathematics*

This *Companion* follows the highly successful *Princeton Companion to Mathematics* (PCM), edited by Gowers, Barrow-Green, and Leader (2008), which focuses on modern pure mathematics. We have tried to build on the PCM and avoid overlap with it. Thus we do not cover many of the basic mathematical concepts treated in parts I and II of the PCM, but rather assume the reader is familiar with them.

Some crucial concepts that are already in the PCM are included here as well, but they are approached from a rather different viewpoint, typically with more discussion of applications and computational aspects.

Some articles in the PCM, listed in table 1, could equally well have appeared here, and the editors therefore made a decision not to solicit articles on these same general topics. However, particular aspects of several of these topics are included.

6 How to Use This Book

Authors were asked to make their articles as self-contained as possible and to define specific notation and technical terms. You should familiarize yourself with the material in THE LANGUAGE OF APPLIED MATHEMATICS [I.2], as this background is assumed for many of the later articles. If you are unsure about notation consult table 3 in I.2 or, for a definition, see if it is in the index. The editors, with the help of a professional indexer, have tried very hard to produce a thorough and usable index, so there is a good chance that the index will lead you to a place in the book where a particular piece of notation or a definition is clarified.

The extensive cross-references provide links between articles. A phrase such as “this vector can be computed by the FAST FOURIER TRANSFORM [II.10]” indicates that

Table 1 Relevant articles from *The Princeton Companion to Mathematics* whose topic is not duplicated here.

Title	PCM article number
Mathematics and Chemistry	VII.1
Mathematical Biology	VII.2
Wavelets and Applications	VII.3
The Mathematics of Traffic in Networks	VII.4
Mathematics and Cryptography	VII.7
Mathematical Statistics	VII.10
Mathematics and Medical Statistics	VII.11
Mathematics and Music	VII.13

article 10 in part II contains more information on the fast Fourier transform.

In the research literature it is normal to support statements by citations to items in a bibliography. It is a style decision of *The Companion* not to include citations in the articles. The articles present core knowledge that is generally accepted in the field, and omitting citations makes for a smoother reading experience as the reader does not constantly have to refer to a list of references a few pages away. Many authors found it quite difficult to adopt this style, being so used to liberally sprinkling \cite commands through their L^AT_EX documents! Most articles have a further reading section, which provides a small number of sources that provide an entrée into the literature on that topic.

7 The Companion Project

I was invited to lead the project in late 2009. After the editorial board was assembled and the format of the book and the outline of its contents were agreed at a meeting of the board in Manchester, invitations to authors began to go out in 2011. We aimed to invite authors who are both leaders in their field and excellent writers. We were delighted with the high acceptance rate.

Ludwig Boltzmann was a contributor to the six-volume *Encyclopedia of Mathematical Sciences* (1898–1933) edited by Felix Klein, Wilhelm Meyer, and others. In 1905, he wrote, apropos of the selected author of an article:

He must first be persuaded to promise a contribution; then, he must be instructed and pressed with all means of persuasion to write a contribution which fits into the general framework; and last, but not least, he must be urged to fulfill his promise in a timely matter.

Over a hundred years later these comments remain true, and one of the reasons for the long gestation period of a book such as this is that it does take a long time to sign up authors and collect articles. Occasionally, we were unable to find an author willing and able to deliver an article on a particular topic, so a small number of topics that we would have liked to include had to be omitted.

Of the 165 authors, at least two had babies during the course of preparing their articles. Sadly, one author, David Broomhead, did not live to see the project completed.

If the project has gone well, one of the reasons is the thoroughly professional and ever-cheerful support provided by Sam Clark of T&T Productions Ltd in London. Sam acted as project manager, copy editor, and typesetter, and made the process as smooth and painless for the editors and contributors as it could be. Sam played the same role for the *The Princeton Companion to Mathematics*, and his experience of that project was invaluable.

8 Acknowledgments

I am grateful to the members of the editorial board for their advice and their work on the project, and for traveling to three editorial board meetings, in Manchester, Minneapolis, and London.

A number of people beyond the editorial board have given me valuable comments on my own draft articles, especially those in part I, at different stages of the project. I thank, in particular, Doug Arnold, Des Higham, David Nelson, Nick Trefethen, and my Manchester colleagues Mary Aprahamian, Edvin Deadman, Stefan Güttel, Sven Hammarling, Oliver Jensen,

Ramaseshan Kannan, Lijing Lin, Martin Lotz, Jennifer Pestana, Sam Relton, Vedran Šego, Nataša Strabić, Leo Tasleman, and Françoise Tisseur. Nick Trefethen also provided many valuable comments on a late version of the whole book.

It has been a pleasure to work with Sam Clark, with our level of cooperation being demonstrated by the 3000-plus emails that have traveled between us. I was constantly impressed not only by Sam's ability to find improvements in authors' submitted text during the copyediting phase but also by his ability to turn author-supplied figures of a widely varying standard into high-quality figures with a consistent style.

The original Princeton University Press editor for the project was Anne Savarese, who had also worked on *The Princeton Companion to Mathematics*. Anne's experience and advice was invaluable in formulating the plans for *The Companion*, and she shepherded the project through to the late stages with skill and patience. Vickie Kearn took over from Anne for the last eighteen months of the project, after Anne moved to another editorial role at the Press. A smooth transition was aided by Vickie's extensive knowledge of the world of mathematics publishing and by my having known her since the early 1990s when, as an editor at the Society for Industrial and Applied Mathematics (SIAM), she published my first book.

I would also like to thank Terri O'Prey, who oversaw the production at the Press, and indexer Julie Shawvan.

Finally, I thank my wife Françoise Tisseur and my sons Freddie and Thomas for uncomplainingly allowing me to spend many evenings and weekends working on *The Companion*.

Part I

Introduction to Applied Mathematics

I.1 What Is Applied Mathematics?

Nicholas J. Higham

1 The Big Picture

Applied mathematics is a large subject that interfaces with many other fields. Trying to define it is problematic, as noted by William Prager and Richard Courant, who set up two of the first centers of applied mathematics in the United States in the first half of the twentieth century, at Brown University and New York University, respectively. They explained that:

Precisely to define applied mathematics is next to impossible. It cannot be done in terms of subject matter: the borderline between theory and application is highly subjective and shifts with time. Nor can it be done in terms of motivation: to study a mathematical problem for its own sake is surely not the exclusive privilege of pure mathematicians. Perhaps the best I can do within the framework of this talk is to describe applied mathematics as the bridge connecting pure mathematics with science and technology.

Prager (1972)

Applied mathematics is not a definable scientific field but a human attitude. The attitude of the applied scientist is directed towards finding clear cut answers which can stand the test of empirical observation. To obtain the answers to theoretically often insuperably difficult problems, he must be willing to make compromises regarding rigorous mathematical completeness; he must supplement theoretical reasoning by numerical work, plausibility considerations and so on.

Courant (1965)

Garrett Birkhoff offered the following view in 1977, with reference to the mathematician and physicist Lord Rayleigh (John William Strutt, 1842–1919):

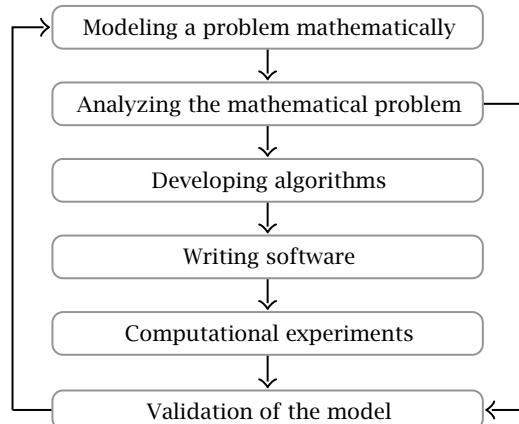

Figure 1 The main steps in solving a problem in applied mathematics.

Essentially, mathematics becomes “applied” when it is used to solve real-world problems “neither seeking nor avoiding mathematical difficulties” (Rayleigh).

Rather than define what applied mathematics is, one can describe the methods used in it. Peter Lax stated of these methods, in 1989, that:

Some of them are organic parts of pure mathematics: rigorous proofs of precisely stated theorems. But for the greatest part the applied mathematician must rely on other weapons: special solutions, asymptotic description, simplified equations, experimentation both in the laboratory and on the computer.

Here, instead of attempting to give our own definition of applied mathematics we describe the various facets of the subject, as organized around solving a problem. The main steps are described in figure 1. Let us go through each of these steps in turn.

Modeling a problem. Modeling is about taking a physical problem and developing equations—differential, difference, integral, or algebraic—that capture the essential features of the problem and so can be used to obtain qualitative or quantitative understanding of its behavior. Here, “physical problem” might refer to a vibrating string, the spread of an infectious disease, or the influence of people participating in a social network. Modeling is necessarily imperfect and requires simplifying assumptions. One needs to retain enough aspects of the system being studied that the model reproduces the most important behavior but not so many that the model is too hard to analyze. Different types of models might be feasible (continuous, discrete, stochastic), and for a given type there can be many possibilities. Not all applied mathematicians carry out modeling; in fact, most join the process at the next step.

Analyzing the mathematical problem. The equations formulated in the previous step are now analyzed and, ideally, solved. In practice, an explicit, easily evaluated solution usually cannot be obtained, so approximations may have to be made, e.g., by discretizing a differential equation, producing a reduced problem. The techniques necessary for the analysis of the equations or reduced problem may not exist, so this step may involve developing appropriate new techniques. If analytic or perturbation methods have been used then the process may jump from here directly to validation of the model.

Developing algorithms. It may be possible to solve the reduced problem using an existing algorithm—a sequence of steps that can be followed mechanically without the need for ingenuity. Even if a suitable algorithm exists it may not be fast or accurate enough, may not exploit available structure or other problem features, or may not fully exploit the architecture of the computer on which it is to be run. It is therefore often necessary to develop new or improved algorithms.

Writing software. In order to use algorithms on a computer it is necessary to implement them in software. Writing reliable, efficient software is not easy, and depending on the computer environment being targeted it can be a highly specialized task. The necessary software may already be available, perhaps in a package or program library. If it is not, software is ideally developed and documented to a high standard and made available to others. In many cases the software stage consists simply of writing short programs, scripts, or

notebooks that carry out the necessary computations and summarize the results, perhaps graphically.

Computational experiments. The software is now run on problem instances and solutions obtained. The computations could be numeric or symbolic, or a mixture of the two.

Validation of the model. The final step is to take the results from the experiments (or from the analysis, if the previous three steps were not needed), interpret them (which may be a nontrivial task), and see if they agree with the observed behavior of the original system. If the agreement is not sufficiently good then the model can be modified and the loop through the steps repeated. The validation step may be impossible, as the system in question may not yet have been built (e.g., a bridge or a building).

Other important tasks for some problems, which are not explicitly shown in our outline, are to calibrate parameters in a model, to quantify the uncertainty in these parameters, and to analyze the effect of that uncertainty on the solution of the problem. These steps fall under the heading of **UNCERTAINTY QUANTIFICATION** [II.34].

Once all the steps have been successfully completed the mathematical model can be used to make predictions, compare competing hypotheses, and so on. A key aim is that the mathematical analysis gives new insights into the physical problem, even though the mathematical model may be a simplification of it.

A particular applied mathematician is most likely to work on just some of the steps; indeed, except for relatively simple problems it is rare for one person to have the skills to carry out the whole process from modeling to computer solution and validation.

In some cases the original problem may have been communicated by a scientist in a different field. A significant effort can be required to understand what the mathematical problem is and, when it is eventually solved, to translate the findings back into the language of the relevant field. Being able to talk to people outside mathematics is therefore a valuable skill for the applied mathematician.

It would be wrong to give the impression that all applied mathematics is done in the context of modeling. Frequently, a mathematical problem will be tackled because of its inherent interest (see the quote from Prager above) with the hope or expectation that a relevant application will be found. Indeed some applied

mathematicians spend their whole careers working in this way. There are many examples of mathematical results that provide the foundations for important practical applications but were developed without knowledge of those applications (sections 3.1 and 3.2 provide such examples).

Before the twentieth century, applied mathematics was driven by problems in astronomy and mechanics. In the twentieth century physics became the main driver, with other areas such as biology, chemistry, economics, engineering, and medicine also providing many challenging mathematical problems from the 1950s onward. With the massive and still-growing amounts of data available to us in today's digital society we can expect information, in its many guises, to be an increasingly important influence on applied mathematics in the twenty-first century.

For more on the definition and history of applied mathematics, including the development of the term "applied mathematics," see the article HISTORY OF APPLIED MATHEMATICS [I.6].

2 Applied Mathematics and Pure Mathematics

The question of how applied mathematics compares with pure mathematics is often raised and has been discussed by many authors, sometimes in controversial terms. We give a few highlights.

Paul Halmos wrote a 1981 paper provocatively titled "Applied mathematics is bad mathematics." However, much of what Halmos says would not be disputed by many applied mathematicians. For example:

Pure mathematics can be practically useful and applied mathematics can be artistically elegant....

Just as pure mathematics can be useful, applied mathematics can be more beautifully useless than is sometimes recognized....

Applied mathematics is an intellectual discipline, not a part of industrial technology....

Not only, as is universally admitted, does the applied need the pure, but, in order to keep from becoming inbred, sterile, meaningless, and dead, the pure needs the revitalization and the contact with reality that only the applied can provide.

G. H. Hardy's book *A Mathematician's Apology* (1940) is well known as a defense of mathematics as a subject that can be pursued for its own sake and beauty. As such it contains some criticism of applied mathematics:

But is not the position of an ordinary applied mathematician in some ways a little pathetic? If he wants to be useful, he must work in a humdrum way, and he cannot give full play to his fancy even when he wishes to rise to the heights. "Imaginary" universes are so much more beautiful than this stupidly constructed "real" one; and most of the finest products of an applied mathematician's fancy must be rejected, as soon as they have been created, for the brutal but sufficient reason that they do not fit the facts.

Halmos and Hardy were pure mathematicians. Applied mathematicians C. C. Lin and L. A. Segel offer some insights in the introductory chapter of their classic 1974 book *Mathematics Applied to Deterministic Problems in the Natural Sciences*:

The differences in motivation and objectives between pure and applied mathematics—and the consequent differences in emphasis and attitude—must be fully recognized. In pure mathematics, one is often dealing with such abstract concepts that logic remains the only tool permitting judgment of the correctness of a theory. In applied mathematics, empirical verification is a necessary and powerful judge. However...in some cases (e.g., celestial mechanics), rigorous theorems can be proved that are also valuable for practical purposes. On the other hand, there are many instances in which new mathematical ideas and new mathematical theories are stimulated by applied mathematicians or theoretical scientists.

They also opine that:

Much second-rate pure mathematics is concealed beneath the trappings of applied mathematics (and vice versa). As always, knowledge and taste are needed if quality is to be assured.

The applied versus pure discussion is not always taken too seriously. Chandler Davis quotes the applied mathematician Joseph Keller as saying, "pure mathematics is a subfield of applied mathematics"!

The discussion can also focus on where in the spectrum a particular type of mathematics lies. An interesting story was told in 1988 by Clifford Truesdell of his cofounding in 1952 of the *Journal of Rational Mechanics and Analysis* (which later became *Archive for Rational Mechanics and Analysis*). He explained that

In those days papers on the foundation of continuum mechanics were rejected by journals of mathematics as being applied, by journals of "applied" mathematics as being physics or pure mathematics, by journals of physics as being mathematics, and by all of them as too long, too expensive to print, and of interest to no one.

3 Applied Mathematics in Everyday Life

We now give three examples of applied mathematics in use in everyday life. These examples were chosen because they can be described without delving into too many technicalities and because they illustrate different characteristics. Some of the terms used in the descriptions are explained in THE LANGUAGE OF APPLIED MATHEMATICS [I.2].

3.1 Searching Web Pages

In the early to mid-1990s—the early days of the World Wide Web—search engines would find Web pages that matched a user’s search query and would order the results by a simple criterion such as the number of times that the search query appears on a page. This approach became unsatisfactory as the Web grew in size and spammers learned how to influence the search results. From the late 1990s onward, more sophisticated criteria were developed, based on analysis of the links between Web pages. One of these is Google’s PAGERANK ALGORITHM [VI.9]. Another is the hyperlink-induced topic search (HITS) algorithm of Kleinberg.

The HITS algorithm is based on the idea of determining hubs and authorities. *Authorities* are Web pages with many links to them and for which the linking pages point to many authorities. For example, the *New York Times* home page or a Wikipedia article on a popular topic might be an authority. *Hubs* are pages that point to many authorities. An example might be a page on a programming language that provides links to useful pages about that language but that does not necessarily contain much content itself. The authorities are the pages that we would like to rank higher among pages that match a search term. However, the definition of hubs and authorities is circular, as each depends on the other.

To resolve this circularity, associate an authority weight x_i and a hub weight y_i with page i , with both weights nonnegative. Let there be n pages to be considered (in practice this is a much smaller number than the total number of pages that match the search term). Define an $n \times n$ matrix $A = (a_{ij})$ by $a_{ij} = 1$ if there is a hyperlink from page i to page j and by $a_{ij} = 0$ otherwise. Let us make initial guesses $x_i^{(0)} = 1$ and $y_i^{(0)} = 1$, for $i = 1, 2, \dots, n$. It is reasonable to update the authority weight x_i for page i by replacing it by the sum of the weights of the hubs that point to it. Similarly, the hub weight y_i for page i can be replaced by the sum of the weights of the authorities to which it

points. In equations, these updates can be written as $x_i^{(1)} = \sum_{a_{ji} \neq 0} y_j^{(0)}$ and $y_i^{(1)} = \sum_{a_{ij} \neq 0} x_j^{(1)}$; note that in the latter equation we are using the updated authority weights, and the sums are over those j for which a_{ji} or a_{ij} is nonzero, respectively. This process can be iterated:

$$\left. \begin{aligned} x_i^{(k+1)} &= \sum_{a_{ji} \neq 0} y_j^{(k)} \\ y_i^{(k+1)} &= \sum_{a_{ij} \neq 0} x_j^{(k+1)} \end{aligned} \right\} \quad k = 0, 1, 2, \dots$$

The circular definition of hubs and authorities has been turned into an iteration. The iteration is best analyzed by rewriting it in matrix–vector form. Defining the n -vectors

$$\begin{aligned} x_k &= [x_1^{(k)}, x_2^{(k)}, \dots, x_n^{(k)}]^T, \\ y_k &= [y_1^{(k)}, y_2^{(k)}, \dots, y_n^{(k)}]^T \end{aligned}$$

and recalling that the elements of A are 0 or 1, we can rewrite the iteration as

$$\left. \begin{aligned} x_{k+1} &= A^T y_k \\ y_{k+1} &= A x_{k+1} \end{aligned} \right\} \quad k = 0, 1, 2, \dots,$$

where $A^T = (a_{ji})$ is the transpose of A . Combining the two formulas into one gives $x_{k+1} = A^T y_k = A^T (A x_k) = (A^T A)x_k$. Hence the x_k are generated by repeatedly multiplying by the matrix $A^T A$. Each element of $A^T A$ is either zero or a positive integer, so the powers of $A^T A$ will usually grow without bound. In practice we should therefore normalize the vectors x_k and y_k so that the largest element is 1; this avoids overflow and has no effect on the relative sizes of the components, which is all that matters. Our iteration is then

$$x_{k+1} = c_k^{-1} A^T A x_k,$$

where c_k is the largest element of $A^T A x_k$. If the sequences x_k and c_k converge, say to x_* and c_* , respectively, then $A^T A x_* = c_* x_*$. This equation says that x_* is an eigenvector of $A^T A$ with corresponding eigenvalue c_* . A similar argument shows that, if the normalized sequence of vectors y_k converges, then it must be to an eigenvector of $A A^T$.

This process of repeated multiplication by a matrix is known as the POWER METHOD [IV.10 §5.5]. The PERRON-FROBENIUS THEOREM [IV.10 §11.1] can be used to show that, provided the matrix $A^T A$ has a property called irreducibility, it has a unique eigenvalue of largest magnitude and this eigenvalue is real and positive, with an associated eigenvector x having positive entries. Convergence theory for the power method then shows that

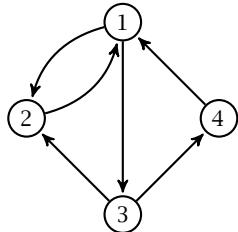

Figure 2 Graph representing four Web pages and the links between them.

x_k converges to a multiple of x . Therefore, the vectors x_* and y_* required for the HITS algorithm are the eigenvectors corresponding to the dominant eigenvalues of $A^T A$ and $A A^T$, respectively. Another interpretation of these vectors is that they are the right and left SINGULAR VECTORS [II.32] corresponding to the dominant singular value of A .

We give a simple example to illustrate the algorithm. Consider the network of four Web pages shown in figure 2 in a DIRECTED GRAPH [II.16] representation. The corresponding matrix is

$$A = \begin{bmatrix} 0 & 1 & 1 & 0 \\ 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 \end{bmatrix}.$$

The HITS algorithm produces

$$x = \begin{bmatrix} 0 \\ 1 \\ 0.5 \\ 0.5 \end{bmatrix}, \quad y = \begin{bmatrix} 1 \\ 0 \\ 1 \\ 0 \end{bmatrix}.$$

This tells us that page 2 is the highest-ranked authority and pages 1 and 3 are the jointly highest-ranked hubs, which is an intuitively reasonable ranking.

This Web search example illustrates the steps in figure 1. The first step, modeling, yields the notion of hubs and authorities. The production of the iteration for the weights is the analysis step, which for this problem overlaps with the third step of developing algorithms, because the iteration is a practical means for computing the hubs and authorities. However, other algorithms could be used for this purpose, so much more can be done in the third step. Implementing the iteration in software (the fourth step) is straightforward if we assume the matrix A is given. The computational experiments in the fifth step should use real data from particular Web searches. Probably the most difficult step is the final one: validating the model. The

reason for this is that there is no natural quantitative measure of the goodness of a ranking based on the computed authorities; this assessment requires human judgment.

A final point to note is that further insight into the HITS algorithm can be obtained using GRAPH THEORY [II.16]. In general, there may be multiple ways to analyze a problem and it may be necessary to employ more than one technique to obtain a complete understanding.

3.2 Digital Imaging

Image retouching refers to the process of changing a digital image to make it more visually pleasing by removing a color cast, creatively adjusting color and contrast, smoothing out wrinkles on a subject's face in a portrait, and so on. In the days of film cameras, image retouching was carried out by professionals on scanned images using expensive hardware and software. Since the advent of digital cameras retouching has become something that anyone can attempt, even on a smartphone with a suitable app. An operation called "cloning" is of particular interest. Cloning is the operation of copying one area of an image over another and is commonly used to remove defects or unwanted elements from an image, such as dust spots on the camera sensor, litter in a landscape, or someone's limbs intruding into the edge of an image.

Cloning tools in modern software use sophisticated mathematics to blend the image fragment being copied into the target area. Let us represent the image as a function f of two variables, where $f(x, y)$ is an RGB (red, green, blue) triple corresponding to the point (x, y) . In practice, an image is a discrete grid of points and the RGB values are integers. Our goal is to replace an open target region Ω by a source region that has the same shape and size but is in a different location in the image, and that therefore corresponds to a translation $(\delta x, \delta y)$. If we simply copy the source region into the target, the result will not be convincing visually, as it neither preserves texture nor matches up well around the boundary $\partial\Omega$ (see figure 3). To alleviate these problems we can replace f inside Ω by the function g defined by the partial differential equation (PDE) problem

$$\begin{aligned} \Delta g(x, y) &= \Delta f(x + \delta x, y + \delta y), & (x, y) \in \Omega, \\ g(x, y) &= f(x, y), & (x, y) \in \partial\Omega, \end{aligned}$$

where $\Delta = \partial^2/\partial x^2 + \partial^2/\partial y^2$ is the LAPLACE OPERATOR [III.18]. We are forcing g to be identical to f on

the boundary of the target region, but inside the region the Laplacian of g has to match that of f in the source region. This is a Poisson equation with Dirichlet boundary condition. Since the Laplace operator is connected with diffusion effects in equilibrium, we can think of the pixels in the image diffusing to form a more convincing visual result. Another interpretation, which shows that the solution has optimal smoothness in a certain sense, is that we are minimizing $\int_{\Omega} \|\nabla g - \nabla f\|^2 d\Omega$, where $\nabla = [\partial/\partial x \ \partial/\partial y]^T$ is the gradient operator and $\|\cdot\|$ is the L_2 -NORM [I.2 §19.3]. In practice, the PDE is solved by a NUMERICAL METHOD [IV.13].

Adobe Photoshop, the digital image manipulation software originally released in 1990, introduced a new feature called the healing brush in 2002. It carries out the sophisticated cloning just outlined but solves the biharmonic equation $\Delta^2 g(x, y) = \Delta^2 f(x + \delta x, y + \delta y)$, where $\Delta^2 = \partial^4/\partial x^4 + 2\partial^4/(\partial x^2 \partial y^2) + \partial^4/\partial y^4$, because this has been found to provide better matching of derivatives on the boundary and thereby produces a better blending of the source into the area containing the target. In this case we are minimizing $\int_{\Omega} (\Delta g - \Delta f)^2 d\Omega$. See figure 3.

The idea of using the Poisson equation or the biharmonic equation to fill in gaps in two-dimensional data appears in other application areas too, such as in mapping and contouring of geophysical data, where it was proposed as early as the 1950s.

A related problem is how to detect when an image has been subject to cloning. Applications include checking the veracity of images appearing in the media or used as evidence in legal cases and checking the eligibility of entries to a photographic competition in which image manipulation is disallowed. The same ideas that make cloning possible also enable its use to be detected. For example, even though the values in the target and source areas are different, the Laplacian or biharmonic operators yield the same values, so a systematic search can be done to find different areas with this property. One complication is that if the image has been compressed after cloning, as is typically done with JPEG COMPRESSION [VII.7 §5], the uncompressed image contains noise that causes the derivatives in question no longer to match exactly. Having to deal with noise is a common requirement in applied mathematics.

3.3 Computer Arithmetic

In modern life we rely on computers to carry out arithmetic calculations for a wide range of tasks, including

computation of financial indices, aircraft flight paths, and utility bills. We take it for granted that these calculations produce the “correct result,” but they do not always do so, and there are infamous examples where inaccurate results have had disastrous consequences. Applied mathematicians and computer scientists have been responsible for ensuring that today’s computer calculations are more reliable than ever.

Probably the most important advance in computer arithmetic in the last fifty years was the development of the 1985 IEEE standard for binary FLOATING-POINT ARITHMETIC [II.13]. Prior to the development of the standard, different computers used different implementations of floating-point arithmetic that were of varying quality. For example, on some computers of the 1980s a test such as

```

1  if x ≠ y
2    f = f / (x - y)
3  end

```

could fail with division by zero because the difference $x - y$ evaluated to zero even though x was not equal to y . This failure is not possible in IEEE-compliant arithmetic.

Some features of the IEEE standard are more unexpected. For example, it includes a special number inf that represents ∞ and satisfies the natural relations. For example, $1/0$ evaluates to inf , $1/\text{inf}$ evaluates to 0 , and $1 + \text{inf}$ and $\text{inf} + \text{inf}$ produce inf . If a program does divide by zero then this does not halt the program and it can be tested for and appropriate action taken. But division by zero does not necessarily signify a problem. For example, if we evaluate the function

$$f(x) = \frac{1}{1 + \frac{1}{1-x}}$$

at $x = 1$, IEEE arithmetic correctly yields $f(1) = 1/(1 + \infty) = 0$. In 1997 the USS Yorktown, a guided missile cruiser, was paralyzed (“dead in the water” according to the commander) for $2\frac{3}{4}$ hours when a crewman entered a zero into a database and a division by zero was triggered that caused the program to crash. The incident could have been avoided if IEEE standard features such as inf had been fully utilized.

The development of the IEEE standard took many years and required much mathematical analysis of the various options. The benefits brought by the standard include increased portability of programs

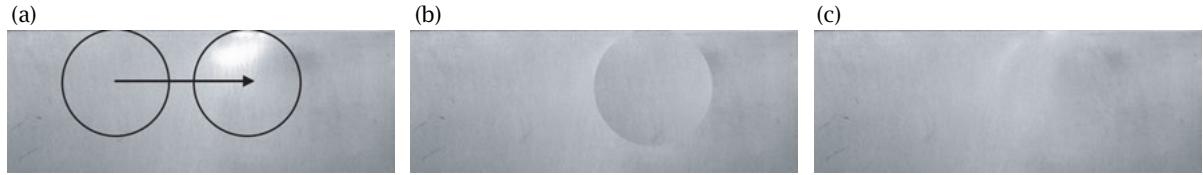

Figure 3 Close-up of part of a metal sign with a hot spot from a reflection. (a) Original image showing source and target regions. (b) The result of copying source to target. (c) The result of one application of Photoshop healing brush with same target area. In practice, multiple applications of the healing brush would be used with smaller, overlapping target areas.

between different computers and an improved ability for mathematicians to understand the way algorithms will behave when implemented in floating-point arithmetic.

In IEEE double-precision arithmetic, numbers are represented to a precision equivalent to about sixteen significant decimal digits. In many situations in life, results are needed to far fewer figures and a final result must be *rounded*. For example, a conversion from euros to dollars producing an answer \$110.89613 might be rounded up to \$110.90: the nearest amount in whole cents. A bank paying the dollars into a customer's account might prefer to round down to \$110.89 and keep the remainder. However, deciding on the rules for rounding was not so simple when the euro was founded in 1997. A twenty-nine-page document was needed to specify precisely how conversions among the fifteen currencies of the member states and the euro should be done. Its pronouncements included how many significant figures each individual conversion rate should have (six was the number that was chosen), how rounding should be done (round to the nearest six-digit number), and how ties should be handled (always round up).

Even when rounding should be straightforward it is often carried out incorrectly. In 1982 the Vancouver Stock Exchange established an index with an initial value of 1000. After twenty-two months the index had been hitting lows in the 520s, despite the exchange apparently performing well. The index was recorded to three decimal places and it was discovered that the computer program calculating the index always rounded down, hence always underestimating the index. Upon recalculation (presumably with round to nearest) the index almost doubled.

In 2006 athlete Justin Gatlin was credited with a new world record of 9.76 seconds for the 100 meters. Almost a week after the race the time was changed to 9.77 seconds, meaning that he had merely equaled the existing record held by Asafa Powell. The reason for the

change was that his recorded time of 9.766 had incorrectly been rounded down to the nearest hundredth of a second instead of up as the International Association of Athletics Federations rules require.

4 What Do Applied Mathematicians Do?

Applied mathematicians can work in academia, industry, or government research laboratories. Their work may involve research, teaching, and (especially for more senior mathematicians) administrative tasks such as managing teams of people. They usually spend only part of their time doing mathematics in the traditional sense of sitting with pen and paper scribbling formulas on paper and trying to solve equations or prove theorems. Under the general heading of research, a lot of time is spent writing papers, books, grant proposals, reports, lecture notes, and talks; attending seminars, conferences, and workshops; writing and running computer programs; reading papers in the research literature; refereeing papers submitted to journals and grant proposals submitted to funding bodies; and commenting on draft papers and theses written by Ph.D. students.

Mathematics can be a lonely endeavor: one may be working on different problems from one's colleagues or may be the only mathematician in a company. Although some applied mathematicians prefer to work alone, many collaborate with others, often in faraway countries. Collaborations are frequently initiated through discussions at conferences, though sometimes papers are coauthored by people who have never met, thanks to the ease of email communication.

Applied mathematics societies provide an important source of identity and connectivity, as well as opportunities for networking and professional development. They mostly focus on particular countries or regions, an exception being the Society for Industrial and Applied Mathematics (SIAM), based in Philadelphia. SIAM is the largest applied mathematics organization

in the world and has a strong international outlook, with about one-third of its members residing outside the United States. A mathematician's activities are frequently connected with societies, whether it be through publishing in or editing their journals, attending their conferences, or keeping up with news through their magazines and newsletters. Most societies offer greatly reduced membership fees (sometimes free membership) for students.

Applied mathematicians can be part of multidisciplinary teams. Their skills in problem solving, thinking logically, modeling, and programming are sought after in other subjects, such as medical imaging, weather prediction, and financial engineering.

In the business world, applied mathematics can be invisible because it is called “analytics,” “modeling,” or simply generic “research.” But whatever their job title, applied mathematicians play a crucial role in today’s knowledge-based economy.

5 What Is the Impact of Applied Mathematics?

The impact of applied mathematics is illustrated in many articles in this volume, and in this section we provide just a brief overview, concentrating on the impact outside mathematics itself.

Applied mathematics provides the tools and algorithms to enable understanding and predictive modeling of many aspects of our planet, including WEATHER [V.18] (for which the accuracy of forecasts has improved greatly in recent decades), ATMOSPHERE AND THE OCEANS [IV.30], TSUNAMIS [V.19], and SEA ICE [V.17]. In many cases the models are used to inform policy makers.

At least two mathematical algorithms are used by most of us almost every day. The FAST FOURIER TRANSFORM [II.10] is found in any device that carries out signal processing, such as a smartphone. Photos that we take on our cameras or view on a computer screen are usually stored using JPEG COMPRESSION [VII.7 §5].

X-ray tomography devices, ranging from AIRPORT LUGGAGE SCANNERS [VII.19] to HUMAN BODY SCANNERS [VII.9], rely on the fast and accurate solution of INVERSE PROBLEMS [IV.15], which are problems in which we need to recover information about the internals of a system from (noisy) measurements taken outside the system.

Investments are routinely made on the basis of mathematical models, whether for individual options or collections of assets (portfolios): see FINANCIAL MATHEMATICS [V.9] and PORTFOLIO THEORY [V.10].

The clever use of mathematical modeling offers a competitive advantage in sports, such as YACHT RACING [V.2], SWIMMING [V.2], and FORMULA ONE RACING [V.3], where small improvements can be the difference between success and failure.

I.2 The Language of Applied Mathematics

Nicholas J. Higham

This article provides background on the notation, terminology, and basic results and concepts of applied mathematics. It therefore serves as a foundation for the later articles, many of which cross-reference it.

In view of the limited space, the material has been restricted to that common to many areas of applied mathematics. A number of later articles provide their own careful introduction to the language of their particular topic.

1 Notation

Table 1 lists the Greek alphabet, which is widely used to denote mathematical variables. Note that almost always δ and ε are used to denote small quantities, and π is used as a variable as well as for $\pi = 3.14159\dots$.

Mathematics has a wealth of notation to express commonly occurring concepts. But notation is both a blessing and a curse. Used carefully, it can make mathematical arguments easier to read and understand. If overused it can have the opposite effect, and often it is better to express a statement in words than in symbols (see MATHEMATICAL WRITING [VIII.1]). Table 2 gives some notation that is common in informal contexts such as lectures and is occasionally encountered in this book. Table 3 summarizes basic notation used throughout the book.

2 Complex Numbers

Most applied mathematics takes place in the set of complex numbers, \mathbb{C} , or the set of real numbers, \mathbb{R} . A complex number $z = x + iy$ has real and imaginary parts $x = \operatorname{Re} z$ and $y = \operatorname{Im} z$ belonging to \mathbb{R} , and the *imaginary unit* i denotes $\sqrt{-1}$. The imaginary unit is sometimes written as j , e.g., in electrical engineering and in the programming language PYTHON [VII.11].

We can represent complex numbers geometrically in the *complex plane*, in which a complex number $a + ib$ is represented by the point with coordinates (a, b) .

Table 1 The Greek alphabet. Where an uppercase Greek letter is the same as the Latin letter it is not shown.

α	alpha	ν	nu
β	beta	ξ, Ξ	xi
γ, Γ	gamma	σ	omicron
δ, Δ	delta	π, ϖ, Π	pi
ϵ, ε	epsilon	ρ, ϱ	rho
ζ	zeta	$\sigma, \varsigma, \Sigma$	sigma
η	eta	τ	tau
$\theta, \vartheta, \Theta$	theta	υ, Υ	upsilon
ι	iota	ϕ, φ, Φ	phi
κ	kappa	χ	chi
λ, Λ	lambda	ψ, Ψ	psi
μ	mu	ω, Ω	omega

Table 2 Other notation.

\Rightarrow	Implies	\exists	There exists
\Leftarrow	Implied by	\nexists	There does not exist
\Leftrightarrow	If and only if	\forall	For all

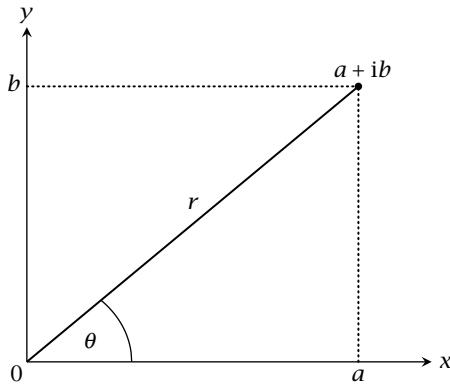

Figure 1 Complex plane with $z = a + ib = re^{i\theta}$.

(see figure 1). The corresponding diagram is called the *Argand diagram*. Important roles are played by the *right half-plane* $\{z: \operatorname{Re} z \geq 0\}$ and the *left half-plane* $\{z: \operatorname{Re} z \leq 0\}$. If we exclude the pure imaginary numbers ($\operatorname{Im} z = 0$) from these sets we obtain the *open* half-planes. Euler's formula, $e^{i\theta} = \cos \theta + i \sin \theta$, is fundamental.

The *polar form* of a complex number is $z = re^{i\theta}$, where $r \geq 0$ and the *argument* $\arg z = \theta$ are real, and θ can be restricted to any interval of length 2π , such as $[0, 2\pi]$ or $(-\pi, \pi]$. The *complex conjugate* of $z = x + iy$ is $\bar{z} = x - iy$, sometimes written z^* . The *modulus*, or *absolute value*, $|z| = (\bar{z}z)^{1/2} = (x^2 + y^2)^{1/2} = r$.

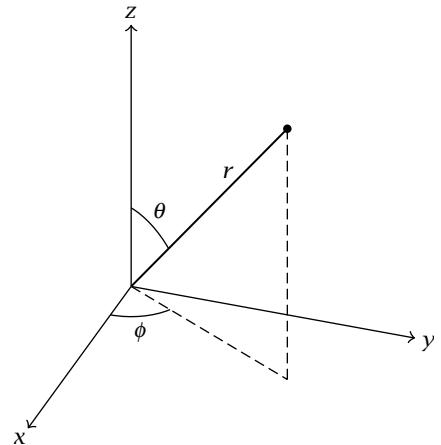

Figure 2 Spherical coordinates.

Complex arithmetic is defined in terms of real arithmetic according to the following rules, for $z_1 = x_1 + iy_1$ and $z_2 = x_2 + iy_2$:

$$\begin{aligned} z_1 \pm z_2 &= x_1 \pm x_2 + i(y_1 \pm y_2), \\ z_1 z_2 &= x_1 x_2 - y_1 y_2 + i(x_1 y_2 + x_2 y_1), \\ \frac{z_1}{z_2} &= \frac{x_1 x_2 + y_1 y_2}{x_2^2 + y_2^2} + i \frac{x_2 y_1 - x_1 y_2}{x_2^2 + y_2^2}. \end{aligned}$$

In polar form multiplication and division become notationally simpler: if $z_1 = r_1 e^{i\theta_1}$ and $z_2 = r_2 e^{i\theta_2}$ then $z_1 z_2 = r_1 r_2 e^{i(\theta_1 + \theta_2)}$ and $z_1/z_2 = (r_1/r_2) e^{i(\theta_1 - \theta_2)}$.

3 Coordinate Systems

We are used to specifying a point in two dimensions by its *x*- and *y*-coordinates, and a point in three dimensions by its *x*-, *y*-, and *z*-coordinates. These are called *Cartesian coordinates*. In two dimensions we can also use *polar coordinates*, which are as described in the previous section if we identify (x, y) with $x + iy$. *Spherical coordinates*, illustrated in figure 2, are an extension of polar coordinates to three dimensions. Here, (x, y, z) is represented by (r, θ, ϕ) , where

$$x = r \sin \theta \cos \phi, \quad y = r \sin \theta \sin \phi, \quad z = r \cos \theta,$$

with nonnegative radius r and angles θ and ϕ in the ranges $0 \leq \theta \leq \pi$ and $0 \leq \phi < 2\pi$.

Cylindrical coordinates provide another three-dimensional coordinate system. Here, polar coordinates are used in the *xy*-plane and *z* is retained, so (x, y, z) is represented by (r, θ, z) .

Table 3 Notation frequently used in this book.

Notation	Meaning	Example
\mathbb{R}, \mathbb{C}	The real numbers, the complex numbers	
$\mathbb{R}^n, \mathbb{R}^{m \times n}$	The real n -vectors and real $m \times n$ matrices; similarly for \mathbb{C}^n and $\mathbb{C}^{m \times n}$	
$\operatorname{Re} z, \operatorname{Im} z$	Real and imaginary parts of the complex number z	
\mathbb{Z}, \mathbb{N}	The integers, $\{0, \pm 1, \pm 2, \dots\}$, and the positive integers, $\{1, 2, \dots\}$	
$i = 1, 2, \dots, n$	The integer variable i takes on the values 1, 2, 3, and so on, up to n ; also written $1 \leq i \leq n$ and $i = 1:n$	
\approx	Approximately equal; also written \simeq	$\pi \approx 3.14$
\in	Belongs to	$x \in \mathbb{R}, n \in \mathbb{Z}$
\equiv	Identically equal to $f \equiv 0$ means that f is the zero function, that is, f is zero for all values, not just some values, of its argument(s)	
$n!$	Factorial, $n! = n(n - 1) \cdots 1$	
\rightarrow	Tends to, or converges to	$n \rightarrow \infty$
\sum	Summation	$\sum_{i=1}^3 x_i = x_1 + x_2 + x_3$
\prod	Product	$\prod_{i=1}^3 x_i = x_1 x_2 x_3$
\ll, \gg	Much less than, much greater than	$n \gg 1, 0 \leq \varepsilon \ll 1$
δ_{ij}	Kronecker delta: $\delta_{ij} = 1$ if $i = j$ and $\delta_{ij} = 0$ if $i \neq j$	
$[a, b], (a, b), [a, b)$	The closed interval $\{x : a \leq x \leq b\}$, the open interval $\{x : a < x < b\}$, and the half-closed, half-open interval $\{x : a \leq x < b\}$	
$f : P \rightarrow Q$	The function f maps the set P to the set Q , that is, $x \in P$ implies $f(x) \in Q$	
$f', f'', f''', f^{(k)}$	First, second, third, and k th derivatives of the function f	
\dot{f}, \ddot{f}	First and second derivatives of the function f	
$C[a, b]$	Real-valued continuous functions on $[a, b]$	$f \in C[a, b]$
$C^k[a, b]$	Real-valued functions with continuous derivatives of order $0, 1, \dots, k$ on $[a, b]$	$f \in C^2[a, b]$
$L^2[a, b]$	The functions $f : \mathbb{R} \rightarrow \mathbb{R}$ such that the Lebesgue integral $\int_a^b f(x)^2 dx$ exists	
$f \circ g$	Composition of functions: $(f \circ g)(x) = f(g(x))$	$e^{x^2} = e^x \circ x^2$
$:=, =:$	Definition of a variable or function, to distinguish from mathematical equality	$y' = 1 + y^4 =: f(y)$

4 Functions

A *function* f is a rule that assigns for each value of x a unique value $f(x)$. It can be thought of as a black box that takes an input x and produces an output $y = f(x)$. A function is sometimes called a *mapping*. If we write $y = f(x)$ then y is the *dependent variable* and x is the *independent variable*, also called the *argument* of f .

For some functions there is not a unique value of $f(x)$ for a given x , and these *multivalued functions* are not true functions unless restrictions are imposed. For example, consider $y = \log x$, which in general denotes any solution of the equation $e^y = x$. There are infinitely many solutions, which can be written as $y = y_0 + 2\pi i k$ for $k \in \mathbb{Z}$, where y_0 is the *principal logarithm*, defined

as the logarithm whose imaginary part lies in $(-\pi, \pi]$. The principal logarithm is often the one that is needed in practice and is usually the one computed by software. Multivalued functions of a complex variable can be elegantly handled using RIEMANN SURFACES [IV.1 §2] and BRANCH CUTS [IV.1 §2].

A function is *linear* if the independent variable appears only to the first power. Thus the function $f(x) = ax + b$, where a and b are constants, is linear in x . In some contexts, e.g., in convex optimization, $ax + b$ is called an *affine function* and the term linear is reserved for $f(x) = ax$, for which $f(tx) = t f(x)$ for all t .

A function f is *odd* if $f(x) = -f(-x)$ for all x and it is *even* if $f(x) = f(-x)$ for all x . For example, the sine function is odd, whereas x^2 and $|x|$ are even.

It is worth noting the distinction between the function f and its value $f(x)$ at a particular point x . Sometimes this distinction is blurred; for example, one might write “the function $f(u, v)$,” in order to emphasize the symbols being used for the independent variables.

Functions with more than one independent variable are called *multivariate functions*. For ease of notation the independent variables can be collected into a vector. For example, the multivariate function $f(u, v) = \cos u \sin v$ can be written $f(x) = \cos x_1 \sin x_2$, where $x = [x_1, x_2]^T$.

5 Limits and Continuity

The notion of a function converging to a limit as its argument approaches a certain value seems intuitively obvious. For example, the statement that $x^2 \rightarrow 4$ as $x \rightarrow 2$, where the symbol “ \rightarrow ” means tends to or converges to, is clearly true, as can be seen by considering the graph of x^2 . However, we need to make the notion of convergence precise because a large number of definitions are built on it.

Let f be a real function of a real variable. We say that $f(x) \rightarrow \ell$ as $x \rightarrow a$, and we write $\lim_{x \rightarrow a} f(x) = \ell$, if for every $\varepsilon > 0$ there is a $\delta > 0$ such that $0 < |x - a| < \delta$ implies $|f(x) - \ell| < \varepsilon$. In other words, by choosing x close enough to a , $f(x)$ can be made as close as desired to ℓ . Showing that the definition holds in a particular case boils down to determining δ as a function of ε .

It is implicit in this definition that ℓ is finite. We say that $f(x) \rightarrow \infty$ as $x \rightarrow a$ if for every $\rho > 0$ there is a $\delta > 0$ such that $|x - a| < \delta$ implies $f(x) > \rho$.

In practice, mathematicians rarely prove existence of a limit by exhibiting the appropriate $\delta = \delta(\varepsilon)$ in these definitions. For example, one would argue that $\tan x \rightarrow \infty$ as $x \rightarrow \pi/2$ because $\sin x \rightarrow 1$ and $\cos x \rightarrow 0$ as $x \rightarrow \pi/2$. However, the definition might be used if f is an implicitly defined function whose behavior is not well understood.

We can also define one-sided limits, in which the limiting value of x is approached from the right or the left. For the right-sided limit $\lim_{x \rightarrow a^+} f(x) = \ell$, the definition of limit is modified so that $0 < |x - a| < \delta$ is replaced by $a < x < a + \delta$, and the left-sided limit $\lim_{x \rightarrow a^-} f(x)$ is defined analogously. The standard limit exists if and only if the right- and left-sided limits exist and are equal.

The function f is *continuous* at $x = a$ if $f(a)$ exists and $\lim_{x \rightarrow a} f(x) = f(a)$.

The definitions of limit and continuity apply equally well to functions of a complex variable. Here, the condition $|x - a| < \delta$ places x in a disk of radius less than δ in the complex plane instead of an open interval on the real axis.

The function f is continuous on $[a, b]$ if it is continuous at every point in that interval. A more restricted form of continuity is Lipschitz continuity. The function f is *Lipschitz continuous* on $[a, b]$ if

$$|f(x) - f(y)| \leq L|x - y| \quad \text{for all } x, y \in [a, b]$$

for some constant L , which is called the *Lipschitz constant*. This definition, which is quantitative as opposed to the purely qualitative usual definition of continuity, is useful in many settings in applied mathematics. A function may, however, be continuous without being Lipschitz continuous, as $f(x) = x^{1/2}$ on $[0, 1]$ illustrates.

A *sequence* a_1, a_2, a_3, \dots of real or complex numbers, written $\{a_n\}$, has limit c if for every $\varepsilon > 0$ there is a positive integer N such that $|a_n - c| < \varepsilon$ for all $n \geq N$. We write $c = \lim_{n \rightarrow \infty} a_n$. An *infinite series* $\sum_{i=1}^{\infty} a_i$ converges if the sequence of *partial sums* $\sum_{i=1}^n a_i$ converges.

6 Bounds

In applied mathematics we are often concerned with deriving bounds for quantities of interest. For example, we might wish to find a constant u such that $f(x) \leq u$ for all x on a given interval. Such a u , if it exists, is called an *upper bound*. Similarly, a lower bound is a constant ℓ such that $f(x) \geq \ell$ for all x on the interval. Of particular interest is the *least upper bound*, also called the *supremum* or sup, which is the smallest possible upper bound. The supremum might not actually be attained, as illustrated by the function $f(x) = x/(1+x)$ on $[0, \infty)$, which has supremum 1. The *infimum*, or inf, is the greatest possible lower bound.

A function that has an upper (or lower) bound is said to be *bounded above* (or *bounded below*). If the function is bounded both above and below it is said to be *bounded*. A function that is not bounded is *unbounded*.

Determining whether a certain function, perhaps a function of several variables or one defined in a FUNCTION SPACE [II.15], is bounded can be nontrivial and it is often a crucial step in proving the convergence of a process or determining the quality of an approximation.

Physical considerations sometimes imply that a function is bounded. For example, a function that represents energy must be nonnegative.

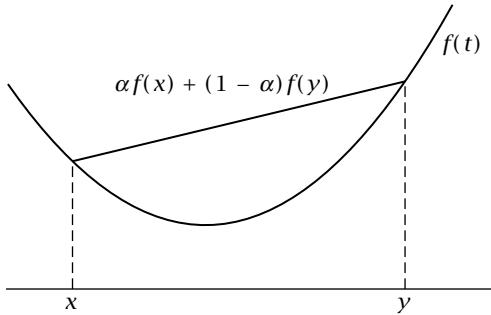

Figure 3 A convex function, illustrating the inequality (1).

7 Sets and Convexity

Three types of sets in \mathbb{R} or \mathbb{C} are commonly used in applied mathematics.

An *open set* is a set such that for every point in the set there is an open disk around it lying entirely in the set. An *open disk* (or *open ball*) around a point a in \mathbb{R} or \mathbb{C} is the set of all points z satisfying $|z - a| < \varepsilon$ for some specified $\varepsilon > 0$. For example, $\{z \in \mathbb{C} : |z| < 1\}$ is an open disk. In \mathbb{R} , an open disk reduces to an open interval $(a - \varepsilon, a + \varepsilon)$. A *closed set* is a set that is the complement of an open set; that is, it comprises all the points that are not in some open set. For example, $\{z \in \mathbb{C} : |z| \leq 1\}$ is a closed disk, the complement of the open set $\{z \in \mathbb{C} : |z| > 1\}$.

A *bounded set* is one for which there is a constant M such that $|x| \leq M$ for all x in the set. A set is *compact* if it is closed and bounded.

A *convex set* is a set for which the line joining any two points x and y in the set lies in the set, that is, $\alpha x + (1 - \alpha)y$ is in the set for all $\alpha \in [0, 1]$. A related notion is that of a *convex function*. A real-valued function f is *convex* on a convex set S if

$$f(\alpha x + (1 - \alpha)y) \leq \alpha f(x) + (1 - \alpha)f(y) \quad (1)$$

for all $x, y \in S$ and $\alpha \in [0, 1]$. This inequality says that on the interval defined by x and y the function f lies below the line joining $f(x)$ and $f(y)$ (see figure 3). An example of a convex function is $f(x) = x^2$ on the real line. A *concave function* is one satisfying (1) with the inequality reversed.

8 Order Notation

We write $x \approx y$ to mean that x is approximately equal to y . The accuracy of the approximation may be implied by the context or the way y is written. For

example, the statement that $\pi \approx 3.14$ implies that the approximation is correct to two decimal places.

The big-oh and little-oh notations, $O(\cdot)$ and $o(\cdot)$, are used to give information about the relative behavior of two functions. We write

- (i) $f(z) = O(g(z))$ as $z \rightarrow \infty$ (or $z \rightarrow 0$) if $|f(z)| \leq c|g(z)|$ for some constant c for all sufficiently large $|z|$ (or all sufficiently small $|z|$);
- (ii) $f(z) = o(g(z))$ as $z \rightarrow \infty$ (or $z \rightarrow 0$) if $f(z)/g(z) \rightarrow 0$ as $z \rightarrow \infty$ (or $z \rightarrow 0$).

In both cases, g is usually a well-understood function and f is a function whose behavior we are trying to understand.

To illustrate: $z^3 + z^2 + z + 1 = O(z^3)$ as $z \rightarrow \infty$ and $z^3 + z^2 + z = O(z)$ as $z \rightarrow 0$, while $z = o(e^z)$ as $z \rightarrow \infty$.

Big-oh notation is frequently used when comparing the cost of algorithms measured as a function of problem size. For example, the cost of multiplying two $n \times n$ matrices by the usual formulas is $n^3 + q(n)$ additions and n^3 multiplications, where q is a quadratic function. We can say that matrix multiplication costs $2n^3 + O(n^2)$ operations, or simply $O(n^3)$ operations.

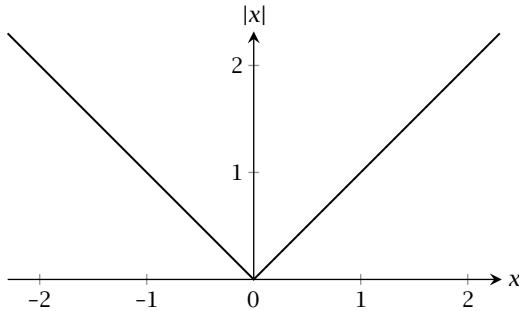

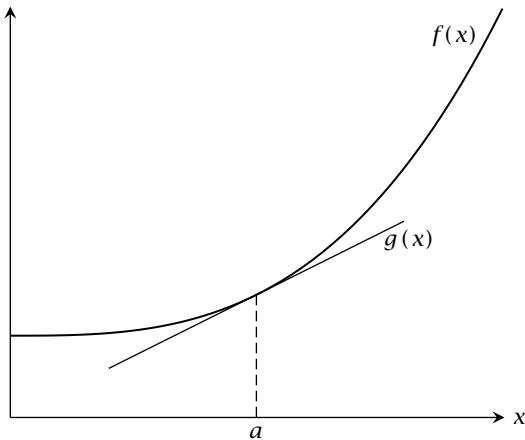

We write $f(z) \sim g(z)$ (in words, “ $f(z)$ twiddles $g(z)$ ”) if $f(z)/g(z)$ tends to 1 as z tends to some quantity z_0 (sometimes the ratio is required only to tend to a finite, nonzero limit). For example, $\sin z \sim z$ as $z \rightarrow 0$, $\sum_{i=1}^n i^2 \sim n^2/3$ as $n \rightarrow \infty$, and $n! \sim \sqrt{2\pi n}(n/e)^n$ as $n \rightarrow \infty$, the last approximation, called *Stirling's approximation*, being good even for small n .

9 Calculus

The rate of change of a quantity is a fundamental concept. The rate of change of the distance of a moving object from a given point is its speed, and the rate of change of speed is acceleration. In economics, inflation is the rate of change of a price index. The rate of change of a function is its derivative. Let f be a real function of a real variable. Intuitively, the rate of change of f at x is obtained by making a small change in x and taking the ratio of the corresponding change in f to the change in x , that is, $(f(x + \varepsilon) - f(x))/\varepsilon$ for small ε . In order to get a unique quantity we take the limit as $\varepsilon \rightarrow 0$, which gives the derivative

$$\frac{df}{dx} = f'(x) = \lim_{\varepsilon \rightarrow 0} \frac{f(x + \varepsilon) - f(x)}{\varepsilon}.$$

The derivative may or may not exist. For example, the absolute value function $f(x) = |x|$ is not differentiable at the origin because the left- and right-sided limits

Figure 4 The absolute value function, $|x|$.Figure 5 The function $f(x)$ and the tangent g to f at $x = a$. The tangent is $g(x) = f'(a)(x - a) + f(a)$.

are different: $\lim_{\varepsilon \rightarrow 0^-} (f(x + \varepsilon) - f(x))/\varepsilon = -1$ and $\lim_{\varepsilon \rightarrow 0^+} (f(x + \varepsilon) - f(x))/\varepsilon = 1$ (see figure 4). Higher derivatives are defined by applying the definition recursively; thus $f''(x)$ is the derivative of $f'(x)$.

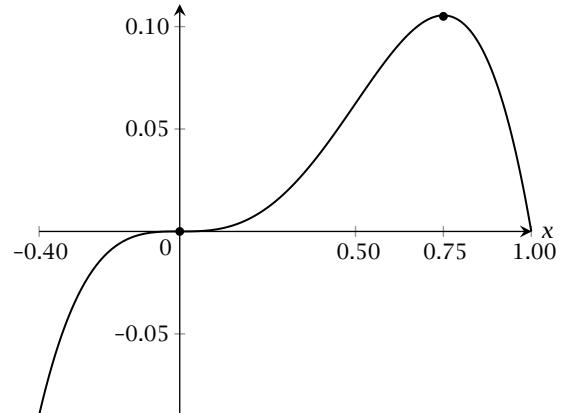

A graphical interpretation of the derivative is that it is the slope of the tangent to the curve $y = f(x)$ (see figure 5).

Another way to write the definition of derivative is as

$$f(x + \varepsilon) - f(x) - f'(x)\varepsilon = o(\varepsilon).$$

This definition has the benefit of generalizing naturally to FUNCTION SPACES [II.15], where it yields the *Fréchet derivative*.

A zero derivative identifies stationary points of a function, with the type of stationary point—maximum, minimum, or saddle point (also called a point of inflection)—being determined by the second and possibly higher derivatives. This can be seen with the aid

Figure 6 The function $f(x) = x^3 - x^4$ with a saddle point at $x = 0$ and a maximum at $x = 3/4$.

of a *Taylor series* about the point a of interest:

$$\begin{aligned} f(x) = f(a) + f'(a)(x - a) + f''(a) \frac{(x - a)^2}{2!} \\ + f'''(a) \frac{(x - a)^3}{3!} + \dots \end{aligned}$$

If $f'(a) = 0$ and $f''(a) \neq 0$ then, for x sufficiently close to a , $f(x) \approx f(a) + f''(a)(x - a)^2/2$, and so a is a maximum point if $f''(a) < 0$ and a minimum point if $f''(a) > 0$. If $f'(a) = f''(a) = 0$ then we need to look at the higher-order derivatives to determine the nature of the stationary point; in particular, if $f'''(a) \neq 0$ then a is a saddle point (see figure 6).

The error in truncating a Taylor series is captured in the *Taylor series with remainder*:

$$f(x) = \sum_{k=0}^n f^{(k)}(a) \frac{(x - a)^k}{k!} + f^{(n+1)}(\xi) \frac{(x - a)^{n+1}}{(n+1)!},$$

where ξ is an unknown point on the interval with endpoints a and x . For $n = 0$ this reduces to $f(x) - f(a) = f'(\xi)(x - a)$, which is the *mean-value theorem*.

Rigorous statements of results must include assumptions about the smoothness of the functions involved, that is, how many derivatives are assumed to exist. For example, the Taylor series with remainder is valid if f is $(n+1)$ -times continuously differentiable on an interval containing x and a . In applied mathematics we often avoid clutter by writing “for smooth functions f ” to indicate that the existence of continuous derivatives up to some order is assumed. Underlying such a statement might be some known minimal assumption on f , or just the knowledge that the existence of continuous derivatives of all orders is sufficient and that less restrictive

conditions can usually be derived if necessary. Sometimes, when deriving or using results, it is not possible to check smoothness conditions and one simply carries on anyway (“making compromises,” as mentioned in the quote by Courant on page 1). It may be possible to verify by other means that an answer obtained in a nonrigorous way is valid.

For a function $f(x, y)$ of two variables, partial derivatives with respect to each of the two variables are defined by holding one variable constant and varying the other:

$$\begin{aligned}\frac{\partial f}{\partial x} &= \lim_{\varepsilon \rightarrow 0} \frac{f(x + \varepsilon, y) - f(x, y)}{\varepsilon}, \\ \frac{\partial f}{\partial y} &= \lim_{\varepsilon \rightarrow 0} \frac{f(x, y + \varepsilon) - f(x, y)}{\varepsilon}.\end{aligned}$$

Higher derivatives are defined recursively. For example,

$$\begin{aligned}\frac{\partial^2 f}{\partial x^2} &= \lim_{\varepsilon \rightarrow 0} \frac{\frac{\partial f}{\partial x}(x + \varepsilon, y) - \frac{\partial f}{\partial x}(x, y)}{\varepsilon}, \\ \frac{\partial^2 f}{\partial x \partial y} &= \lim_{\varepsilon \rightarrow 0} \frac{\frac{\partial f}{\partial x}(x, y + \varepsilon) - \frac{\partial f}{\partial x}(x, y)}{\varepsilon}, \\ \frac{\partial^2 f}{\partial y \partial x} &= \lim_{\varepsilon \rightarrow 0} \frac{\frac{\partial f}{\partial y}(x + \varepsilon, y) - \frac{\partial f}{\partial y}(x, y)}{\varepsilon}.\end{aligned}$$

Common abbreviations are $f_x = \partial f / \partial x$, $f_{xy} = \partial^2 f / (\partial x \partial y)$, $f_{yy} = \partial^2 f / \partial y^2$, and so on. As long as they are continuous the two mixed second-order partial derivatives are equal: $f_{xy} = f_{yx}$.

For a function of n variables, $F: \mathbb{R}^n \rightarrow \mathbb{R}$, a Taylor series takes the form, for $x, a \in \mathbb{R}^n$,

$$\begin{aligned}F(x) &= F(a) + \nabla F(a)^T(x - a) \\ &\quad + \frac{1}{2}(x - a)^T \nabla^2 F(a)(x - a) + \dots,\end{aligned}$$

where $\nabla F(x) = (\partial F / \partial x_j) \in \mathbb{R}^n$ is the *gradient vector* and $\nabla^2 F(x) = (\partial^2 F / (\partial x_i \partial x_j)) \in \mathbb{R}^{n \times n}$ is the symmetric *Hessian matrix*, with x_j denoting the j th component of the vector x . The symbol ∇ is called nabla. Stationary points of F are zeros of the gradient and their nature (maximum, minimum, or saddle point) is determined by the eigenvalues of the Hessian (see CONTINUOUS OPTIMIZATION [IV.11 §2]).

Now we return to functions of a single (real) variable. The *indefinite integral* of $f(x)$ is $\int f(x) dx$, while integrating between limits a and b gives the *definite integral* $\int_a^b f(x) dx$. The definite integral can be interpreted as the area under the curve $f(x)$ between a and b . The inverse of differentiation is integration, as shown by the *fundamental theorem of calculus*, which

states that, if f is continuous on $[a, b]$, then the function $g(x) = \int_a^x f(t) dt$ is differentiable on (a, b) and $g'(x) = f(x)$. Generalizations of the fundamental theorem of calculus to functions of more than one variable are given in section 24.

For functions of two or more variables there are other kinds of integrals. When there are two variables, x and y , we can integrate over regions in the xy -plane (double integrals) or along curves in the plane (line integrals). For functions of three variables, x , y , and z , there are more possibilities. We can integrate over volumes (triple integrals) or over surfaces or along curves within xyz -space. As the number of variables increases, so does the number of different kinds of integrals. Multidimensional calculus shows how these different integrals can be calculated, used, and related. The number of variables can be very large (e.g., in mathematical finance) and the CURSE OF DIMENSIONALITY [I.3 §2] poses major challenges for numerical evaluation. Numerical integration in more than one dimension is an active area of research, and Monte Carlo methods and quasi-Monte Carlo methods are among the methods in use.

The *product rule* gives a formula for the derivative of a product of two functions:

$$\frac{d}{dx} f(x)g(x) = f'(x)g(x) + f(x)g'(x).$$

Integrating this equation gives the rule for *integration by parts*:

$$\int f(x)g'(x) dx = f(x)g(x) - \int f'(x)g(x) dx.$$

In many problems functions are composed: the argument of a function is another function. Consider the example $f(x) = g(h(x))$. We would hope to be able to determine the derivative of f in terms of the derivatives of g and h . The *chain rule* provides the necessary formula: $f'(x) = h'(x)g'(h(x))$. An equivalent formulation is that, if f is a function of u , which is itself a function of x , then

$$\frac{df}{dx} = \frac{df}{du} \frac{du}{dx}.$$

For example, if $f(x) = \sin x^2$ then with $f(x) = \sin u$ and $u = x^2$ we have $df/dx = 2x \cos x^2$.

10 Ordinary Differential Equations

A differential equation is an equation containing one or more derivatives of an unknown function. It provides a relation among a function, its rate of change, and (possibly) higher-order rates of change. The independent

variable usually represents a spatial coordinate (x) or time (t). The differential equation may be accompanied by additional information about the function, called *boundary conditions* or *initial conditions*, that serve to uniquely determine the solution. A solution to a differential equation is a function that satisfies the equation for all values of the independent variables (perhaps in some region) and also satisfies the required boundary conditions or initial conditions. A differential equation can express a law of motion, a conservation law, or concentrations of constituents of a chemical reaction, for example.

Ordinary differential equations (ODEs) contain just one independent variable. The simplest nontrivial ODE is $dy/dt = ay$, where $y = y(t)$ is a function of t . This equation is linear in y and it is *first order* because only the first derivative of y appears. The general solution is $y(t) = ce^{at}$, where c is an arbitrary constant. To determine c , some value of y must be supplied, say $y(0) = y_0$, whence $c = y_0$.

A general first-order ODE has the form $y' = f(t, y)$ for some function f of two variables. The *initial-value problem* supplies an initial condition and asks for y at later times:

$$y' = f(t, y), \quad a \leq t \leq b, \quad y(a) = y_a.$$

A specific example is the Riccati equation

$$y' = t^2 + y^2, \quad 0 \leq t \leq 1, \quad y(0) = 0,$$

which is nonlinear because of the appearance of y^2 .

For an example of a second-order ODE initial-value problem, that is, one involving y'' , consider a mass m attached to a vertical spring and to a damper, as shown in figure 7. Let $y = y(t)$ denote how much the spring is stretched from its natural length at time t . Balancing forces using Newton's second law (force equals mass times acceleration) and HOOKE'S LAW [III.15] gives

$$my'' = mg - ky - cy',$$

where k is the spring constant, c is the damping constant, and g is the gravitational constant. With prescribed values for $y(0)$ and $y'(0)$ this is an initial-value problem. More generally, the spring might also be subjected to an external force $f(t)$, in which case the equation of motion becomes

$$my'' + cy' + ky = mg + f(t).$$

Second-order ODEs also arise in electrical networks. Consider the flow of electric current $I(t)$ in a simple RLC circuit composed of an inductor with inductance

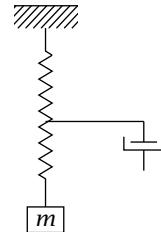

Figure 7 A spring system with damping.

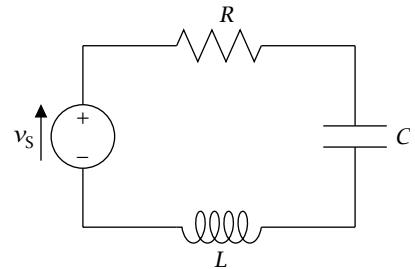

Figure 8 A simple RLC electric circuit.

L , a resistor with resistance R , a capacitor with capacitance C , and a source with voltage v_s , as illustrated in figure 8. The Kirchhoff voltage law states that the sum of the voltage drops around the circuit equals the input voltage, v_s . The voltage drops across the resistor, inductor, and capacitor are RI , LdI/dt , and Q/C , respectively, where $Q(t)$ is the charge on the capacitor, so

$$L \frac{dI}{dt} + RI + \frac{Q}{C} = v_s(t).$$

Since $I = dQ/dt$, this equation can be rewritten as the second-order ODE

$$L \frac{d^2Q}{dt^2} + R \frac{dQ}{dt} + \frac{1}{C} Q = v_s(t).$$

The unknown function y may have more than one component, as illustrated by the predator-prey model derived by Lotka and Volterra in the 1920s. In a population of rabbits (the prey) and foxes (the predators) let $r(t)$ be the number of rabbits at time t and $f(t)$ the number of foxes at time t . The model is

$$\begin{aligned} \frac{dr}{dt} &= r - \alpha rf, & r(0) &= r_0, \\ \frac{df}{dt} &= -f + \alpha rf, & f(0) &= f_0. \end{aligned}$$

The rf term represents an interaction between the foxes and the rabbits (a fox eating a rabbit) and the parameter $\alpha \geq 0$ controls the amount of interaction. For $\alpha = 0$ there is no interaction and the solution is

$r(t) = r_0 e^{rt}$, $f(t) = f_0 e^{-rt}$: the foxes die from starvation and the rabbits go forth and multiply, unhindered. The aim is to investigate the behavior of the solutions for various parameters α and starting populations r_0 and f_0 .

As we have described it, the predator-prey model has the apparent contradiction that r and f are integers by definition yet the solutions to the differential equation are real-valued. The way around this is to assume that r and f are large enough for the error in representing them by continuous variables to be small.

A *boundary-value problem* specifies the function at more than one value of the independent variable, as in the two-point boundary-value problem

$$y'' = f(t, y, y'), \quad a \leq t \leq b, \quad y(a) = y_a, \quad y(b) = y_b.$$

An example is the Thomas-Fermi equation

$$y'' = t^{-1/2} y^{3/2}, \quad y(0) = 1, \quad y(\infty) = 0,$$

which arises in a semiclassical description of the charge density in atoms of high atomic number. Another example, this time of third order, is the BLASIUS EQUATION [IV.28 §7.2]

$$2y''' + yy'' = 0, \quad y(0) = y'(0) = 0, \quad y'(\infty) = 1,$$

which describes the boundary layer in a fluid flow.

A special type of ODE boundary-value problem is the *Sturm-Liouville problem*

$$-(p(x)y'(x))' + q(x)y(x) = \lambda r(x)y(x),$$

$$x \in [a, b], \quad y(a) = y(b) = 0.$$

This is an *eigenvalue problem*, meaning that the aim is to determine values of the parameter λ for which the boundary-value problem has a solution that is not identically zero.

11 Partial Differential Equations

Many important physical processes are modeled by partial differential equations (PDEs): differential equations containing more than one independent variable. We summarize a few key equations and basic concepts. We write the equations in forms where the unknown u has two space dimensions, $u = u(x, y)$, or one space dimension and one time dimension, $u = u(x, t)$. Where possible, the equations are given in parameter-free form, a form that is obtained by the process of NON-DIMENSIONALIZATION [II.9]. Recall the abbreviations $u_t = \partial u / \partial t$, $u_{xx} = \partial^2 u / \partial x^2$, etc.

LAPLACE'S EQUATION [III.18] is

$$u_{xx} + u_{yy} = 0.$$

The left-hand side of the equation is the *Laplacian* of u , written Δu . This equation is encountered in electrostatics (for example), where u is the potential function. The equation $\Delta u = f$, for a given function $f(x, y)$, is known as *Poisson's equation*.

To define a problem with a unique solution it is necessary to augment the PDE with conditions on the solution: either boundary conditions for static problems or, for time-dependent problems, initial conditions. In the former class there are three main types of boundary conditions, with the problem being to determine u inside the boundary of a closed region.

- *Dirichlet conditions*, in which the function u is specified on the boundary.
- *Neumann conditions*, where the inner product (see section 19.1) of the gradient

$$\nabla u = [\partial u / \partial x, \partial u / \partial y]^T$$

with the normal to the boundary is specified.

- *Cauchy conditions*, which comprise a combination of Dirichlet and Neumann conditions.

For time-dependent problems, which are known as evolution problems and represent equations of motion, initial conditions at the starting time, usually taken to be $t = 0$, are needed, the number of initial conditions depending on the highest order of time derivative in the PDE.

The WAVE EQUATION [III.31] is

$$u_{tt} = u_{xx}.$$

It describes linear, nondispersive propagation of a wave, represented by the wave function u , e.g., a vibrating string. Two initial conditions, prescribing $u(x, 0)$ and $u_t(x, 0)$, for example, are needed to determine u .

The HEAT EQUATION [III.8] (*diffusion equation*) is

$$u_t = u_{xx}, \tag{2}$$

which describes the diffusion of heat in a solid or the spread of a disease in a population. An initial condition prescribing u at $t = 0$ is usual. When a term $f(x, t, u)$ is added to the right-hand side of (2) the equation becomes a *reaction-diffusion equation*.

The *advection-diffusion equation* is

$$u_t + vu_x = u_{xx},$$

where v is a given function of x and t . Again, u is usually given at $t = 0$. For $v = 0$ this is just the heat equation. This PDE models the convection (or transport) of a quantity such as a pollutant in the atmosphere.

The general linear second-order PDE

$$au_{xx} + 2bu_{xt} + cu_{tt} = f(x, t, u, u_x, u_t) \quad (3)$$

is classified into different types according to the (constant) coefficients of the second derivatives. Let $d = ac - b^2$, which is the determinant of the symmetric matrix $\begin{bmatrix} a & b \\ b & c \end{bmatrix}$.

- If $d > 0$ the PDE is *elliptic*. These PDEs, of which the Laplace equation is a particular case, are associated with equilibrium or steady-state processes. The independent variables are denoted by x and y instead of x and t .
- If $d = 0$ the PDE is *parabolic*. This is an evolution problem governing a diffusion process. The heat equation is an example.
- If $d < 0$ the PDE is *hyperbolic*. This is an evolution problem, governing wave propagation. The wave equation is an example.

Some elliptic PDEs and parabolic PDEs have *maximum principles*, which say that the solution must take on its maximum value on the boundary of the domain over which it is defined.

In (3) we took a , b , and c to be constants, but they may also be specified as functions of x and t , in which case the nature of the PDE can change as x and t vary in the domain. For example, the TRICOMI EQUATION [III.30]

$$u_{xx} + xu_{yy} = 0$$

is hyperbolic for $x < 0$, elliptic for $x > 0$, and parabolic for $x = 0$.

The PDEs stated so far are all linear. Nonlinear PDEs, in which the unknown function appears nonlinearly, are of great practical importance. Examples are the KORTEWEG-DE VRIES EQUATION [III.16]

$$u_t + uu_x + u_{xxx} = 0,$$

the CAHN-HILLIARD EQUATION [III.5]

$$u_t = \Delta(-u + u^3 + \varepsilon^2 \Delta u),$$

and *Fisher's equation*

$$u_t = u_{xx} + u(1 - u),$$

a reaction-diffusion equation that describes PATTERN FORMATION [IV.27] and the propagation of genes in a population.

PDEs also occur in the form of eigenvalue problems. A famous example is the eigenvalue problem corresponding to the Laplace equation:

$$\Delta u + \lambda u = 0$$

on a membrane Ω , with boundary conditions that u vanishes on the boundary of Ω . A nonzero solution u is called an *eigenfunction* and λ is the corresponding *eigenvalue*. In a 1966 paper titled “Can one hear the shape of a drum?” Mark Kac asked the question of whether one can determine Ω given all the eigenvalues. In other words, do the frequencies at which a drum vibrates uniquely determine its shape? It was shown in a 1992 paper by Gordon, Webb, and Wolpert that the answer is no in general.

Higher-order PDEs also arise. For example, fluid dynamics problems involving surface tension forces are generally modeled by PDEs in space and time with fourth-order derivatives in space. The same is true of the *Euler-Bernoulli equation* for a beam, which has the form

$$\rho A \frac{\partial^2 u}{\partial t^2} + EI \frac{\partial^4 u}{\partial x^4} = f(x, t),$$

where $u(x, t)$ is the vertical displacement of the beam at time t and position x along the beam, ρ is the density of the beam, A its cross-sectional area, E is Young's modulus, I is the second moment of inertia, and $f(x, t)$ is an applied force.

12 Other Types of Differential Equations

Delay differential equations are differential equations in which the derivative of the unknown function y at time t (in general, a vector function) depends on past values of y and/or its derivatives. For example, $y'(t) = Ay(t-1)$ is a delay differential equation analogue of the familiar $y'(t) = Ay(t)$. Looking for a solution of the form $y(t) = e^{wt}$ leads to the equation $w e^{wt} = A$, whose solutions are given by the LAMBERT W FUNCTION [III.17].

INTEGRAL EQUATIONS [IV.4] contain the unknown function inside an integral. Examples are *Fredholm equations*, which are of the form either

$$\int_0^1 K(x, y) f(y) dy = g(x),$$

where K and g are given and the task is to find f , or

$$\lambda \int_0^1 K(x, y) f(y) dy + g(x) = f(x),$$

where λ is an eigenvalue and again f is unknown. These two types of equations are analogous to a matrix linear system $Kf = g$ and an eigenvalue problem $(I - \lambda K)f = g$, respectively. *Integro-differential equations* involve both integrals and derivatives (see, for example, MODELING A PREGNANCY TESTING KIT [VII.18 §2]).

Fractional differential equations contain fractional derivatives. For example, $(d/dx)^{1/2}$ is defined to be an operator such that applying $(d/dx)^{1/2}$ twice in succession to a function $f(x)$ is the same as differentiating it once (that is, applying d/dx).

Differential-algebraic equations (DAEs) are systems of equations that contain both differential and algebraic equations. For example, the DAE

$$\begin{aligned}x'' &= -2\lambda x, \\y'' &= -2\lambda y - g, \\x^2 + y^2 &= L^2\end{aligned}$$

describes the coordinates of an infinitesimal ball of mass 1 at the end of a pendulum of length L , where g is the gravitational constant and λ is the tension in the rod. DAEs often arise in the form $M\dot{y}' = f(t, y)$, where the matrix M is singular.

13 Recurrence Relations

Recurrence relations are the discrete counterpart of differential equations. They define a sequence x_0, x_1, x_2, \dots recursively, by specifying x_n in terms of earlier terms in the sequence. Such equations are also called *difference equations*, as they arise when derivatives in differential equations are replaced by FINITE DIFFERENCES [II.11].

A famous recurrence is the three-term recurrence that defines the *Fibonacci numbers*:

$$f_n = f_{n-1} + f_{n-2}, \quad n \geq 2, \quad f_0 = f_1 = 1.$$

This recurrence has the explicit solution $f_n = (\phi^n - (-\phi)^{-n})/\sqrt{5}$, where $\phi = (1 + \sqrt{5})/2$ is the *golden ratio*. An example of a two-term recurrence is $f(n) = nf(n-1)$, with $f(0) = 1$, which defines the factorial function $f(n) = n!$. Both the examples so far are linear recurrences, but in some recurrences the earlier terms appear nonlinearly, as in the LOGISTIC RECURRENCE [III.19] $x_{n+1} = \mu x_n(1 - x_n)$.

Although one can evaluate the terms in a recurrence one often needs an explicit formula for the general solution of the recurrence. Recurrence relations have a theory analogous to that of differential equations, though it is much less frequently encountered in courses and textbooks than it was fifty years ago.

The elements in a recurrence can be functions as well as numbers. Most transcendental functions that carry subscripts satisfy a recurrence. For example, the BESSEL FUNCTION [III.2] $J_n(x)$ of order n satisfies the three-term recurrence

$$J_{n+1}(x) = \frac{2n}{x} J_n(x) - J_{n-1}(x).$$

An important source of three-term recurrences is ORTHOGONAL POLYNOMIALS [II.29].

14 Polynomials

Polynomials are one of the simplest and most familiar classes of functions and they find wide use in applied mathematics. A degree- n polynomial

$$p_n(x) = a_0 + a_1 x + \cdots + a_n x^n$$

is defined by its $n + 1$ coefficients $a_0, \dots, a_n \in \mathbb{C}$ (with $a_n \neq 0$). Addition of two polynomials is carried out by adding the corresponding coefficients. Thus, if $q_n(x) = b_0 + b_1 x + \cdots + b_n x^n$ then $p_n(x) + q_n(x) = a_0 + b_0 + (a_1 + b_1)x + \cdots + (a_n + b_n)x^n$. Multiplication is carried out by expanding the product term by term and collecting like powers of x :

$$\begin{aligned}p_n(x)q_n(x) &= a_0b_0 + (a_0b_1 + a_1b_0)x + \cdots \\&\quad + (a_0b_n + a_1b_{n-1} + \cdots + a_nb_0)x^n.\end{aligned}$$

The coefficient of x^n , $\sum_{i=0}^n a_i b_{n-i}$, is the *convolution* of the vectors $a = [a_0, a_1, \dots, a_n]^T$ and $b = [b_0, b_1, \dots, b_n]^T$. Polynomial division is also possible. Dividing p_n by q_m with $m \leq n$ results in

$$p_n(x) = q_m(x)g(x) + r(x), \quad (4)$$

where the quotient g and remainder r are polynomials and the degree of r is less than that of q_m .

The *fundamental theorem of algebra* says that a degree- n polynomial p_n has a *root* in \mathbb{C} ; that is, there exists $z_1 \in \mathbb{C}$ such that $p_n(z_1) = 0$. If we take $q_m(x) = x - z_1$ in (4) then we have $p_n(x) = (x - z_1)g(x) + r(x)$, where $\deg r < 1$, so r is a constant. But setting $x = z_1$ we see that $0 = p_n(z_1) = r$, so $p_n(x) = (x - z_1)g(x)$ and g clearly has degree $n - 1$. Repeating this argument inductively on g , we end up with a factorization $p_n(x) = (x - z_1)(x - z_2) \cdots (x - z_n)$, which shows that p_n has n roots in \mathbb{C} (not necessarily distinct). If the coefficients of p_n are real it does not follow that the roots are real, and indeed there may be no real roots at all, as the polynomial $x^2 + 1$ shows; however, nonreal roots must occur in complex conjugate pairs $x_j \pm iy_j$.

Three basic problems associated with polynomials are as follows.

Evaluation: given the polynomial (specified by its coefficients), find its value at a given point. A standard way of doing this is HORNER'S METHOD [I.4 §6].

Interpolation: given the values of a degree- n polynomial at a set of $n + 1$ distinct points, find its coefficients. This can be done by various INTERPOLATION SCHEMES [I.3 §3.1].

Root finding: given the polynomial and the ability to evaluate it, find its roots. This is a classic problem with a vast literature, including methods specific to polynomials and specializations of general-purpose nonlinear equation solvers.

15 Rational Functions

A rational function is the ratio of two polynomials:

$$r_{mn}(x) = \frac{p_m(x)}{q_n(x)} = \frac{\sum_{i=0}^m a_i x^i}{\sum_{i=0}^n b_i x^i}, \quad a_m, b_n \neq 0.$$

Rational functions are more versatile than polynomials as a means of approximating other functions. As x grows larger, a polynomial of degree 1 or higher necessarily blows up to infinity. In contrast, a rational function r_{mn} with equal-degree numerator and denominator is asymptotic to a_m/b_m , as $x \rightarrow \infty$, while for $m < n$, $r_{mn}(x)$ converges to zero as $x \rightarrow \infty$. Moreover, a rational function has *poles*: certain finite values of x for which it is infinite (the roots of the denominator polynomial q_n).

The representation of a rational function as a ratio of polynomials is just one of several possibilities. We can write r_{mn} in *partial fraction* form, for example. If $m < n$ and q_n has distinct roots x_1, \dots, x_n , then

$$r_{mn}(x) = \sum_{i=1}^n \frac{c_i}{x - x_i} \quad (5)$$

for some c_1, \dots, c_n . One reason to put a rational function in partial fraction form is in order to integrate it, since the integral of (5) is immediate: $\int r_{mn}(x) dx = \sum_{i=1}^n c_i \log|x - x_i| + C$, where C is a constant.

An important class of rational functions is the *Padé approximants* to a given function f , which are defined by the property that $r_{mn}(x) - f(x) = O(x^k)$ with k as large as possible. Since r_{mn} has $m+n+1$ degrees of freedom (one having been lost due to the division), generically $k = m+n+1$, but k can be smaller or larger than this value (see APPROXIMATION THEORY [IV.9 §2.4]). When $m = 0$, a Padé approximant reduces to a truncated Taylor series.

16 Special Functions

Applied mathematicians make much use of functions that are not polynomial or rational, though they may ultimately use polynomial or rational approximations to such functions. A larger class of functions is the *elementary functions*, which are made up of polynomials, rationals, the exponential, the logarithm, and

all functions that can be obtained from these by addition, subtraction, multiplication, division, composition, and the taking of roots. Another important class is the *transcendental functions*: those that are not algebraic, that is, that are not the solution $f(x)$ of an equation $p(x, f(x)) = 0$, where $p(x, y)$ is a polynomial in x and y with integer coefficients. Examples of transcendental functions include the exponential, the logarithm, the trigonometric functions, and the hyperbolic functions.

In solving problems we talk about the ability to obtain the solution in *closed form*, which is an informal concept meaning that the solution is expressed in terms of elementary functions or functions that are “well understood,” in that they have a significant literature and good algorithms exist for computing them.

The SPECIAL FUNCTIONS [IV.7] provide a large set of examples of well-understood functions. They arise in different areas, such as physics, number theory, and probability and statistics, often as the solution to a second-order ODE or as the integral of an elementary function. A general example is the HYPERGEOMETRIC FUNCTION [IV.7 §5]

$$\begin{aligned} F(a, b; c; x) &= 1 + \frac{ab}{c} x + \frac{a(a+1)b(b+1)}{2!c(c+1)} x^2 + \dots \\ &= \sum_{i=0}^{\infty} \frac{(a)_i (b)_i}{i! (c)_i} x^i. \end{aligned}$$

Here, $a, b, c \in \mathbb{R}$, c is not zero or a negative integer, and $(a)_i \equiv a(a+1)\cdots(a+i-1)$ for $i \geq 1$, with $(a)_0 = 1$. The hypergeometric function is a solution of the second-order differential equation

$$x(1-x)w''(x) + (c - (a+b+1)x)w'(x) - abw(x) = 0.$$

The hypergeometric functions contain many interesting special cases, such as $F(a, b; b; x) = (1-x)^{-a}$ and $F(1, 1; 2; x) = -x^{-1} \log(1-x)$.

Other special functions include the following.

- The *error function*

$$\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt,$$

which is closely related to the standard normal distribution in probability and statistics.

- The GAMMA FUNCTION [III.13]

$$\Gamma(z) = \int_0^\infty e^{-t} t^{z-1} dt,$$

which satisfies $\Gamma(n) = (n-1)!$ for positive integers n and so generalizes the factorial function. Note that the argument z is a complex number.

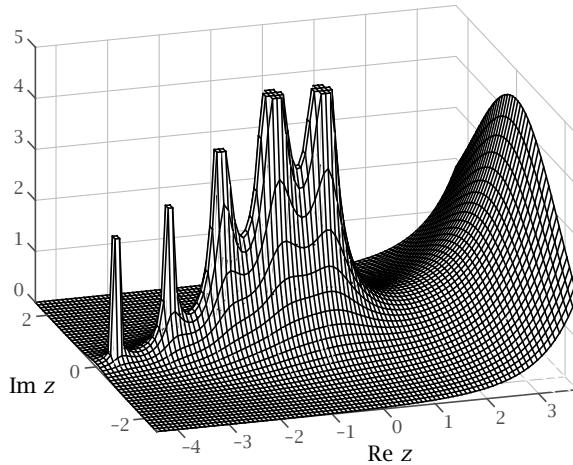

Figure 9 The gamma function in the complex plane. The height of the surface is $|\Gamma(z)|$. The function has poles at the negative integers; in this plot the infinite peaks have been truncated at different heights.

Figure 9 is modeled on a classic, hand-drawn plot of the gamma function in the complex plane from the book *Tables of Functions with Formulas and Curves* by Eugene Jahnke and Fritz Emde, first published in 1909.

- BESSEL FUNCTIONS [III.2], the LAMBERT W FUNCTION [III.17], elliptic functions, and the RIEMANN ZETA FUNCTION [IV.7 §4].

The class of special functions can be enlarged by identifying useful functions, giving them a name, studying their properties, and deriving algorithms and software for evaluating them. Of the examples mentioned above, the most recent is the Lambert W function, whose significance was realized, and to which the name was given, only in the 1990s.

17 Power Series

A power series is an infinite expansion of the form

$$a_0 + a_1 z + a_2 z^2 + a_3 z^3 + \dots,$$

where z is a complex variable and the a_i are complex constants. Results from COMPLEX ANALYSIS [IV.1 §5] tell us that such a series has a *radius of convergence* R such that the series converges for $|z| < R$, diverges for $|z| > R$, and may either converge or diverge for $|z| = R$. For example, the power series $1 + z + z^2 + \dots$ converges for $|z| < 1$, and inside this disk it agrees with

the function $f(z) = (1 - z)^{-1}$. More generally, a power-series expansion can be taken about an arbitrary point z_0 : $a_0 + a_1(z - z_0) + a_2(z - z_0)^2 + a_3(z - z_0)^3 + \dots$

Some functions have power series with an infinite radius of convergence, $R = \infty$. Perhaps the most important example is the exponential:

$$e^z = 1 + z + \frac{z^2}{2!} + \frac{z^3}{3!} + \dots$$

Suppose a function f has a power-series expansion $f(z) = a_0 + a_1 z + a_2 z^2 + a_3 z^3 + \dots$. Then $f(0) = a_0$ and differentiating gives $f'(z) = a_1 + 2a_2 z + 3a_3 z^2 + \dots$ and, hence, on setting $z = 0$, $a_1 = f'(0)$. What we have just done is to differentiate this infinite series term by term, something that in general is of dubious validity but in this case is justified because a power series can always be differentiated term by term within its radius of convergence. Continuing in this way we find that all the a_k are derivatives of f evaluated at the origin and the expansion can be written as the Taylor series expansion

$$f(z) = f(0) + f'(0)z + f''(0)\frac{z^2}{2!} + f'''(0)\frac{z^3}{3!} + \dots$$

18 Matrices and Vectors

A matrix is an $m \times n$ (read as “ m -by- n ”) array of real or complex numbers, written as

$$A = (a_{ij}) = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m1} & a_{m2} & \cdots & a_{mn} \end{bmatrix}.$$

The element at the intersection of row i and column j is a_{ij} . The matrix is *square* if $m = n$ and *rectangular* otherwise. A vector is a matrix with one row or column: an $m \times 1$ matrix is a column vector and a $1 \times n$ matrix is a row vector. A number is often referred to as a *scalar* in order to distinguish it from a vector or matrix.

The sets of $m \times n$ matrices and $n \times 1$ vectors over \mathbb{R} are denoted by $\mathbb{R}^{m \times n}$ and \mathbb{R}^n , respectively, and similarly for \mathbb{C} .

A notation that is common, though not ubiquitous, in applied mathematics employs uppercase letters for matrices and lowercase letters for vectors or, when subscripted, matrix elements. Similarly, matrices or vectors are sometimes written in boldface.

What distinguishes a matrix from a mere array of numbers is the algebraic operations defined on it. For two matrices A, B of the same dimensions, addition is defined element-wise: $C = A + B$ means that

$c_{ij} = a_{ij} + b_{ij}$ for all i and j . Multiplication by a scalar is defined in the natural way, so $C = \alpha A$ means that $c_{ij} = \alpha a_{ij}$ for all i and j . However, matrix multiplication is *not* defined element-wise. If A is $m \times r$ and B is $r \times n$ then the product $C = AB$ is $m \times n$ and is defined by

$$c_{ij} = \sum_{k=1}^r a_{ik} b_{kj}.$$

This formula can be obtained as follows. Write $B = [b^1, b^2, \dots, b^n]$, where b^j is the j th column of B ; this is a *partitioning* of B into its columns. Then $AB = A[b^1, b^2, \dots, b^n] = [Ab^1, Ab^2, \dots, Ab^n]$, where each Ab^j is a matrix-vector product. Matrix-vector products Ax with x an $r \times 1$ vector are in turn defined by

$$Ax = [a^1, a^2, \dots, a^r] \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_r \end{bmatrix} = x_1 a^1 + x_2 a^2 + \dots + x_r a^r,$$

so that Ax is a *linear combination* of the columns of A .

Matrix multiplication is not commutative: $AB \neq BA$ in general, as is easily checked for 2×2 matrices. In some contexts the *commutator* (or *Lie bracket*) $[A, B] = AB - BA$ plays a role.

A linear system $Ax = b$ expresses the vector b as a linear combination of the columns of A . When A is square and of dimension n , this system provides n linear equations for the n components of x . The system has a unique solution when A is nonsingular, that is, when A has an inverse. An *inverse* of a square matrix A is a matrix A^{-1} such that $AA^{-1} = A^{-1}A = I$, where I is the *identity matrix*, which has ones on the diagonal and zeros everywhere else. We can write $I = (\delta_{ij})$, where δ_{ij} is the *Kronecker delta* defined in table 3. The inverse is unique when it exists. If A is nonsingular then $x = A^{-1}b$ is the solution to $Ax = b$. While this formula is useful mathematically, in practice one almost never solves a linear system by inverting A and then multiplying the right-hand side by the inverse. Instead, GAUSSIAN ELIMINATION [IV.10 §2] with some form of pivoting is used.

Transposition turns an $m \times n$ matrix into an $n \times m$ one by interchanging the rows and columns: $C = A^T \iff c_{ij} = a_{ji}$ for all i and j . *Conjugate transposition* also conjugates the elements: $C = A^* \iff c_{ij} = \overline{a_{ji}}$ for all i and j . The conjugate transpose of a product satisfies a useful reverse-order law: $(AB)^* = B^*A^*$.

Matrices can have a variety of different structures that can be exploited both in theory and in computation. A matrix $A \in \mathbb{R}^{n \times n}$ is *upper triangular* if $a_{ij} = 0$

for $i > j$, *lower triangular* if A^T is upper triangular, and *diagonal* if $a_{ij} = 0$ for $i \neq j$. For $n = 3$, such matrices have the forms

$$\begin{bmatrix} \times & \times & \times \\ 0 & \times & \times \\ 0 & 0 & \times \end{bmatrix}, \quad \begin{bmatrix} \times & 0 & 0 \\ \times & \times & 0 \\ \times & \times & \times \end{bmatrix}, \quad \begin{bmatrix} d_1 & 0 & 0 \\ 0 & d_2 & 0 \\ 0 & 0 & d_3 \end{bmatrix},$$

respectively, where \times denotes a possibly nonzero entry; the third matrix is abbreviated $\text{diag}(d_1, d_2, d_3)$. The matrix $A \in \mathbb{R}^{n \times n}$ is *symmetric* if $A^T = A$, while $A \in \mathbb{C}^{n \times n}$ is *Hermitian* if $A^* = A$. If in addition the quadratic form $x^T Ax$ (or $x^* Ax$) is always positive for nonzero vectors in \mathbb{R}^n (or \mathbb{C}^n), then A is *positive-definite*. The term *self-adjoint* is sometimes used instead of symmetric or Hermitian. Also fundamental is the notion of orthogonality: $A \in \mathbb{R}^{n \times n}$ is *orthogonal* if $A^T A = I$, and $A \in \mathbb{C}^{n \times n}$ is *unitary* if $A^* A = I$. These properties mean that the inverse of A is its (conjugate) transpose, but deeper properties of unitary matrices such as preservation of angles, norms, etc., under multiplication are what make them so important.

Structures can correspond to the pattern of the elements. A *Toeplitz matrix* has constant diagonals, made up from $2n - 1$ parameters a_i , $i = -(n - 1), \dots, n - 1$. Thus a 5×5 Toeplitz matrix has the form

$$\begin{bmatrix} a_0 & a_1 & a_2 & a_3 & a_4 \\ a_{-1} & a_0 & a_1 & a_2 & a_3 \\ a_{-2} & a_{-1} & a_0 & a_1 & a_2 \\ a_{-3} & a_{-2} & a_{-1} & a_0 & a_1 \\ a_{-4} & a_{-3} & a_{-2} & a_{-1} & a_0 \end{bmatrix}.$$

Toeplitz matrices arise in SIGNAL PROCESSING [IV.35]. A *circulant matrix* is a special type of Toeplitz matrix in which each row is a cyclic permutation (one element to the right) of the row above. Circulant matrices have many special properties, including that an explicit formula exists for their inverses and their eigenvalues.

A *Hamiltonian matrix* is a $2n \times 2n$ matrix of the block form

$$\begin{bmatrix} A & F \\ G & -A^* \end{bmatrix},$$

where A , F , and G are $n \times n$ matrices and F and G are Hermitian. Hamiltonian matrices play an important role in CONTROL THEORY [III.25].

The *determinant* of an $n \times n$ matrix A is a scalar that can be defined inductively by

$$\det(A) = \sum_{j=1}^n (-1)^{i+j} a_{ij} \det(A_{ij})$$

for any $i \in \{1, 2, \dots, n\}$, where A_{ij} denotes the $(n-1) \times (n-1)$ matrix obtained from A by deleting row i and column j , and $\det(a) = a$ for a scalar a . This formula is called the expansion by minors because $\det(A_{kj})$ is a *minor* of A . The determinant is sometimes written with vertical bars, as $|A|$. Although determinants came before matrices historically, determinants have only a minor role in applied mathematics.

The quantity obtained by modifying the definition of determinant to remove the $(-1)^{i+j}$ term is the *permanent*, which is the sum of all possible products of n elements of A in which exactly one is taken from each row and each column. The permanent arises in combinatorics and in quantum mechanics.

19 Vector Spaces and Norms

A *vector space* is a mathematical structure in which a linear combination of elements can be taken, with the result remaining in the vector space. A vector space V has a binary operation, which we will write as addition, that is associative, is commutative, and has an identity (the “zero vector,” written 0) and additive inverses. In other words, for any $a, b, c \in V$ we have $(a + b) + c = a + (b + c)$, $a + b = b + a$, $a + 0 = a$, and there is a d such that $a + d = 0$. There is also an underlying set of scalars, \mathbb{R} or \mathbb{C} , such that V is closed under scalar multiplication. Moreover, for all $x, y \in V$ and scalars α, β we have $\alpha(x + y) = \alpha x + \alpha y$, $(\alpha + \beta)x = \alpha x + \beta x$, and $\alpha(\beta x) = (\alpha\beta)x$.

A vector space can take many possible forms. For example, the set of real-valued functions on an interval $[a, b]$ is a vector space over \mathbb{R} , and the set of polynomials of degree less than or equal to n with complex coefficients is a vector space over \mathbb{C} . Most importantly, the sets of n -vectors with real or complex coefficients are vector spaces over \mathbb{R} and \mathbb{C} , respectively.

An important concept is that of linear independence. Vectors v_1, v_2, \dots, v_n in V are *linearly independent* if no nontrivial linear combination of them is zero, that is, if the equation $\alpha_1 v_1 + \alpha_2 v_2 + \dots + \alpha_n v_n = 0$ holds only when the scalars α_i are all zero. If a collection of vectors is not linearly independent then it is *linearly dependent*.

Given vectors v_1, v_2, \dots, v_n in V we can form their *span*, which is the set of all possible linear combinations of them. A linearly independent collection of vectors whose span is V is a *basis* for V , and any vector in V can be written uniquely as a linear combination of these vectors.

The number of vectors in a basis for V is the *dimension* of V , written $\dim V$, and it can be finite or infinite. The vector space of functions mentioned above is infinite dimensional, while the vector space of polynomials of degree at most n has dimension $n + 1$, with a basis being $1, x, x^2, \dots, x^n$ or any other sequence of polynomials of degrees $0, 1, 2, \dots, n$.

A *subspace* of a vector space V is a subset of V that is itself a vector space under the same operations of addition and scalar multiplication.

19.1 Inner Products

Some vector spaces can be equipped with an *inner product*, which is a function $\langle x, y \rangle$ of two arguments that satisfies the conditions (i) $\langle x, x \rangle \geq 0$ and $\langle x, x \rangle = 0$ if and only if $x = 0$, (ii) $\langle x + y, z \rangle = \langle x, z \rangle + \langle y, z \rangle$, (iii) $\langle \alpha x, y \rangle = \alpha \langle x, y \rangle$, and (iv) $\langle x, y \rangle = \langle y, x \rangle$ for all $x, y, z \in V$ and scalars α . The usual (Euclidean) inner product on \mathbb{R}^n is $\langle x, y \rangle = x^T y$; on \mathbb{C}^n the conjugate transpose must be used: $\langle x, y \rangle = x^* y$. For the vector space $C[a, b]$ of real-valued continuous functions on $[a, b]$ an inner product is

$$\langle f, g \rangle = \int_a^b w(x) f(x) g(x) dx, \quad (6)$$

where $w(x)$ is some given, positive weight function, while for the vector space of n -vectors of the form $[f(x_1), f(x_2), \dots, f(x_n)]^T$ for fixed points $x_i \in [a, b]$ and real-valued functions f an inner product is

$$\langle f, g \rangle = \sum_{i=1}^n w_i f(x_i) g(x_i), \quad (7)$$

where the w_i are positive weights. Note that (7) is not an inner product on the space of real-valued continuous functions because $\langle f, f \rangle = 0$ implies only that $f(x_i) = 0$ for all i and not that $f \equiv 0$.

The vector space \mathbb{R}^n with the Euclidean inner product is known as *n-dimensional Euclidean space*.

19.2 Orthogonality

Two vectors u, v in an inner product space are *orthogonal* if $\langle u, v \rangle = 0$. For \mathbb{R}^n and \mathbb{C}^n this is just the usual notion of orthogonality: $u^T v = 0$ and $u^* v = 0$, respectively. A set of vectors $\{u_i\}$ forms an *orthonormal set* if $\langle u_i, u_j \rangle = \delta_{ij}$ for all i and j .

For an inner product space with inner product (6) or (7), useful examples of orthogonal functions are **ORTHOGONAL POLYNOMIALS** [II.29], which have the important property that they satisfy a three-term recurrence relation. For example, the *Chebyshev polynomials*

T_k satisfy $T_0(x) = 1$, $T_1(x) = x$, and

$$T_{k+1}(x) = 2xT_k(x) - T_{k-1}(x), \quad k \geq 1, \quad (8)$$

and they are orthogonal on $[-1, 1]$ with respect to the weight function $(1 - x^2)^{-1/2}$:

$$\int_{-1}^1 \frac{T_i(x)T_j(x)}{(1 - x^2)^{1/2}} dx = 0, \quad i \neq j.$$

Another commonly occurring class of orthogonal polynomials is the *Legendre polynomials* P_k , which are orthogonal with respect to $w(x) \equiv 1$ on $[-1, 1]$ and satisfy the recurrence

$$P_{k+1}(x) = \frac{2k+1}{k+1}xP_k(x) - \frac{k}{k+1}P_{k-1}(x), \quad (9)$$

with $P_0(x) = 1$ and $P_1(x) = x$, when they are normalized so that $P_i(1) = 1$.

Figure 10 plots some Chebyshev polynomials and Legendre polynomials on $[-1, 1]$. Both sets of polynomials are odd for odd degrees and even for even degrees. The values of the Chebyshev polynomials oscillate between -1 and 1 , which is explained by the fact that $T_k(x) = \cos(k\theta)$, where $\theta = \cos^{-1} x$.

A beautiful theory surrounds orthogonal polynomials and their relations to various other areas of mathematics, including Padé approximation, spectral theory, and matrix eigenvalue problems.

If ϕ_1, ϕ_2, \dots is an orthogonal system, that is, $\langle \phi_i, \phi_j \rangle = 0$ for $i \neq j$, then the ϕ_i are necessarily linearly independent. Moreover, in an expansion

$$f(x) = \sum_{i=1}^{\infty} a_i \phi_i(x) \quad (10)$$

there is an explicit formula for the a_i . To determine it, we take the inner product of this equation with ϕ_j and use the orthogonality:

$$\langle f, \phi_j \rangle = \sum_{i=1}^{\infty} a_i \langle \phi_i, \phi_j \rangle = a_j \langle \phi_j, \phi_j \rangle,$$

so that $a_j = \langle f, \phi_j \rangle / \langle \phi_j, \phi_j \rangle$.

An important example of an orthogonal system of functions that are not polynomials is $1, \cos x, \sin x, \cos(2x), \sin(2x), \cos(3x), \dots$, which are orthogonal with respect to the weight function $w(x) \equiv 1$ on $[-\pi, \pi]$, and for this basis (10) is a *Fourier series expansion*.

19.3 Norms

A common task is to approximate an element of a vector space V by the closest element in a subspace S . To define “closest” we need a way to measure the size of a vector. A norm provides such a measure.

A *norm* is a mapping $\|\cdot\|$ from V to the nonnegative real numbers such that $\|x\| = 0$ precisely when $x = 0$, $\|\alpha x\| = |\alpha| \|x\|$ for all scalars α and $x \in V$, and the *triangle inequality* $\|x + y\| \leq \|x\| + \|y\|$ holds for all $x, y \in V$. There are many possible norms, and on a finite-dimensional vector space all are *equivalent* in the sense that for any two norms $\|\cdot\|$ and $\|\cdot\|'$ there are positive constants c_1 and c_2 such that $c_1 \|x\|' \leq \|x\| \leq c_2 \|x\|'$ for all $x \in V$.

An example of a norm on $C[a, b]$ is

$$\|f\|_{\infty} = \max_{x \in [a, b]} |f(x)|, \quad (11)$$

known as the L_{∞} -norm, the supremum norm, the maximum norm, or the uniform norm. For $p \in [1, \infty)$,

$$\|f\|_p = \left(\int_a^b |f(x)|^p dx \right)^{1/p}$$

is the L_p -norm on the space $L^p[a, b]$ of functions for which the (Lebesgue) integral is finite. Important special cases are the L_2 -norm and the L_1 -norm.

In an inner product space the natural norm is $\|x\| = \langle x, x \rangle^{1/2}$, and indeed the L_2 -norm corresponds to the inner product (6) with unit weight function. A very useful inequality involving this norm is the *Cauchy-Schwarz inequality*:

$$|\langle x, y \rangle|^2 \leq \langle x, x \rangle \langle y, y \rangle = \|x\|^2 \|y\|^2$$

for all $x, y \in V$. This inequality shows that we can define the *angle* θ between two vectors x and y by $\cos \theta = \langle x, y \rangle / (\|x\| \|y\|) \in [-1, 1]$. Thus orthogonality corresponds to an angle $\theta = \pm \pi/2$.

Several different norms are commonly used on the vector spaces \mathbb{R}^n and \mathbb{C}^n . The vector p -norm is defined for real p by

$$\|x\|_p = \left(\sum_{i=1}^n |x_i|^p \right)^{1/p}, \quad 1 \leq p < \infty.$$

It includes the important special cases

$$\|x\|_1 = \sum_{i=1}^n |x_i|,$$

$$\|x\|_2 = \left(\sum_{i=1}^n |x_i|^2 \right)^{1/2} = (x^* x)^{1/2},$$

$$\|x\|_{\infty} = \max_{1 \leq i \leq n} |x_i|.$$

The 2-norm is Euclidean length. The 1-norm is sometimes called the “Manhattan” or “taxi cab” norm, as when $x, y \in \mathbb{R}^2$ contain the coordinates of two locations in Manhattan (which has a regular grid of streets), $\|x - y\|_1$ measures the distance by taxi cab from x to y . Figure 11 shows the boundaries of the unit balls

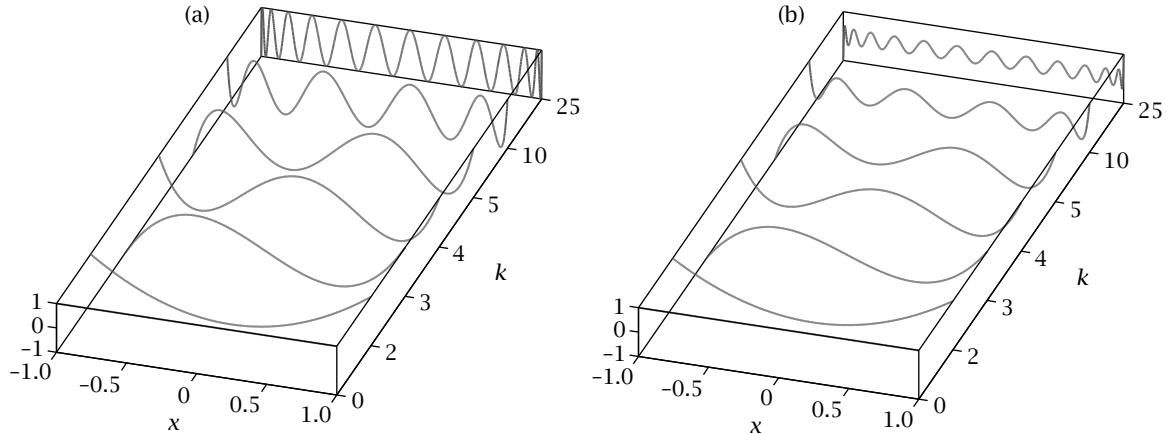

Figure 10 Selected (a) Chebyshev polynomials $T_k(x)$ and (b) Legendre polynomials $P_k(x)$ on $[-1, 1]$.

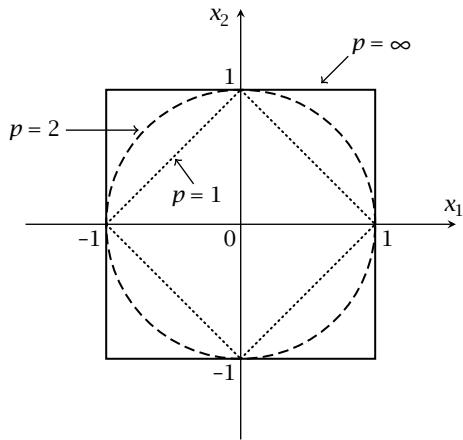

Figure 11 The boundary of the unit ball in \mathbb{R}^2 for the 1-, 2-, and ∞ -norms.

$\{x \in \mathbb{R}^n : \|x\| = 1\}$ for the latter three p -norms. The very different shapes of the unit balls suggest that the appropriate choice of norm will depend on the problem, as is the case, for example, in DATA FITTING [IV.9 §3.2].

Related to norms is the notion of a *metric*, defined on a set M called a *metric space*. A metric on M is a nonnegative function d such that $d(x, y) = d(y, x)$ (symmetry), $d(x, z) \leq d(x, y) + d(y, z)$ (the *triangle inequality*), and for all $x, y, z \in M$, $d(x, y) = 0$ precisely when $x = y$. An example of a metric on the set of positive real numbers is $d(x, y) = |\log(x/y)|$. For a normed vector space, the function $d(x, y) = \|x - y\|$ is always a metric, so a normed vector space is always a metric space.

19.4 Convergence

We say that a sequence of points x_1, x_2, \dots , each belonging to a normed vector space V , converges to a limit $x_* \in V$, written $\lim_{i \rightarrow \infty} x_i = x_*$ (or $x_i \rightarrow x_*$ as $i \rightarrow \infty$), if for any $\varepsilon > 0$ there exists a positive integer N such that $\|x_* - x_i\| < \varepsilon$ for all $i \geq N$.

The sequence is a *Cauchy sequence* if for any $\varepsilon > 0$ there exists a positive integer N such that $\|x_i - x_j\| < \varepsilon$ for all $i, j \geq N$. A convergent sequence is a Cauchy sequence, but whether or not the converse is true depends on the space V .

A normed vector space is *complete* if every Cauchy sequence in V has a limit in V . A complete normed vector space is called a *Banach space*. In a Banach space we can therefore prove convergence of a sequence without knowing its limit by showing that it is a Cauchy sequence.

A complete inner product space is called a *Hilbert space*. The spaces \mathbb{R}^n and \mathbb{C}^n with the Euclidean inner product are standard examples of Hilbert spaces.

20 Operators

An *operator* is a mapping from one vector space, U , to another, V (possibly the same one). A *linear operator* (or *linear transformation*) A is an operator such that $A(\alpha_1 x_1 + \alpha_2 x_2) = \alpha_1 A x_1 + \alpha_2 A x_2$ for all scalars α_1, α_2 and vectors $x_1, x_2 \in U$. For example, the differentiation operator is a linear operator that maps the vector space of polynomials of degree at most n to the vector space of polynomials of degree at most $n - 1$.

A natural measure of the size of a linear operator A mapping U to V is the *induced norm* (also called the

operator norm or subordinate norm),

$$\|A\| = \max \left\{ \frac{\|Ax\|}{\|x\|} : x \in U, x \neq 0 \right\},$$

where on the right-hand side $\|\cdot\|$ denotes both a norm on U (in the denominator) and a norm on V (in the numerator). For the rest of this section we assume that $U = V$ for simplicity. If $\|A\|$ is finite then A is said to be a *bounded* linear operator. On a finite-dimensional vector space all linear operators are bounded.

The definition of an operator norm yields the inequalities $\|Ax\| \leq \|A\| \|x\|$ (immediate) and $\|AB\| \leq \|A\| \|B\|$ (using the previous inequality), both of which are indispensable.

The operator A maps vectors in U to other vectors in U , and it may change the norm by as much as $\|A\|$. For some vectors, called *eigenvectors*, it is only the norm, and not the direction, that changes. A nonzero vector v is an eigenvector, with *eigenvalue* λ , if $Av = \lambda v$. Eigenvalues and eigenvectors play an important role in many areas of applied mathematics and appear in many places in this book. For example, SPECTRAL THEORY [IV.8] is about the eigenvalues and eigenvectors of linear operators on appropriate function spaces. The adjective *spectral* comes from *spectrum*, which is a set that contains the eigenvalues of an operator.

On taking norms in the relation $Av = \lambda v$ and using $\|v\| \neq 0$ we obtain $|\lambda| \leq \|A\|$. Thus all the eigenvalues of the operator A lie in a disk of radius $\|A\|$ centered at the origin. This is an example of a localization result.

An *invariant subspace* of an operator A that maps a vector space U to itself is a subspace X of U such that AX is a subset of X , so that $x \in X$ implies $Ax \in X$. An eigenvector is the special case of a one-dimensional invariant subspace.

For $n \times n$ matrices, the eigenvalue equation $Av = \lambda v$ says that $A - \lambda I$ is a singular matrix, which is equivalent to the condition $p(\lambda) = \det(\lambda I - A) = 0$. The polynomial p is the *characteristic polynomial* of A , and since it has degree n it follows from the fundamental theorem of algebra (section 14) that it has n roots in the complex plane, which are the eigenvalues of A . Whether there are n linearly independent eigenvectors associated with the eigenvalues depends on A and can be elegantly answered in terms of the JORDAN CANONICAL FORM [II.22]. For real symmetric and complex Hermitian matrices, the eigenvalues are all real and there is a set of n linearly independent eigenvectors, which can be taken to be orthonormal. If A is in addition positive-definite, then the eigenvalues are all positive.

For matrices on $\mathbb{C}^{m \times n}$ the operator matrix norms corresponding to the 1, 2, and ∞ vector norms have explicit formulas:

$$\begin{aligned}\|A\|_1 &= \max_{1 \leq i \leq n} \sum_{j=1}^m |a_{ij}|, \quad \text{"max column sum,"} \\ \|A\|_\infty &= \max_{1 \leq i \leq m} \sum_{j=1}^n |a_{ij}|, \quad \text{"max row sum,"} \\ \|A\|_2 &= (\rho(A^*A))^{1/2}, \quad \text{spectral norm,}\end{aligned}$$

where the *spectral radius*

$$\rho(B) = \max\{|\lambda| : \lambda \text{ is an eigenvalue of } B\}.$$

Another useful formula is $\|A\|_2 = \sigma_{\max}(A)$, where $\sigma_{\max}(A)$ is the largest SINGULAR VALUE [II.32] of A . A further matrix norm that is commonly used is the Frobenius norm, given by

$$\|A\|_F = \left(\sum_{i=1}^m \sum_{j=1}^n |a_{ij}|^2 \right)^{1/2} = (\text{trace}(A^*A))^{1/2},$$

where the *trace* of a square matrix is the sum of its diagonal elements. Note that $\|A\|_F$ is just the 2-norm of the vector obtained by stringing the columns of A out into one long vector. The Frobenius norm is not induced by any vector norm, as can be seen by taking A as the identity matrix.

21 Linear Algebra

Associated with a matrix $A \in \mathbb{C}^{m \times n}$ are four important subspaces, two in \mathbb{C}^m and two in \mathbb{C}^n : the ranges and the nullspaces of A and A^* . The *range* of A is the set of all linear combinations of the columns: $\text{range}(A) = \{Ax : x \in \mathbb{C}^n\}$. The *null space* of A is the set of vectors annihilated by A : $\text{null}(A) = \{x \in \mathbb{C}^n : Ax = 0\}$.

The two most important laws of linear algebra are

$$\begin{aligned}\dim \text{range}(A) &= \dim \text{range}(A^*), \\ \dim \text{range}(A) + \dim \text{null}(A) &= n,\end{aligned}$$

where \dim denotes dimension. These equalities can be proved in various ways, one of which is via the SINGULAR VALUE DECOMPOSITION [II.32].

Suppose $x \in \text{null}(A)$. Then x is orthogonal to every row of A and hence is orthogonal to the subspace spanned by the rows of A . Since the rows of A are the columns of A^* , it follows that $\text{null}(A)$ is orthogonal to $\text{range}(A^*)$, where two subspaces are said to be orthogonal if every vector in one of the subspaces is orthogonal to every vector in the other. In fact, it can be shown that $\text{null}(A)$ and $\text{range}(A^*)$ together span \mathbb{C}^n , and this

implies that $\dim \text{range}(A^*) + \dim \text{null}(A) = n$, which can also be obtained by combining the two laws.

The *rank* of A is the maximum number of linearly independent rows or columns of A . The rank plays an important role in linear equation problems. For example, a linear system $Ax = b$ has a solution if and only if A and the augmented matrix $[A \ b]$ have the same rank.

The *Fredholm alternative* says that the equation $Ax = b$ has a solution if and only if $b^*v = 0$ for every vector v satisfying $A^*v = 0$. This is a special case of more general versions of the alternative, e.g., in INTEGRAL EQUATIONS [IV.4 §3]. The “only if” part is easy, since if $A^*v = 0$ and $Ax = b$ then $b^*v = (v^*b)^* = (v^*Ax)^* = ((A^*v)^*x)^* = 0$. For the “if” part, suppose $b^*v = 0$ for every vector v such that $A^*v = 0$. The latter equation says that $v \in \text{null}(A^*)$, and from what we have just seen this means that v is orthogonal to $\text{range}(A)$. So every vector orthogonal to $\text{range}(A)$ is orthogonal to b , which means that b is in $\text{range}(A)$ and so $Ax = b$ has a solution.

22 Condition Numbers

A condition number of a problem measures the sensitivity of the solution to perturbations in the data. For some problems there is not a unique solution and the problem can be regarded as infinitely sensitive; such problems fall into the class of ILL-POSED PROBLEMS [I.5 §1.2]. Consider a function f mapping a vector space to itself such that $f(x)$ is defined in some neighborhood of x . A (relative) condition number for f at x is defined by

$$\text{cond}(f, x) = \lim_{\varepsilon \rightarrow 0} \sup_{\|\delta x\| \leq \varepsilon \|x\|} \frac{\|f(x + \delta x) - f(x)\|}{\varepsilon \|f(x)\|}.$$

The condition number cond measures by how much, at most, small changes in the data can be magnified in the function value when both changes are measured in a relative sense. This definition implies that

$$\frac{\|f(x + \delta x) - f(x)\|}{\|f(x)\|} \leq \text{cond}(f, x) \frac{\|\delta x\|}{\|x\|} + o(\|\delta x\|) \quad (12)$$

and so provides an approximate perturbation bound for small perturbations δx . In practice, δx in the latter bound might represent inherent errors in the data from a physical experiment or rounding errors when the data is stored on a computer.

A problem is said to be *ill-conditioned* if its condition number is large and *well-conditioned* if its condition number is small, where the meaning of “large” and “small” depends on the context.

For many problems, explicit expressions can be obtained for the condition number. For a continuously differentiable function $f: \mathbb{R} \rightarrow \mathbb{R}$, $\text{cond}(f, x) = |xf'(x)/f(x)|$. For the problem of matrix inversion, $f(A) = A^{-1}$, the condition number turns out to be $\kappa(A) = \|A\| \|A^{-1}\|$ for any matrix norm; this is known as the *condition number of A with respect to inversion*. For the linear system $Ax = b$, with data the matrix A and vector b , the condition number is also essentially $\kappa(A)$.

One role of the condition number is to provide a link between the residual of an approximate solution of an equation and the error of that approximation. This is most easily seen for a nonsingular linear system $Ax = b$. For any approximate solution \hat{x} the residual satisfies $r = b - A\hat{x} = A(x - \hat{x})$, so the error is related to the residual by $x - \hat{x} = A^{-1}r$, which leads to the upper bound $\|x - \hat{x}\| \leq \kappa(A) \|r\| / \|A\|$.

23 Stability

The term “stability” is widely used in applied mathematics, with different meanings that depend on the context. A general meaning is that errors introduced in the initial stages of a process do not grow (or at least are bounded) as the process evolves. Here “process” could mean an iteration, a recurrence, or the evolution of a time-dependent differential equation. Stability is usually a necessary attribute and so a lot of effort is put into analyzing whether processes are stable or not. Discussions of stability can be found throughout this book.

Here we focus on *numerical stability*, in the context of evaluating a function $y = f(x)$ in floating-point arithmetic by some given algorithm, where x and y are scalars. If \hat{y} is an approximation to y then one measure of its quality is the *forward error* $\hat{y} - y$, which is often called, simply, “the error.” The forward error is usually unknown and may be difficult to estimate. As an alternative we can ask whether we can perturb the data x so that \hat{y} is the exact solution to the perturbed problem; that is, can we find a δx such that $\hat{y} = f(x + \delta x)$? In general, there may be many such δx ; the smallest possible value of $|\delta x|$ is called the *backward error*. If the backward error is sufficiently small relative to the precision of the underlying arithmetic, then the algorithm is said to be *backward stable*.

It can be much easier to analyze the backward error than the forward error. Backward error analysis originates in NUMERICAL LINEAR ALGEBRA [IV.10 §8], where

the underlying errors are rounding errors, but it has been used in various other contexts, including in the numerical solution of ordinary differential equations. Once the backward error is known, the forward error can be bounded by using the inequality (12), provided that an estimate of the relevant condition number is available.

24 Vector Calculus

While n -dimensional vector spaces, with n possibly infinite, are the appropriate setting for much applied mathematics, the world we live in is three dimensional and so three coordinates are enough in many situations, such as in mechanics. Let \mathbf{i} , \mathbf{j} , and \mathbf{k} denote unit vectors along the x -, y -, and z -axes, respectively. As this notation suggests, we will use boldface to denote vectors in this subsection. A vector \mathbf{x} in \mathbb{R}^3 can then be expressed as $\mathbf{x} = x_1\mathbf{i} + x_2\mathbf{j} + x_3\mathbf{k}$. The *scalar product* or *dot product* of two vectors \mathbf{x} and \mathbf{y} is $\mathbf{x} \cdot \mathbf{y} = x_1y_1 + x_2y_2 + x_3y_3$, which is a special case of the Euclidean inner product of vectors in \mathbb{R}^n . The *cross product* or *vector product* does not have an n -dimensional analogue; it is the vector

$$\begin{aligned}\mathbf{x} \times \mathbf{y} &= \begin{vmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \end{vmatrix} \\ &= (x_2y_3 - x_3y_2)\mathbf{i} + (x_3y_1 - x_1y_3)\mathbf{j} \\ &\quad + (x_1y_2 - x_2y_1)\mathbf{k},\end{aligned}$$

which is orthogonal to the plane in which \mathbf{x} and \mathbf{y} lie. Note that $\mathbf{x} \times \mathbf{y} = -\mathbf{y} \times \mathbf{x}$. The *vector triple product* of three vectors \mathbf{x} , \mathbf{y} , and \mathbf{z} is the vector $\mathbf{x} \times (\mathbf{y} \times \mathbf{z})$, which can be expressed as

$$\mathbf{x} \times (\mathbf{y} \times \mathbf{z}) = (\mathbf{x} \cdot \mathbf{z})\mathbf{y} - (\mathbf{x} \cdot \mathbf{y})\mathbf{z}.$$

If f is a scalar function of three variables, then its *gradient* is

$$\nabla f = \frac{\partial f}{\partial x}\mathbf{i} + \frac{\partial f}{\partial y}\mathbf{j} + \frac{\partial f}{\partial z}\mathbf{k}.$$

We can think of

$$\nabla = \frac{\partial}{\partial x}\mathbf{i} + \frac{\partial}{\partial y}\mathbf{j} + \frac{\partial}{\partial z}\mathbf{k}$$

as an operator: the *gradient operator*. There is nothing to stop us forming the dot product of the two vectors ∇ and ∇f :

$$\nabla \cdot \nabla f = \frac{\partial^2 f}{\partial x^2} + \frac{\partial^2 f}{\partial y^2} + \frac{\partial^2 f}{\partial z^2}.$$

This “del squared” operator is called the *Laplacian*, $\Delta = \nabla^2 \equiv \nabla \cdot \nabla$.

Now let $\mathbf{F} = F_1\mathbf{i} + F_2\mathbf{j} + F_3\mathbf{k}$ be a vector function mapping \mathbb{R}^3 to \mathbb{R}^3 . The *divergence* of \mathbf{F} is the dot product of ∇ and \mathbf{F} :

$$\operatorname{div} \mathbf{F} = \nabla \cdot \mathbf{F} = \frac{\partial F_1}{\partial x} + \frac{\partial F_2}{\partial y} + \frac{\partial F_3}{\partial z}.$$

Another operator on vector functions that is commonly encountered is the *curl*: $\operatorname{curl} \mathbf{F} = \nabla \times \mathbf{F}$.

The *divergence theorem* says that, if V is a vector field enclosed by a smooth surface S oriented by an outward-pointing unit normal \mathbf{n} and F is a continuously differentiable vector field over V , then

$$\iiint_V \operatorname{div} \mathbf{F} dV = \iint_S \mathbf{F} \cdot \mathbf{n} dS.$$

In other words, the triple integral of the divergence of F over V is equal to the surface integral of the normal component, $\mathbf{F} \cdot \mathbf{n}$. Many equations of physical interest can be derived using the divergence theorem.

Another important theorem is *Stokes's theorem*. It says that, for an oriented smooth surface S with outward-pointing unit normal \mathbf{n} , bounded by a smooth simple closed curve C , if F is a continuously differentiable vector field over S , then

$$\iint_S (\nabla \times \mathbf{F}) \cdot \mathbf{n} dS = \int_C \mathbf{F} \cdot \mathbf{t} ds,$$

where $\mathbf{t} = \mathbf{t}(x, y, z)$ is a unit vector tangential to the curve C . Stokes's theorem says that the integral of the normal component of the curl of F over a surface S is equal to the integral of the tangential component of F along the boundary C of the surface.

I.3 Methods of Solution

Nicholas J. Higham

Problems in applied mathematics come in many shapes and forms, and a wide variety of methods and techniques are used to solve them. In this article we outline some key ideas that underlie many different solution approaches.

1 Specifying the Problem

Before we can set about choosing a method to solve a problem we need to be clear about our assumptions. For example, if our problem is defined by a function (which could be the right-hand side of a differential equation), what can we assume about the smoothness of the function, that is, the number of continuous derivatives? If our problem is to find the eigenvalues of an $n \times n$ matrix A , are the elements of A explicitly stored and accessible or is A given only in the form of

a “black box” that takes a vector x as input and returns the product Ax ?

The problem of finding a minimum or maximum of a scalar function f of n variables provides a good example of a wide range of possible scenarios. At one extreme, f has derivatives of all orders and we can compute f and its first and second derivatives at any point (most methods do not use derivatives of higher than second order). At another extreme, f may be discontinuous and only function values may be available. It may even be that we are not able to evaluate f but only to test whether, for a given x and y , $f(x) < f(y)$ or vice versa. This is precisely the scenario for an optometrist formulating a prescription for a patient. The optometrist asks the patient to compare pairs of lenses and say which one gives the better vision. By suitably choosing the lenses the optometrist is able to home in on a prescription within a few minutes. In numerical optimization, DERIVATIVE-FREE METHODS [IV.11 §4.3] use only function values and many of them are based solely on comparisons of these values.

Another fundamental question is what is meant by a solution. If the solution is a function, would we accept its representation as an infinite series in some basis functions, or as an integral, or would we accept values of the function on a finite grid of points? If an inexact representation is allowed, how accurate must it be and what measure of error is appropriate?

2 Dimension Reduction

A common theme in many contexts is that of approximating a problem by one of smaller dimension and using the solution of the smaller problem to approximate the solution of the original problem. The motivation is that the large problem may be too expensive to solve, but of course this approach is viable only if the smaller problem can be constructed at low cost. In some situations the smaller problem is solved repeatedly, perhaps as some parameter varies, thereby amortizing the cost of producing it.

A ubiquitous example of this general approach concerns images displayed on Web pages. Modern digital cameras (even smartphones) produce images of 5 megapixels (million pixels) or more. Yet even a 27-inch monitor with a resolution of 2560×1440 pixels displays only about 3.7 megapixels. Since most images on Web pages are displayed at a small size within a page, it would be a great waste of storage and bandwidth to deal with them at their original size. They

are therefore interpolated down to smaller dimensions appropriate for the intended usage (e.g., with longest side 400 pixels for an image on a news site). Here, dimension reduction is relatively straightforward and error is not an issue.

Often, though, an image is of intrinsic interest and we wish to keep it at its original dimensions and reduce the required storage, with minimal loss of quality. This is the more typical scenario for dimension reduction. The reason that dimension reduction is possible is that many images contain a high degree of redundancy. The SINGULAR VALUE DECOMPOSITION [II.32] (SVD) provides a way of capturing the important information in an image in a small number of vectors, at least for some images. A generally more effective reduction is produced by JPEG COMPRESSION [VII.7 §5], which uses two successive changes of basis in order to identify information that can be discarded.

A dynamical system may have many parameters but the behavior of interest may take place in a low-dimensional subspace. In this case we can try to identify that subspace and work within it, gaining a reduction in computation and storage. The general term for reducing dimension in a dynamical system is MODEL REDUCTION [II.26]. Model reduction has been an area of intensive research in the last thirty years, with applications ranging from the design of very large scale integration circuits to data assimilation in modeling the atmosphere.

Dimension reduction is fundamental to DATA ANALYSIS [IV.17 §4], where large data sets are transformed via a change of basis into lower-dimensional spaces that capture the behavior of the original data. Classic techniques are principal component analysis and application of the SVD. In the context of linear matrix equations such as the LYAPUNOV EQUATION [III.28], an approximation to a dominant invariant subspace of the solution (that is, an invariant subspace corresponding to the k eigenvalues of largest magnitude, for some k) can be as useful as an approximation to the whole solution, and such an approximation can often be computed at much lower cost.

A term often used in the context of dimension reduction is *curse of dimensionality*, which refers to the fact that many problems become much harder in higher dimensions and, more informally, that intuition gained from two and three dimensions does not necessarily translate to higher dimensions. A simple illustration is given by an n -sphere, or hypersphere, of radius r in \mathbb{R}^n , which comprises all n -vectors of 2-norm (Euclidean

norm) r . A hypersphere has volume

$$S_n = \frac{\pi^{n/2} r^n}{\Gamma(n/2 + 1)},$$

where Γ is the GAMMA FUNCTION [III.13]. Since $\Gamma(x) \sim \sqrt{2\pi/x}(x/e)^x$ (STIRLING'S APPROXIMATION [IV.7 §3]), for any fixed r we find that S_n tends to 0 as n tends to ∞ , that is, the volume of the hypersphere tends to zero, which is perhaps surprising. For a means of comparison, consider the n -cube, or hypercube, with sides of length $2r$. It has volume

$$H_n = (2r)^n$$

and therefore $S_n/H_n \rightarrow 0$ as $n \rightarrow \infty$. In other words, most of the volume of a hypercube lies away from the enclosed hypersphere, and hence "in the corners." For $n = 2$, the ratio $S_2/H_2 = 0.785$ (see figure 11 in THE LANGUAGE OF APPLIED MATHEMATICS [I.2 §19.3]), which is already substantially less than 1. The sequence S_n/H_n continues 0.524, 0.308, 0.164, 0.081, This behavior is not too surprising when one realizes that any corner of the unit hypercube centered on the origin has coordinates $[\pm 1, \pm 1, \dots, \pm 1]^T$, and so is at distance \sqrt{n} from the origin, whereas any point on the unit hypersphere centered on the origin is at distance 1 from the origin, so the latter distance divided by the former tends to 0 as $n \rightarrow \infty$. The term curse of dimensionality was introduced by Richard Bellman in 1961, with reference to the fact that sampling a function of n variables on a grid with a fixed spacing requires a number of points that grows exponentially with n .

3 Approximation of Functions

We consider the problem of approximating a scalar function f , which may be given either as an explicit formula or implicitly, for example as the solution to an algebraic or differential equation. How the problem is solved depends on what is known about the function and what is required of the solution. We summarize some of the questions that must be answered before choosing a method.

- What form do we want the approximation to take: power series, polynomial, rational, Fourier series, ...?
- Do we want an approximation that has a desired accuracy within a certain region? If so, what measure of error should be used?
- Do we want an approximation that has certain qualitative features, such as convexity, monotonicity, or nonnegativity?

In this section we discuss a few examples of different types of approximation, touching on all the questions in this list. In the next three subsections f is assumed to be real (its argument being written x), whereas in the fourth subsection it can be complex (so its argument is written z). We consider first approximations based on polynomials.

3.1 Polynomials

Perhaps the simplest class of approximating functions is the polynomials, $p_n(x) = a_0 + a_1 x + \dots + a_n x^n$. Polynomials are easy to add, multiply, differentiate, and integrate, and their roots can be found by standard algorithms. Justification for the use of polynomials comes from *Weierstrass's theorem* of 1885, which states that for any $f \in C[a, b]$ and any $\varepsilon > 0$ there is a polynomial $p_n(x)$ such that $\|f - p_n\|_\infty < \varepsilon$, where the norm is the L_∞ -NORM [I.2 §19.3] given by $\|f\|_\infty = \max_{x \in [a, b]} |f(x)|$. Weierstrass's theorem assures us that any desired degree of accuracy in the maximum norm can be obtained by polynomials, though it does not bound the degree n , which may have to be high. Here are some of the ways in which polynomial approximations are constructed.

Truncated Taylor series. If f is sufficiently smooth that it has a Taylor series expansion and its derivatives can be evaluated, then a polynomial approximation can be obtained simply by truncating the Taylor series. The Taylor series with remainder tells us that we can write $f(x) = p_n(x) + E_n(x)$, where $p_n(x) = f(0) + f'(0)x + \dots + f^{(n)}(0)x^n/n!$ is a degree- n polynomial and the remainder term has the form $E_n(x) = f^{(n+1)}(\xi)x^{n+1}/(n+1)!$ for some ξ on the interval with endpoints 0 and x . The value of n and the range of x for which the approximation $f(x) \approx p_n(x)$ is applied will depend on f and the desired accuracy. Figure 1 shows the degree-1, degree-3, and degree-5 Taylor approximants to the sine function.

Interpolation. We may require $p_n(x)$ to agree with $f(x)$ at certain specified points $x_i \in [a, b]$. Since p_n contains $n+1$ coefficients and each condition $p_n(x_i) = f(x_i)$ provides one equation, we need $n+1$ points in order to specify p_n . It can be shown that the $n+1$ interpolation equations in $n+1$ unknowns have a unique solution provided that the interpolation points $\{x_i\}_{i=0}^n$ are distinct, in which case there is a unique *interpolating polynomial*. There is a variety of ways of representing p_n (e.g., Lagrange form, barycentric form, and

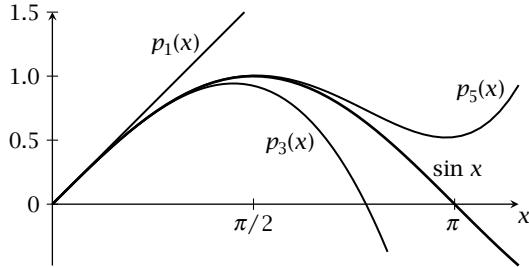

Figure 1 $\sin x$ and its Taylor approximants $p_1(x) = x$, $p_3(x) = x - x^3/3!$, and $p_5(x) = x - x^3/3! + x^5/5!$.

divided difference form). An explicit formula is available for the error: if f has $n+1$ continuous derivatives on $[a, b]$ then for any $x \in [a, b]$

$$f(x) - p_n(x) = \frac{f^{(n+1)}(\xi_x)}{(n+1)!} \prod_{i=0}^n (x - x_i),$$

where ξ_x is some unknown point in the interval determined by x_0, x_1, \dots, x_n , and x . This error formula can be used to obtain insight into how to choose the x_i . It turns out that equally spaced points are poor, whereas points derived by rescaling to $[a, b]$ the ZEROS OR EXTREMA OF THE CHEBYSHEV POLYNOMIAL [IV.9 §2.2] of degree $n+1$ or n , respectively, are good.

Least-squares approximation. In least-squares approximation we fix the degree n and then choose the polynomial p_n to minimize the L_2 -norm

$$\left(\int_a^b |f(x) - p_n(x)|^2 dx \right)^{1/2},$$

where $[a, b]$ is the interval of interest. It turns out that there is a unique p_n minimizing the error, and its coefficients satisfy a linear system of equations called the *normal equations*. The normal equations tend to be ill-conditioned when p_n is represented in the *monomial basis*, $\{1, x, x^2, \dots\}$, so in this context it is usual to write $p_n = \sum_{i=0}^n a_i \phi_i(x)$, where the ϕ_i are ORTHOGONAL POLYNOMIALS [II.29] on $[a, b]$. In this case the normal equations are diagonal and there is an explicit expression for the optimal coefficients: $a_i = \int_a^b \phi_i(x) f(x) dx / \int_a^b \phi_i(x)^2 dx$.

L_∞ approximation. Instead of using the L_2 -norm we can use the L_∞ -norm and so minimize $\|f - p_n\|_\infty$. A best L_∞ approximation always exists and is unique, and there is a beautiful theory that characterizes the solution in terms of *equioscillation*, whereby the error achieves its maximum magnitude at a certain number of points with alternating sign. An algorithm called

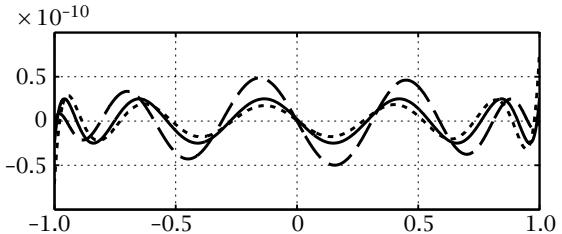

Figure 2 Error in polynomial approximations to e^x on $[-1, 1]$: solid line, L_∞ approximation; dashed line, Chebyshev interpolant; dotted line, least squares (L_2 approximation).

the Remez algorithm is available for computing the best L_∞ approximation. One use of it is in EVALUATING ELEMENTARY FUNCTIONS [VI.11].

Figure 2 plots the absolute error $|f - p_n(x)|$ in three degree-10 polynomial approximations to e^x on $[-1, 1]$: the least-squares approximation; the L_∞ approximation; and a polynomial interpolant based on the Chebyshev points, $\cos(j\pi/n)$, $j = 0 : n$. Note that the L_∞ approximation has equioscillating error with maximum error strictly less than that for the other two approximations, and that the error of the Chebyshev interpolant is zero at the eleven points where it interpolates, which include the endpoints. It is also clear that the Chebyshev approximation is not much worse than the L_∞ one—something that is true in general.

3.2 Piecewise Polynomials

High-degree polynomials have a tendency to wiggle. A degree-100 polynomial p has up to 100 points at which it crosses the x -axis on a plot of $y = p(x)$: the distinct real zeros of p . This can make high-degree polynomials unsatisfactory as approximating functions. Instead of using one polynomial of large degree it can be better to use many polynomials of low degree. This can be done by breaking the interval of interest into pieces and using a different low-degree polynomial on each piece, with the polynomials joined together smoothly to make up the complete approximating function. Such *piecewise polynomials* can produce functions with high approximating power while avoiding the oscillations possible with high-degree polynomials.

A trivial example of a piecewise polynomial is the absolute value function $|x|$, which is equal to $-x$ for $x \leq 0$ and x for $x \geq 0$ (see figure 4 on p. 13 in THE LANGUAGE OF APPLIED MATHEMATICS [I.2]). More generally, a piecewise polynomial g defined on an interval

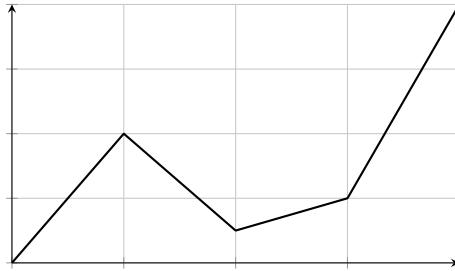

Figure 3 A piecewise-linear function (spline).

$[a, b] =: [x_0, x_n]$ that is the union of n subintervals $[x_0, x_1], [x_1, x_2], \dots, [x_{n-1}, x_n]$ is defined by the property that $g(x) = p_i(x)$ for $x \in [x_i, x_{i+1}]$, where each p_i is a polynomial. Thus on each interval g is a polynomial, but each of these individual polynomials is in general different and possibly of different degree. Such a function is generally discontinuous, but we can ensure continuity by insisting that $p_{i-1}(x_i) = p_i(x_i)$, $i = 1 : n - 1$.

Important examples of piecewise polynomials are *splines*, which are piecewise polynomials g for which each individual polynomial has degree k or less and for which g has $k - 1$ continuous derivatives on the interval. A spline therefore has the maximum possible smoothness. The most commonly used splines are linear splines and cubic splines, and an important application is in the FINITE-ELEMENT METHOD [II.12]. Figure 3 shows an example of a linear spline. Splines are commonly used in plotting data, where they provide a way of “joining up the dots,” e.g., by straight lines in the case of a linear spline.

In computer-aided design the individual polynomials in a piecewise polynomial are often constructed as *Bézier curves*, which have the form

$$B_n(x) = \sum_{i=0}^n \binom{n}{i} \frac{(b-x)^{n-i}(x-a)^i}{(b-a)^n} \mathbf{p}_i$$

for an interval $[a, b]$. The \mathbf{p}_i are control points in the plane that the user chooses via a graphical interface in order to achieve a desired form of curve. Figure 4 shows a cubic Bézier curve. The polynomials that multiply the \mathbf{p}_i are called *Bernstein polynomials*, and they were originally introduced by Bernstein in 1912 in order to give a constructive proof of Weierstrass’s theorem. The use of Bézier curves as a design tool to intuitively construct and manipulate complex shapes was initiated at the Citroën and Renault car companies in the 1960s. Today, cubic Bézier curves are widely used, e.g., in the design of fonts, in image manipulation programs such

as Adobe Photoshop, and in the ISO standard for the Portable Document Format (PDF).

3.3 Wavelets

FOURIER ANALYSIS [I.2 §19.2] decomposes a function into a linear combination of trigonometric functions (sines and cosines) with different frequencies and so is a natural way to deal with periodic functions. Wavelet analysis, which was first developed in the 1980s, is designed to handle nonperiodic functions and does so by using basis functions that are rough and localized. Rather than varying the frequency as with the Fourier basis, a wavelet basis is constructed by translation ($f(x) \rightarrow f(x - 1)$) and dilation ($f(x) \rightarrow f(2x)$). Given a mother wavelet $\psi(x)$, which has compact support (that is, it is zero outside a bounded interval), translations and dilations are created as $\psi(2^n x - k)$ with integer n and k . This leads to many different resolutions, and hence the term *multiresolution analysis* is used in this context. Larger n correspond to finer resolutions, and as k varies the support moves around.

The localized nature of the wavelet basis functions makes wavelet representations of many functions and data relatively sparse, which makes wavelets particularly suitable for data compression, detection of features in images (such as edges and other discontinuities), and noise reduction. These are some of the reasons for the success of wavelets in (for example) imaging, where they are used in the JPEG2000 STANDARD [VII.7 §5].

3.4 Series Solution

We now turn to the development of explicit series representations of a function. As an example we take the Airy function $w(z)$, which satisfies the differential equation

$$w'' - zw = 0.$$

We can look for a solution $w(z) = \sum_{k=0}^{\infty} a_k z^k$, where $a_0 = w(0)$ and $a_1 = w'(0)$ can be regarded as given. For simplicity we will take $a_0 = 1$ and $a_1 = 0$. Differentiating twice gives $w''(z) = \sum_{k=2}^{\infty} k(k-1)a_k z^{k-2}$. Substituting the power series for w and w'' into the differential equation we obtain $\sum_{k=2}^{\infty} k(k-1)a_k z^{k-2} - \sum_{k=0}^{\infty} a_k z^{k+1} = 0$. Since this equation must hold for all z we can equate coefficients of z^0, z^1, z^2, \dots on both sides to obtain a sequence of equations that provide recurrence relations for the a_k , specifically $(k+1)(k+2)a_{k+2} = a_{k-1}$ along with $a_2 = 0$. We find that

$$w(z) = 1 + \frac{z^3}{6} + \frac{z^6}{180} + \frac{z^9}{12960} + \dots$$

The modulus of the ratio of successive nonzero terms tends to zero as the index of the terms tends to infinity, which ensures that the series is convergent for all z . Since a power series can be differentiated term by term within its radius of convergence, it follows that our series does indeed satisfy the Airy equation.

Constructing a series expansion does not always lead to a convergent series. Consider the exponential integral

$$E_1(z) = \int_z^{\infty} \frac{e^{-t}}{t} dt.$$

Integrating by parts repeatedly gives

$$\begin{aligned} E_1(z) &= \frac{e^{-z}}{z} - \int_z^{\infty} \frac{e^{-t}}{t^2} dt \\ &= \frac{e^{-z}}{z} - \frac{e^{-z}}{z^2} + 2 \int_z^{\infty} \frac{e^{-t}}{t^3} dt \\ &= \frac{e^{-z}}{z} \left(1 - \frac{1}{z} + \frac{2!}{z^2} + \dots + (-1)^{k-1} \frac{(k-1)!}{z^{k-1}} \right) + R_k. \end{aligned}$$

The remainder term, $R_k = (-1)^k k! \int_z^{\infty} (e^{-t}/t^{k+1}) dt$, does not tend to zero as $k \rightarrow \infty$ for fixed z , so the series is not convergent. Nevertheless, $|R_k|$ does decrease with k before it increases, and a reasonable approximation to $E_1(z)$ can be obtained by choosing a suitable value of k . For example, with $z = 10$ the remainder starts increasing at $k = 11$, and taking $k = 10$ we obtain the approximation $E_1(10) \approx 4.156 \times 10^{-6}$, which is to be compared with $E_1(10) = 4.157 \times 10^{-6}$, where both results have been rounded to four significant figures. The series above is an example of an *asymptotic series*. In general, we say that the series $\sum_{k=0}^{\infty} a_k z^{-k}$ is an *asymptotic expansion* of f as $z \rightarrow \infty$ if

$$\lim_{z \rightarrow \infty} z^n \left(f(z) - \sum_{k=0}^n a_k z^{-k} \right) = 0$$

for every n , and we write $f(z) \sim \sum_{k=0}^{\infty} a_k z^{-k}$, where the symbol “ \sim ” is read as “is asymptotic to.” This condition

can also be written as

$$f(z) = \sum_{k=0}^{n-1} a_k z^{-k} + O(z^{-n}).$$

For the series for E_1 we have

$$\begin{aligned} |z^k R_k| &= |z|^k k! \left| \int_z^{\infty} \frac{e^{-t}}{t^{k+1}} dt \right| \\ &\leq \frac{k!}{|z|} \left| \int_z^{\infty} e^{-t} dt \right| = \frac{k!}{|z|} |e^{-z}|, \end{aligned}$$

and the latter bound tends to zero as $|z| \rightarrow \infty$ if $\arg z \in (-\pi/2, \pi/2)$, so the series is asymptotic under this constraint on z .

By summing an appropriate number of terms, asymptotic series can deliver approximations of up to a certain, possibly good, accuracy, for large enough $|z|$, but beyond a certain point the accuracy worsens.

Suppose we have the quadratic $q_{\varepsilon}(x) = x^2 - x + \varepsilon = 0$, where ε is a small parameter and we wish to obtain a series expansion for x as a function of ε . This can be done by substituting $x(\varepsilon) = \sum_{k=0}^{\infty} a_k \varepsilon^k$ into the equation and setting the coefficients of each power of ε to zero. This produces a system of equations that can be used to express a_1, a_2, \dots in terms of a_0 . The two solutions of $q_{\varepsilon}(x) = 0$ for $\varepsilon = 0$ are 0 and 1, so we take $a_0 = 0, 1$ and obtain the series

$$x(\varepsilon) = \begin{cases} \varepsilon + \varepsilon^2 + 2\varepsilon^3 + \dots, & a_0 = 0, \\ 1 - \varepsilon - \varepsilon^2 - 2\varepsilon^3 + \dots, & a_0 = 1, \end{cases} \quad (1)$$

which describe how the roots 0 and 1 of $q_0(x)$ behave for small ε . Suppose now that it is the leading term that is small and that we have the quadratic $\tilde{q}_{\varepsilon}(x) = \varepsilon x^2 - x + 1 = 0$. If we repeat the process of looking for an expansion of $x(\varepsilon)$, we obtain $x(\varepsilon) = 1 + \varepsilon + 2\varepsilon^2 + 5\varepsilon^3 + \dots$ describing the behavior of the root 1 of $\tilde{q}_0(x)$. But \tilde{q} is a quadratic and so has two roots. What has happened to the other one? There is a change of degree as we go from $\varepsilon = 0$ to $\varepsilon \neq 0$, and this takes us into SINGULAR PERTURBATION THEORY [IV.5 §3.2]. In this simple case we can use the transformation $y = 1/x$ to write $\tilde{q}_{\varepsilon}(x) = q_{\varepsilon}(y)/y^2$, and so we obtain expansions for $x(\varepsilon)$ by inverting those in (1). Indeed, inverting the second expression in (1) and expanding in a power series recovers the expansion we just derived.

4 Symbolic Solution

Sometimes a useful representation of a solution can be obtained using a computer symbolic manipulation package. Such packages are, for example, very good at determining closed forms for indefinite integrals that

would be too tedious to derive by hand and for finding series expansions. We give four examples, each with a different package.

The MATLAB Symbolic Math Toolbox shows that the terms in x^0, x^1, \dots, x^6 of the Taylor series of $\tan(\sin x) - \sin(\tan x)$ are zero:

```
>> syms x
>> taylor(tan(sin(x)) - sin(tan(x)), ...
    'order', 8) % Terms up to x^7
ans =
x^7/30
```

The SymPy package in Python provides a concise form for a definite integral (here, the backslash \ denotes that a continuation line follows):

```
>>> from sympy import *
>>> x = Symbol('x')
>>> integrate((sin(x) + cos(x) + 1) / \
... (sin(x) + cos(x) + 1 + sin(x)*cos(x)))
2*log(tan(x/2) + 1)
```

Maple finds an explicit form for a definite integral:

```
> int(x^2/sin(x)^2, x = 0 .. Pi/2)
Pi*ln(2)
```

Mathematica solves the first-order PDE initial-value problem $u_t + 9u_x = u^2$, $u(x, 0) = \sin x$, via the input

```
DSolve[{D[u[x, t], t] + 9 D[u[x, t], x]
== u[x, t]^2,
u[x, 0] == Sin[x]}, u[x, t], {x, t}]
```

which yields the output

```
{u[x,t]->-1/(t+Csc[9t-x])}
```

where Csc denotes the cosecant, $csc x = 1/\sin x$.

One should never take such results at face value and should always run some kind of check, e.g., by substituting the claimed solution into the equation or comparing a symbolic solution with a numerically computed one.

5 Working from First Principles

Many mathematical problems can successfully be attacked from first principles, or with the use of heuristics, and applied mathematicians often take this approach rather than have recourse to general theory. Indeed, for unsolved research problems there may

be no other way forward. For easier problems these approaches can provide useful insight and experience. The techniques in question include

- looking for a solution of a particular form, which may be constructed from experience or intuition or just by making an educated guess, and then showing that a solution of that form exists, and
- deducing what the general form of a solution must be and then determining the solution.

A standard example taught to undergraduate students is finding the general solution of the second-order ordinary differential equation (ODE)

$$y'' + ay' + by = 0 \quad (2)$$

for the unknown function $y = y(t)$. The starting point is to look for a solution of the form $y(t) = e^{\lambda t}$. Substituting this purported solution into the equation gives $(\lambda^2 + a\lambda + b)e^{\lambda t} = 0$, which implies $\lambda^2 + a\lambda + b = 0$. If this quadratic has distinct roots λ_1 and λ_2 , then two linearly independent solutions of the differential equation, $e^{\lambda_1 t}$ and $e^{\lambda_2 t}$, have been determined. The general solution can be built up, in all cases, from this starting point.

A guess guided by intuition or experience is called an *ansatz*. The assumed form of solution $y(t) = e^{\lambda t}$ to (2) is an ansatz. The corresponding ansatz for the difference equation $y_n + ay_{n-1} + by_n = 0$ is $y_n = \lambda^n$, which again yields the quadratic $\lambda^2 + a\lambda + b = 0$, and continuing with this line of investigation leads to the theory of difference equations.

An example of working from first principles is to determine a formula for the Vandermonde determinant

$$D(x_1, x_2, x_3) = \det \begin{pmatrix} 1 & 1 & 1 \\ x_1 & x_2 & x_3 \\ x_1^2 & x_2^2 & x_3^2 \end{pmatrix}.$$

Instead of laboriously expanding the determinant one can observe that, since it is a sum of products of terms with one taken from each row, the result must be a multivariate polynomial of the form $\sum x_1^i x_2^j x_3^k$, with i , j , and k distinct nonnegative integers summing to 3. If $x_1 = x_2$ then the first two columns are linearly dependent and the determinant is zero; hence $x_1 - x_2$ is a factor of the determinant. Continuing to argue in this fashion, $(x_1 - x_2)(x_2 - x_3)(x_3 - x_1)$ must be a factor. Since this product has degree 3, it must be that $D(x_1, x_2, x_3) = c(x_1 - x_2)(x_2 - x_3)(x_3 - x_1)$ for some constant c , and by considering the terms in $x_2 x_3^2$ on both sides of this equation it is clear that $c = 1$. The

same argument extends straightforwardly to an $n \times n$ Vandermonde determinant. An advantage of this kind of reasoning is that it is adaptable: if the first row of the matrix is replaced by $[x_1^3 \ x_2^3 \ x_3^3]$, then the same form of argument can be used.

6 Iteration

Suppose we wish to solve the three equations in three unknowns

$$\begin{aligned} 4x - y &= a, \\ -x + 4y - z &= b, \\ -y + 4z &= c \end{aligned}$$

for some given a , b , and c . Because the coefficients on the diagonal (the 4s) are the largest coefficients in each row, it is reasonable to expect that $x \approx a/4$, $y \approx b/4$, $z \approx c/4$ are reasonable approximations. Note that this corresponds to rewriting the equations as

$$\begin{aligned} x &= \frac{a}{4} + \frac{y}{4}, \\ y &= \frac{b}{4} + \frac{x+z}{4}, \\ z &= \frac{c}{4} + \frac{y}{4} \end{aligned} \tag{3}$$

and setting $x = y = z = 0$ on the right-hand side. If we want to improve our approximation we can try plugging it into the right-hand side of (3) and reading off the new values from the left-hand side. By repeating this process we obtain the iteration

$$\left. \begin{aligned} x_{k+1} &= \frac{a}{4} + \frac{y_k}{4} \\ y_{k+1} &= \frac{b}{4} + \frac{x_k + z_k}{4} \\ z_{k+1} &= \frac{c}{4} + \frac{y_k}{4} \end{aligned} \right\} \quad k = 1, 2, \dots,$$

with $x_0 = y_0 = z_0 = 0$. This notation means that we are defining infinite sequences $\{x_k\}$, $\{y_k\}$, and $\{z_k\}$ by the given formulas.

If the iteration converges, that is, if $\lim_{k \rightarrow \infty} x_k$, $\lim_{k \rightarrow \infty} y_k$, and $\lim_{k \rightarrow \infty} z_k$ all exist, then the limits must satisfy (3), which is equivalent to the original system, so the only possible limits are the required solution components. This iteration is known as the *Jacobi iteration*. It is defined in an analogous way for any linear system of equations $Ax = b$ for which the diagonal elements of A are nonzero. Convergence can be proved if the matrix A has a large diagonal in the sense of being **STRICTLY DIAGONALLY DOMINANT BY ROWS** [IV.10 §1].

The Jacobi iteration is a special case of a powerful technique known as *fixed-point iteration* (or functional iteration) for solving a nonlinear system of equations.

Consider an equation $x = f(x)$, where $f: \mathbb{R} \rightarrow \mathbb{R}$. Any scalar nonlinear equation can be put in this form. We can set up the iteration $x_{k+1} = f(x_k)$, with some choice of $x_0 \in \mathbb{R}$. The iteration may or may not converge, as can be seen by considering the case $f(x) = x^2$, for which we have convergence to 0 for $|x_0| < 1$ and divergence for $|x_0| > 1$. But if it does converge, to \hat{x} , say, then \hat{x} must be a solution of the equation because taking limits in the iteration gives $\hat{x} = f(\hat{x})$.

To analyze the convergence of fixed-point iteration we note that if x_* is a solution then $x_* - x_{k+1} = f(x_*) - f(x_k) = f'(\theta_k)(x_* - x_k)$ for some θ_k lying between x_* and x_k , by the mean-value theorem. Hence $|x_* - x_{k+1}| < |x_* - x_k|$ if $|f'(\theta_k)| < 1$. This observation can be made into a proof that x_k converges to x_* if x_0 lies in a neighborhood of x_* in which $|f'(x)|$ is less than 1.

The most widely used iteration for solving nonlinear equations is **NEWTON'S METHOD** [II.28] and its variants. Newton's method for $f(x) = 0$ is

$$x_{n+1} = x_n - \frac{f(x_n)}{f'(x_n)},$$

where x_0 is given. In order to apply the method we need to be able to compute the derivative $f'(x)$. Newton's method has a tendency to wander away from the root we are trying to compute if not started close enough to it. It is therefore common to start the method with a good approximation, possibly one computed by some other method, or to modify Newton's method in some way that encourages convergence.

In comparing different classes of iteration, the rate of convergence is an important concept. Let $\{x_k\}$ be a sequence of scalars converging to x_* and denote the error in x_n by $e_n = x_* - x_n$. If

$$\lim_{n \rightarrow \infty} \frac{|e_{n+1}|}{|e_n|^p} = C \neq 0,$$

where C is a constant, the sequence is said to converge with *rate p* (or *order p*). This definition generalizes to vectors by replacing the absolute values with a vector norm. Fixed-point iteration has *linear convergence* in general, for which $p = 1$. Newton's method has (local) *quadratic convergence* ($p = 2$) to a simple root x_* , that is, one for which $f'(x_*) \neq 0$. Quadratic convergence is very desirable as it roughly doubles the number of correct figures on each step, while linear convergence merely reduces the error by a fixed percentage each time. Iterations of arbitrarily high order can be derived (e.g., by combining several Newton steps into one).

Fixed-point iteration can be used to iterate on functions as well as numbers. Consider the ODE initial-value

problem

$$y'(x) = f(x, y), \quad y(0) = y_0.$$

Integrating between 0 and x leads to the equivalent problem

$$y(x) = y_0 + \int_0^x f(x, y(x)) dx,$$

which is a type of equation known as an INTEGRAL EQUATION [IV.4] because the unknown function occurs within an integral. Applying the fixed-point iteration idea we can make a guess ϕ_0 for y , plug it into the right-hand side of the integral equation, and call the result ϕ_1 . The process can be iterated to produce a sequence of functions ϕ_k defined by

$$\phi_{k+1}(x) = y_0 + \int_0^x f(x, \phi_k(t)) dt, \quad k \geq 1.$$

In general, none of the ϕ_k will satisfy the differential equation, but we might hope that the sequence has a limit that does. Let us try out this idea on the problem

$$y' = 2x(1+y), \quad y(0) = 0$$

using first guess $\phi_0(x) = 0$. Then $\phi_1(x) = \int_0^x 2t dt = x^2$ and $\phi_2(x) = \int_0^x 2t(1+t^2) dt = x^2 + x^4/2$. Continuing in this fashion yields $\phi_k(x) = x^2 + x^4/2! + x^6/3! + \dots + x^{2k}/k!$. The limit as $k \rightarrow \infty$ exists and is $e^{x^2} - 1$, which is the required solution.

The procedure we have just carried out is known as *Picard iteration*, or the method of successive approximation. Of course, in most cases it will not be possible to evaluate the integrals in closed form, and so Picard iteration is not a practical means for computing a solution. However, Picard iteration is the basis of the proof of the standard result on existence and uniqueness of solutions for ODEs. The result says that, if $f(x, y)$ is continuous for $x \in [a, b]$ and for all y and satisfies a *Lipschitz condition*

$$|f(x, u) - f(x, v)| \leq L|u - v| \quad \forall x \in [a, b], \quad \forall u, v,$$

with Lipschitz constant L , then for any y_0 there is a unique continuously differentiable function $y(x)$ defined on $[a, b]$ that satisfies $y' = f(x, y)$ and $y(a) = y_0$.

7 Conversion to Another Problem

When we cannot solve a problem it can be useful to convert it to a different problem that is more amenable to attack. In this section we give several examples of such conversions.

We note first that it is not always obvious what is meant by a solution to a problem. Consider the ODE problem

$$\frac{dy}{dx} = 1 - 2xy, \quad y(0) = 0.$$

The solution y can be written as

$$y(x) = e^{-x^2} \int_0^x e^{t^2} dt,$$

which is known as *Dawson's integral* or *Dawson's function*. Which representation of y is better? If we need to obtain higher derivatives $d^k y/dx^k$, the differential equation is more convenient. To evaluate $y(x)$ for a given x , numerical methods can be applied to either representation. Both representations therefore have their uses.

7.1 Uncoupling

When we are solving equations, of whatever type, a particularly favorable circumstance is when the first equation involves only one unknown and each successive equation introduces only one new unknown. We can then solve the equations from first to last. The simplest example is a triangular system of linear equations, such as

$$\begin{aligned} a_{11}x_1 &= b_1, \\ a_{21}x_1 + a_{22}x_2 &= b_2, \\ a_{31}x_1 + a_{32}x_2 + a_{33}x_3 &= b_3, \end{aligned}$$

which can be solved by finding x_1 from the first equation, then x_2 from the second, and finally x_3 from the third. This is the process known as *substitution*.

Most linear equation problems do not have this triangular structure, but the process of GAUSSIAN ELIMINATION [IV.10 §2] converts an arbitrary linear system into triangular form.

More generally we might have n nonlinear equations in n unknowns, and a natural way to solve them is to try to manipulate them into an analogous triangular form. In computer algebra a way of doing this for polynomial equations is provided by Buchberger's algorithm for computing a GRÖBNER BASIS [IV.39 §2].

A triangular problem is partially uncoupled. In a fully uncoupled system each equation contains only one unknown. A linear system of ODEs $y' = Ay$ with an $n \times n$ coefficient matrix A can be uncoupled if A is diagonalizable. Indeed, if $A = XDX^{-1}$ with X nonsingular and $D = \text{diag}(\lambda_i)$, then the transformation $z = X^{-1}y$ gives $z' = Dz$, which represents n uncoupled scalar

equations $z'_i = \lambda_i z_i$, $i = 1:n$. The behavior of the vector y can now be understood by looking at the behavior of the n independent scalars z_i .

7.2 Polynomial Roots and Matrix Eigenvalues

Consider the problem of finding the roots (zeros) of a polynomial $p_n(x) = a_n x^n + a_{n-1} x^{n-1} + \dots + a_0$ with $a_n \neq 0$, that is, the values of x for which $p_n(x) = 0$. It is known from Galois theory that there is no explicit formula for the roots when $n \geq 5$. Many methods are available for computing polynomial roots, but not all are able to compute all n roots reliably and software might not be readily available. Consider the $n \times n$ matrix

$$C = \begin{bmatrix} -a_{n-1}/a_n & -a_{n-2}/a_n & \cdots & \cdots & -a_0/a_n \\ 1 & 0 & \cdots & \cdots & 0 \\ 0 & 1 & \ddots & & 0 \\ \vdots & & \ddots & 0 & \vdots \\ 0 & \cdots & \cdots & 1 & 0 \end{bmatrix}.$$

Let λ be a root of p_n . For the vector defined by $y = [\lambda^{n-1} \lambda^{n-2} \dots 1]^T$ we have $Cy = \lambda y$, so λ is an eigenvalue of C with eigenvector y . In fact, the set of roots of p is the set of eigenvalues of C , so the polynomial root problem has been converted into an eigenvalue problem—albeit a specially structured one. The matrix C is called a *companion matrix*. Of course, one can go in the opposite direction: to find the eigenvalues of C one might look for solutions of $\det(C - \lambda I) = 0$, and the determinant is precisely $(-1)^n p_n(\lambda)/a_n$.

The eigenvector problem $Ax = \lambda x$ can be converted into a nonlinear system of equations $F(v) = 0$, where

$$F(v) = \begin{bmatrix} (A - \lambda I)x \\ e_s^T x - 1 \end{bmatrix}, \quad v = \begin{bmatrix} x \\ \lambda \end{bmatrix}.$$

The last component of F serves to normalize the eigenvector and here s is some fixed integer, with e_s denoting the s th column of the identity matrix. By solving $F(v) = 0$ we obtain both an eigenvalue of A and the corresponding eigenvector.

7.3 Dubious Conversions

Converting one problem to an apparently simpler one is not always a good idea. The problem of solving the scalar nonlinear equation $f(x) = 0$ can be converted to the problem of minimizing the function $g(x) = f(x)^2$. Since the latter problem has a global minimum attained when $f(x) = 0$, the conversion might look attractive. However, it has a pitfall: since $g'(x) = 2f'(x)f(x)$, the derivative of g is zero whenever $f'(x) = 0$, and this

means that methods for minimizing g might converge to points that are stationary points of g but not zeros of f .

For another example, consider the generalized eigenproblem in $n \times n$ matrices A and B , $Ax = \lambda Bx$, which arises in problems in engineering and physics. It is natural to attempt to convert it to the standard eigenproblem $B^{-1}Ax = \lambda x$ and then apply standard theory and algorithms. However, if B is singular this transformation is not possible, and when B is nonsingular but ILL-CONDITIONED [I.2 §22] the transformation is inadvisable in floating-point arithmetic as it will be numerically unstable. A further drawback is that if B is SPARSE [IV.10 §6] (has many zeros) then $B^{-1}A$ can have many more nonzeros than A or B .

7.4 High-Order Differential Equations

Methods of solution of differential equations have been more extensively developed for first-order equations than for higher-order ones, where order refers to the highest derivative in the equation. Fortunately, higher-order equations can always be converted to first-order ones. Consider the q th-order ODE

$$y^{(q)} = f(t, y, y', \dots, y^{(q-1)})$$

with $y, y', \dots, y^{(q-1)}$ given at $t = t_0$. Define new variables

$$z_1 = y, \quad z_2 = y', \quad \dots, \quad z_q = y^{(q-1)}.$$

Then we have the first-order system of equations

$$\begin{aligned} z'_1 &= z_2, \\ z'_2 &= z_3, \\ &\vdots \\ z'_{q-1} &= z_q, \\ z'_q &= f(t, z_1, z_2, \dots, z_q), \end{aligned}$$

with z_1, z_2, \dots, z_q given at $t = t_0$. We can write this system in vector form:

$$z' = f(t, z), \quad z = [z_1, z_2, \dots, z_q]^T. \quad (4)$$

So we have traded high order for high dimension. Fortunately, the theory and the numerical methods developed for scalar first-order ODEs generally carry over straightforwardly to vector ODEs. We can go further and remove the explicit time dependence from (4) to put the system in *autonomous form*: with $w = [t, z^T]^T$, we have

$$w' = \begin{bmatrix} 1 \\ f(z) \end{bmatrix} = \begin{bmatrix} 1 \\ f(w_2, \dots, w_n) \end{bmatrix} =: g(w).$$

7.5 Continuation

Suppose we have a hard problem “solve $f(x) = 0$ ” and another problem “solve $g(x) = 0$ ” that is trivial to solve. Consider the parametrized problem “solve $h(x, t) = tf(x) + (1-t)g(x) = 0$.” We know the solution for $t = 0$ and wish to find it for $t = 1$. The idea of *continuation* (also called *homotopy*, or *incremental loading* in elasticity) is to traverse the interval from 0 to 1 in several steps: $0 < t_1 < t_2 < \dots < t_n = 1$. On the k th step we use the solution x_{k-1} of the problem $h(x, t_{k-1}) = 0$ as the starting point for an iteration for solving $h(x, t_k) = 0$. We are therefore solving the original problem by approaching it gradually from a trivial problem. Continuation cannot be expected to work well in all cases. It is particularly well suited to cases where f already depends on a parameter and the problem is simpler for some value of that parameter.

Continuation is a very general technique and has close connections with **BIFURCATION THEORY** [IV.21]. A special case of it is the idea of **SHRINKING** [V.10 §2.2], whereby a convex combination is taken of a given object with another having more desirable properties.

8 Linearization

A huge body of mathematics is concerned with problems that are linear in the variables of interest, such as a system $Ax = b$ of n linear equations in n unknowns or a system of ODEs $dy/dt = A(t)y$. For linear problems it is usually easy to analyze the existence of solutions, to obtain an explicit formula for a solution, and to derive practical methods of solution that exploit the linearity. Unfortunately, many real-world processes are inherently nonlinear. This means, first of all, that it may not be easy to determine whether or not there is a solution at all or, if a solution exists, whether it is unique. Secondly, finding a solution is in general difficult. A general technique for solving nonlinear problems is to transform them into linear ones, thereby converting a problem that we cannot solve into one that we can. The transformation can rarely be done exactly, so what is usually done is to *approximate* the nonlinear problem by a linear one—the process of *linearization*—and carry out some sort of iteration or refinement process.

To illustrate the idea of linear approximations we consider the quadratic equation

$$x^2 - 10x + 1 = 0. \quad (5)$$

Because the coefficient of the linear term, 10, is large compared with that of the quadratic term, 1, we can think of (5) as a linear equation with a small quadratic perturbation:

$$x = \frac{1}{10} + \frac{x^2}{10}. \quad (6)$$

Indeed, if we solve the linear part we obtain $x = 1/10$, which leaves a residual of just 1/100 when substituted into the left-hand side of (5). We can therefore say that $x \approx 1/10$ is a reasonable approximation to a root (in fact, to the smallest root, since the product of the roots must be 1). Note that this approximation is obtained by putting $x = 0$ in the right-hand side of (6). To obtain a better approximation we might try putting $x = 1/10$ into the right-hand side. Repeating this process leads to the fixed-point iteration

$$x_{k+1} = \frac{1 + x_k^2}{10}, \quad x_0 = 0,$$

which yields 0, 0.10, 0.101, After ten iterations we have $x_{10} = 0.101020514433644$, which is correct to the fifteen significant digits shown. Of course we could have obtained this solution as $x = 5 - \sqrt{24}$ using the quadratic formula, but the linearization approach gives an instant approximation and provides insight. For the equation $x^7 - 10x + 1 = 0$, for which there is no explicit formula for the roots, 1/10 is an even better approximation to the smallest root and the analogue of the iteration above converges even more quickly.

Linearization is the key concept underlying **NEWTON'S METHOD** [II.28], which we discussed in section 6. Suppose we wish to solve a nonlinear system $f(x) = 0$, where $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$, and let x be an approximation to a solution x_* . Writing $x_* = x + h$, for sufficiently smooth f we have $0 = f(x_*) = f(x) + J(x)h + O(\|h\|^2)$, where $J(x) = (\partial f_i / \partial x_j) \in \mathbb{R}^{n \times n}$ is the *Jacobian matrix* and the big-oh term includes the second- and higher-order terms from a multidimensional Taylor series. Newton's method approximates f by the linear part of the series and so solves the linear system $J(x)h = -f(x)$ in order to produce a new approximation $x + h$. The process is iterated, yielding $x_{k+1} = x_k - J(x_k)^{-1}f(x_k)$. Theorems are available that guarantee when the linear approximations of the Newton method are good enough to ensure convergence to a solution. Indeed the Newton-Kantorovich theorem even uses Newton's method itself to prove the existence of a solution under certain conditions.

An equilibrium point (or critical point) of a nonlinear autonomous system of ODEs $y'(t) = f(y)$, where $f: \mathbb{R}^n \rightarrow \mathbb{R}^n$, is a vector y_0 such that $f(y_0) = 0$. For

such a point, $y(t) = y_0$ is a constant solution to the differential equations. Linear stability analysis determines the effect of small perturbations away from the equilibrium point. Let $y(t) = y_0 + h(t)$ with $h(0) = h_0$ small. We wish to determine the behavior of $h(t)$ as $t \rightarrow \infty$. A linear approximation to f at y_0 yields $h'(t) = y'(t) = f(y_0) + J(y_0)h = J(y_0)h$. The solution to this first-order system is $h(t) = e^{J(y_0)t}h_0$, and so the behavior of h depends on the behavior of the MATRIX EXPONENTIAL [II.14] $e^{J(y_0)t}$. In particular, whether or not $h(t)$ grows or decays as $t \rightarrow \infty$ depends on the real parts of the eigenvalues of $J(y_0)$. For the case where y has two components ($n = 2$), it is possible to give detailed classifications and plots (called phase-plane portraits) of the different qualitative behaviors that can occur. For more on the stability of ODEs see ORDINARY DIFFERENTIAL EQUATIONS [IV.2 §§8, 9].

An example of a nonlinear problem that can be linearized exactly, without any approximation, is the QUADRATIC EIGENVALUE PROBLEM [IV.10 §5.8].

Many other uses of linearization can be found throughout this book.

9 Recurrence Relations

A useful tactic for solving a problem whose solution is a number or function depending on a parameter is to try to derive a recurrence. For example, consider the integral

$$x_n = \int_0^1 \frac{t^n}{t+5} dt.$$

It is easy to verify that x_n satisfies the recurrence $x_n + 5x_{n-1} = 1/n$ and $x_0 = \log(6/5)$, so values of x_n can easily be generated from the recurrence. However, when evaluating a recurrence numerically, one always needs to be aware of possible instability. Evaluating the recurrence in IEEE double-precision arithmetic (corresponding to about sixteen significant decimal digits) we find that $\hat{x}_{21} = -0.0159\dots$, where the hat denotes the computed result. But

$$\frac{1}{6(n+1)} = \int_0^1 \frac{t^n}{6} dt < x_n < \int_0^1 \frac{t^n}{5} dt = \frac{1}{5(n+1)}$$

for all n , so this result is clearly not even of the right sign. The cause of the inaccuracy can be seen by considering the ideal case in which the only error, ε , say, occurs in evaluating x_0 . That error is multiplied by -5 in computing x_1 and by a further factor of -5 on each step of the recurrence; overall, x_n will be contaminated by an error of $(-5)^n\varepsilon$. This is an example

of *numerical instability* and it is something that recurrences are prone to. We can obtain a more accurate result by using the recurrence in the backward direction, which will result in errors being divided by -5 , so that they are damped out. From the inequalities above we see that for large n , $x_n \approx 1/(5(n+1))$. Let us simply set $y_{20} = 1/105$. Then, using the recurrence backward in the form $x_{n-1} = (1/n - x_n)/5$, we find that x_0 is computed with a relative error of order 10^{-16} . For similar reasons, the recurrence relation in THE LANGUAGE OF APPLIED MATHEMATICS [I.2 §13] for the Bessel functions is also used in the backward direction for $x < n$.

10 Lagrange Multipliers

Optimization problems abound in applied mathematics because in many practical situations one wishes to maximize a desirable attribute (e.g., profit, or the strength of a structure) or minimize something that is desired to be small (such as cost or energy). More often than not, constraints impose limits on the variables and help to balance conflicting requirements. For example, in designing a tripod for cameras we may wish to minimize the weight of the tripod subject to it being able to support cameras up to a certain maximal weight, and a constraint might be a lower bound on the maximal height of the tripod.

Calculus enables us to characterize and find maxima and minima of functions. In the presence of constraints, though, the standard results are not so helpful. Consider the problem in three variables

$$\begin{aligned} &\text{minimize } f(x_1, x_2, x_3) \\ &\text{subject to } c(x_1, x_2, x_3) = 0, \end{aligned} \quad (7)$$

where the objective function f and constraint function c are scalars. We know that any minimizer of the unconstrained problem $\min f(x_1, x_2, x_3)$ has to have a zero gradient; that is, $\nabla f(x) = [\partial f / \partial x_1, \partial f / \partial x_2, \partial f / \partial x_3]^T$ must be the zero vector. How can we take account of the constraint $c(x_1, x_2, x_3) = 0$?

Let $x_* \in \mathbb{R}^3$ be a *feasible point*, that is, a point satisfying the constraint $c(x_*) = 0$. Consider a smooth curve $z(t)$ with $z(0) = x_*$ that remains on the constraint, that is, $c(z(t)) = 0$ for all sufficiently small t . Differentiating the latter equation and using the chain rule gives $(dz(t)/dt)^T \nabla c(z(t)) = 0$. Setting $t = 0$ and putting $p_* = dz/dt|_{t=0}$ gives

$$p_*^T \nabla c(x_*) = 0. \quad (8)$$

For x_* to be optimal, the rate of change of f along z must be zero at x_* , so, using the chain rule again,

$$\begin{aligned} 0 &= \frac{d}{dt} f(z(t)) \Big|_{t=0} = \sum_{i=1}^3 \frac{\partial f}{\partial z_i} \frac{dz_i}{dt} \Big|_{t=0} \\ &= \nabla f(x_*)^T p_*. \end{aligned} \quad (9)$$

Now assume that $\nabla c(x_*) \neq 0$, which is known as a *constraint qualification*. This assumption ensures that every vector p_* satisfying (8) is the tangent at $t = 0$ to some curve $z(t)$. It then follows that since (8) and (9) hold for all p_* ,

$$\nabla f(x_*) = \lambda_* \nabla c(x_*) \quad (10)$$

for some scalar λ_* . The scalar λ_* is called a *Lagrange multiplier*. The constraint equation $c(x) = 0$ and (10) together constitute four equations in four unknowns, x_1, x_2, x_3 , and λ . We have therefore reduced the original constrained minimization problem to a nonlinear system of equations. The latter system can be solved by any means at our disposal, though being nonlinear it is not necessarily an easy problem.

Another way to express our findings is in terms of the *Lagrangian function* $L(x, \lambda) = f(x) - \lambda c(x)$. Since $\nabla_x L(x, \lambda) = \nabla f(x) - \lambda \nabla c(x)$, the Lagrange multiplier condition (10) says that the solution x_* is a stationary point of L with respect to x when $\lambda = \lambda_*$. Moreover, $\nabla_\lambda L(x, \lambda) = -c(x)$, so stationarity of L with respect to λ expresses the constraint $c(x) = 0$.

The development above was presented for a problem with three variables and one constraint, but it generalizes in a straightforward way to n variables and m constraints, with λ becoming an m -vector of Lagrange multipliers.

Let us see how Lagrange multipliers help us to solve the problem

$$\text{maximize } 8xyz \text{ subject to } \frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1,$$

which defines the maximum rectangular block that fits inside the specified ellipsoid. Although our original problem (7) is a minimization problem, there is nothing in the development of (10) that is specific to minimization, and in fact the latter equation must be satisfied at any stationary point, so we can use it here. Setting $\tilde{x} = x/a$, $\tilde{y} = y/b$, $\tilde{z} = z/c$, the problem simplifies to

$$\text{maximize } 8abc\tilde{x}\tilde{y}\tilde{z} \text{ subject to } \tilde{x}^2 + \tilde{y}^2 + \tilde{z}^2 = 1.$$

The Lagrange multiplier condition is

$$8abc \begin{bmatrix} \tilde{y}\tilde{z} \\ \tilde{x}\tilde{z} \\ \tilde{x}\tilde{y} \end{bmatrix} = \lambda \begin{bmatrix} 2\tilde{x} \\ 2\tilde{y} \\ 2\tilde{z} \end{bmatrix}.$$

It is easily seen that these equations yield $\tilde{x} = \tilde{y} = \tilde{z} = 1/\sqrt{3}$ (and $\lambda_* = 4abc/\sqrt{3}$) and that the corresponding volume is $8abc/(3\sqrt{3})$. It is intuitively clear that this is a maximum, though in general checking for optimality requires further analysis involving inspection of second derivatives.

Lagrange multipliers and the Lagrangian function are widely used in applied mathematics in a variety of settings, including the CALCULUS OF VARIATIONS [IV.6] and LINEAR AND NONLINEAR OPTIMIZATION [IV.11]. One of the reasons for the importance of Lagrange multipliers is that they quantify the sensitivity of the optimal value to perturbations in the constraints. We can check this for our problem. If we perturb the constraint to $x^2/a^2 + y^2/b^2 + z^2/c^2 = 1 + \varepsilon$, then it is easy to see that the solution is $V(\varepsilon) = 8abc((1 + \varepsilon)/3)^{1/2}$, and hence $V'(0) = 4abc/\sqrt{3} = \lambda_*$.

11 Tricks and Techniques

As well as the general ideas and principles described in this article, applied mathematicians have at their disposal their own bags of tricks and techniques, which they bring into play when experience suggests they might be useful. Some will work only on very specific problems. Others might be nonrigorous but able to give useful insight. George Pólya is quoted as saying, “A trick used three times becomes a standard technique.” Here are a few examples of tricks and techniques that prove useful on many different occasions, along with a very simple example in each case.

Use symmetry. When a problem has certain symmetries one can often argue that these must carry over into the solution. For example, the maximization problem at the end of the previous section is symmetric in \tilde{x} , \tilde{y} , and \tilde{z} , so one can argue that we must have $\tilde{x} = \tilde{y} = \tilde{z}$ at the solution.

Add and subtract a term, or multiply and divide by a term. As a very simple example, if A and B are $n \times n$ matrices with A nonsingular, then $AB = AB \cdot AA^{-1} = A(BA)A^{-1}$, which shows that AB and BA are similar and that they therefore have the same eigenvalues. A common scenario is that \hat{x} is an approximation to x whose error cannot be directly estimated, but one can find another approximation \tilde{x} whose relation to x and \hat{x} is understood. One then writes $x - \hat{x} = (x - \tilde{x}) + (\tilde{x} - \hat{x})$ and thereby obtains, using the triangle inequality, the bound $\|x - \hat{x}\| \leq \|x - \tilde{x}\| + \|\tilde{x} - \hat{x}\|$. For example, x

might be the solution to a PDE, \tilde{x} the solution to a discretization of the PDE, and \hat{x} an approximate solution to the discretized problem.

Consider special cases. Insight is often obtained by looking at special cases, such as a polynomial in place of a general function, or a diagonal matrix instead of a full matrix, or $n = 2$ or 3 in a problem in n dimensions.

Transform the problem. It is always worth considering whether the problem is stated in the best way. As a simple example, suppose we are asked to find solutions of an equation of the form $1/f(x) = a$. If f is a nearly linear function the problem is better written as $f(x) = 1/a$, and for computing a numerical solution Newton's method should work very well.

Proof by contradiction. A classic technique is to prove a result by assuming that the result is false and then obtaining a contradiction. Sometimes this approach can be used to show that an equation has no solution. For example, if the particular SYLVESTER EQUATION [III.28] in $n \times n$ matrices $AX - XA = I$ has a solution, then $0 = \text{trace}(AX) - \text{trace}(XA) = \text{trace}(AX - XA) = \text{trace}(I) = n$, which is a contradiction; we conclude that the equation has no solution.

Going into the complex plane. It is sometimes possible to solve a problem posed on the real line by making an excursion into the complex plane. This tactic is often used to evaluate real integrals by using the CAUCHY INTEGRAL FORMULA OR THE RESIDUE THEOREM [IV.1 §15]. For another example, let f be an analytic function that is real for real arguments. Then, for real x ,

$$f'(x) \approx \frac{\text{Im } f(x + ih)}{h},$$

where i is the imaginary unit and h is a small real parameter. This *complex step approximation* has error $O(h^2)$. Here is an example with $f(x) = \cos x$ in MATLAB:

```
>> x = pi/6; h = 1e-8;
>> fdash_cs = imag( cos(x + i*h) )/h;
>> error = fdash_cs - (-sin(x))
error =
-5.5511e-17
```

Finally, there are various basic techniques that are learned in elementary courses and are always useful, such as integration by parts, use of the Cauchy-Schwarz inequality, and interchange of the order of

integration in a double integral or of summation in a double sum.

I.4 Algorithms

Nicholas J. Higham

An algorithm is a procedure for accomplishing a certain task in a finite number of steps.

The terms “algorithm” and “method” are often used interchangeably, and there is no clear consensus on the distinction between them. However, many authors use “method” very generally and reserve “algorithm” for a procedure in which every step is precisely defined. For example, Newton's method solves a system of n nonlinear equations in n variables, $F(x) = 0$, using the iteration $x_{k+1} = x_k - J(x_k)^{-1}F(x_k)$, where J is the $n \times n$ Jacobian matrix of F . An algorithm implementing Newton's method has to define how to compute the correction terms $J(x_k)^{-1}F(x_k)$ (e.g., by Gaussian elimination with partial pivoting), what to do if $J(x_k)$ is singular, and when to terminate the iteration (e.g., when $\|F(x_k)\|$ is less than some convergence tolerance).

Developing algorithms has always been an important activity in applied mathematics. George Forsythe put it well when he said:

A useful algorithm is a substantial contribution to knowledge. Its publication constitutes an important piece of scholarship.

This statement was made in the 1960s, when the emergence of standards for PROGRAMMING LANGUAGES [VII.11] had started to make it feasible to publish and share computer implementations of algorithms.

1 Summation

Let us begin with the problem of forming the sum of n numbers, $x_1 + x_2 + \dots + x_n$, on a computer. This problem is deceptively simple, partly because the problem statement is so suggestive of an algorithm. But note that the numbers can be added in any order and that parentheses can be inserted in many ways to break up the overall sum into smaller sums. So there are many ways in which the sum can be computed, and if we simply choose one of them without thinking, we may miss a better alternative. Thinking about the summation process leads to the notion of repeatedly adding two numbers from the set then putting the sum back into the set. This process can be expressed formally in the following algorithm.

Algorithm 1. Given numbers x_1, \dots, x_n this algorithm computes $S_n = \sum_{i=1}^n x_i$.

```

1 Let  $X = \{x_1, \dots, x_n\}$ .
2 while  $X$  contains more than one element
3     Remove two numbers  $y$  and  $z$  from  $X$ 
        and put their sum  $y + z$  back in  $X$ .
4 end
5 Assign the remaining element of  $X$  to  $S_n$ .

```

This algorithm is written in *pseudocode*, which refers to any informal syntax that resembles a programming language. The purpose of pseudocode is to specify an algorithm in a concise, readable way without having to worry about the details of any particular programming language.

It is clear that after execution of line 3, the number of elements of X has decreased by one. The algorithm therefore terminates after exactly $n - 1$ iterations of the while loop, at which point it has carried out $n - 1$ additions.

Clearly, different ways of choosing x and y on line 3 lead to different summation algorithms. The most obvious choice is to take y as the sum computed at the previous step and z as the element with smallest index (and $y = x_1$ and $z = x_2$ at the first step). The resulting algorithm is known as *recursive summation* and can be expressed as

```

1  $s = x_1$ 
2 for  $i = 2:n$  %  $i$  goes from 2 to  $n$  in steps of 1
3      $s = s + x_i$ 
4 end
5  $S_n = s$ 

```

In this pseudocode everything from a % sign to the end of a line is a comment.

An alternative is to add the elements pairwise, then add their sums pairwise, and so on, repeatedly. For $n = 8$ this corresponds to the formula

$$S_8 = [(x_1 + x_2) + (x_3 + x_4)] + [(x_5 + x_6) + (x_7 + x_8)].$$

This summation algorithm is forming a **BINARY TREE** [II.16], as illustrated in figure 1. An attractive feature of pairwise summation is that on a parallel computer the summations on each level of the tree can be done in parallel, so the computation time is proportional to $\log_2 n$ instead of n .

A third summation algorithm, called the *insertion algorithm*, takes the summands y and z as those with the smallest absolute value at each stage.

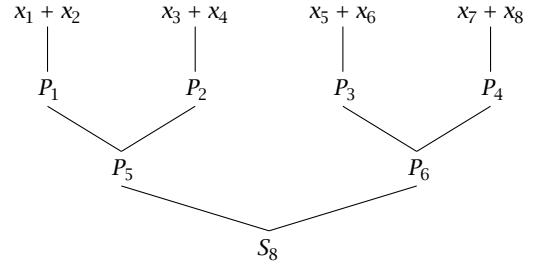

Figure 1 A binary tree for pairwise summation, with partial sums P_i .

One reason for considering these different summation algorithms as special cases of algorithm 1 is that a common analysis can be done of the effects of rounding errors in floating-point arithmetic. Express the i th execution of the while loop in algorithm 1 as $P_i = y_i + z_i$. The standard model of floating-point arithmetic (equation (2) in FLOATING-POINT ARITHMETIC [II.13]) says that the computed \hat{P}_i satisfies

$$\hat{P}_i = \frac{y_i + z_i}{1 + \delta_i}, \quad |\delta_i| \leq u, \quad i = 1:n - 1,$$

where u is the unit roundoff. (The model actually says we should multiply by $1 + \delta_i$, but it can be shown to be equally valid to divide by $1 + \delta_i$, which is more convenient here.) The error introduced in forming \hat{P}_i , namely $y_i + z_i - \hat{P}_i$, is therefore $\delta_i \hat{P}_i$. By summing each of these individual errors we obtain the overall error,

$$E_n := S_n - \hat{S}_n = \sum_{i=1}^{n-1} \delta_i \hat{P}_i,$$

which is bounded by

$$|E_n| \leq u \sum_{i=1}^{n-1} |\hat{P}_i|.$$

This bound provides the insight that to maximize the accuracy of the sum it should be helpful to minimize the size of the intermediate partial sums. The insertion algorithm can be seen as a heuristic way of doing that.

When the x_i are all nonnegative and we use recursive summation, $P_i = \sum_{j=1}^{i+1} x_j$, so the bound for $|E_n|$ is minimized if the x_i are arranged in increasing order. Moreover, since $P_i \leq S_n$, the bound implies $|E_n| \leq (n-1)uS_n + O(u^2)$ for any ordering, which guarantees a relative error of order nu .

This summation example shows that taking a bird's eye view of a computational problem can be beneficial, in that it can reveal algorithmic possibilities that might have been missed and can help a single analysis to be developed that applies to a wide range of

problems. Of course, algorithm 1 does not cover all the possibilities. Another way to compute the sum is as $S_n = \log \prod_{i=1}^n e^{x_i}$. This formula has little to recommend it, but it is not so different from the expression $\exp(n^{-1} \log \sum_{i=1}^n x_i)$, which is a log-Euclidean mean of the x_i that has applications when the x_i are structured matrices or operators.

2 Bisection

The summation problem is unusual in that there is no difficulty in seeing the correctness of algorithm 1 or its computational cost. A slightly trickier algorithm is the bisection algorithm for finding a zero of a continuous function $f(x)$. The bisection algorithm takes as input an interval $[a, b]$ such that $f(a)f(b) < 0$; the intermediate-value theorem tells us that there must be a zero of f on this interval. The bisection algorithm repeatedly halves the interval and retains the half on which f has different signs at the endpoints, that is, the interval on which we can be sure there is a zero. To make the algorithm finite we need a stopping criterion. The following algorithm terminates once the interval is of length at most tol , a given tolerance.

Algorithm 2 (bisection algorithm). *This algorithm finds a zero of a continuous function $f(x)$ given an interval $[a, b]$ such that $f(a)f(b) < 0$ and an error tolerance tol .*

```

1 while  $b - a > \text{tol}$ 
2    $c = (a + b)/2$ 
3   if  $f(c) = 0$ , quit, end
4   if  $f(c)f(b) < 0$ 
5      $a = c$ 
6   else
7      $b = c$ 
8   end
9 end
10  $x = (a + b)/2$ 
```

To show the correctness of this algorithm note first that at the end of the while loop $f(a)f(b) < 0$ still holds; in other words, this inequality is an invariant of the loop. Therefore we have a sequence of intervals each of length half the previous interval and all containing a zero. This means that after k steps we have an interval of length $(b-a)/2^k$ containing a zero. The algorithm therefore terminates after $\lceil \log_2((|b-a|/\text{tol})) \rceil$ steps. Here, we are using the *ceiling function* $\lceil x \rceil$, which is the smallest integer greater than or equal to x . In the

next section we will also need the *floor function* $\lfloor x \rfloor$, which is the largest integer less than or equal to x .

The algorithm returns as the approximate zero the midpoint of the final interval, which has length at most tol ; since a zero lies in this interval, the absolute error is at most $\text{tol}/2$.

Algorithm 2 needs a number of refinements to make it more reliable and efficient for practical use. First, testing whether $f(c)$ and $f(b)$ have opposite signs should not be done by multiplying them, as the product could overflow or underflow in floating-point arithmetic. Instead, the signs should be directly compared. Second, $f(c)$ should not be computed twice, on lines 3 and 4, but rather computed once and its value reused. Finally, the convergence test is an absolute one, so is scale dependent. A better alternative is $|b - a| > \text{tol}(|a| + |b|)$, which is unaffected by scalings $a \leftarrow \theta a$, $b \leftarrow \theta b$.

Bisection is a widely applicable technique. For example, it can be used to search an ordered list to see if a given element is contained in the list; here it is known as *binary search*. It is also used for debugging. If the L^AT_EX source for this article fails to compile and I cannot spot the error, I will move the `\end{document}` command to the middle of the file and try again; I can thereby determine in which half of the file the error lies and can repeat the process to narrow the error down.

3 Divide and Conquer

The *divide and conquer* principle breaks a problem down into two (or more) equally sized subproblems and solves each subproblem recursively.

An example of how divide and conquer can be exploited is in the computation of a large integer power of a number. Computing x^n in the obvious way takes $n - 1$ multiplications. But x^{13} , for example, can be written x^8x^4x , which can be evaluated in just five multiplications instead of twelve by first forming x^2 , $x^4 = (x^2)^2$, and $x^8 = (x^4)^2$. Notice that $13 = (1101)_2$ in base 2, and in general the base 2 representation of n tells us exactly how to break down the computation of x^n into products of terms x^{2^k} . However, by expressing the computation using divide and conquer we can avoid the need to compute the binary representation of n . The idea is to write $x^n = (x^{n/2})^2$ if n is even and $x^n = x(x^{\lfloor n/2 \rfloor})^2$ if n is odd. In either case the problem is reduced to one of half the size. The resulting algorithm is most elegantly expressed in recursive form, as an algorithm that calls itself.

Algorithm 3. This algorithm computes x^n for a positive integer n .

```

1 function  $y = \text{power}(x, n)$ 
2 if  $n = 1$ ,  $y = x$ , return
3 if  $n$  is odd
4    $y = x \text{ power}(x, (n - 1)/2)^2$  % Recursive call
5 else
6    $y = \text{power}(x, n/2)$            % Recursive call
7 end

```

The number of multiplications required by algorithm 3 is bounded above by $2\lceil \log_2 n \rceil$.

Another example of how divide and conquer can be used is for computing the inverse of a nonsingular upper triangular matrix, $T \in \mathbb{C}^{n \times n}$. Write T in partitioned form as

$$T = \begin{bmatrix} T_{11} & T_{12} \\ 0 & T_{22} \end{bmatrix}, \quad (1)$$

where T_{11} has dimension $\lceil n/2 \rceil$. It is easy to check that

$$T^{-1} = \begin{bmatrix} T_{11}^{-1} & -T_{11}^{-1}T_{12}T_{22}^{-1} \\ 0 & T_{22}^{-1} \end{bmatrix}.$$

This formula reduces the problem to the computation of the inverses of two smaller matrices, namely, the diagonal blocks T_{11} and T_{22} , and their inverses can be expressed in the same way. The process can be repeated until scalars are reached and the inversion is trivial.

Algorithm 4. This algorithm computes the inverse of a nonsingular upper triangular matrix T by divide and conquer.

```

1 function  $U = \text{inv}(T)$ 
2  $n = \text{dimension of } T$ 
3 if  $n = 1$ ,  $U_{11} = t_{11}^{-1}$ , return
4 Partition  $T$  according to (1), where  $T_{11}$  has
  dimension  $\lceil n/2 \rceil$ .
5  $U_{11} = \text{inv}(T_{11})$  % Recursive call
6  $U_{22} = \text{inv}(T_{22})$  % Recursive call
7  $U_{12} = -U_{11}T_{12}U_{22}$ .

```

Let us now work out the computational cost of this algorithm, in flops, where a flop is a multiplication, addition, subtraction, or division. Denote the cost of calling inv for an $n \times n$ matrix by c_n and assume for simplicity that $n = 2^k$. We then have $c_n = 2c_{n/2} + 2(n/2)^3$, where the second term is the cost of forming the triangular-full-triangular product $U_{11}T_{12}U_{22}$ of matrices of dimension $n/2$. Solving this recurrence gives $c_n = n^3/3 + O(n^2)$, which is the same as the cost of

inverting a triangular matrix by standard techniques such as solving $TX = I$ by substitution.

As these examples show, recursion is a powerful way to express algorithms. But it is not always the right tool. To illustrate, consider the Fibonacci numbers, 1, 1, 2, 3, 5, ..., which satisfy the recurrence $f_n = f_{n-1} + f_{n-2}$ for $n \geq 2$, with $f_0 = f_1 = 1$. The obvious way to express the computation of the f_i is as a loop:

```

1  $f_0 = 1, f_1 = 1$ 
2 for  $i = 2:n$ 
3    $f_i = f_{i-1} + f_{i-2}$ 
4 end

```

If just f_n is required then an alternative is the recursive function

```

1 function  $f = \text{fib}(n)$ 
2 if  $n \leq 1$ 
3    $f = 1$ 
4 else
5    $f = \text{fib}(n - 1) + \text{fib}(n - 2)$ 
6 end

```

The problem with this recursion is that it computes $\text{fib}(n - 1)$ and $\text{fib}(n - 2)$ independently instead of obtaining $\text{fib}(n - 1)$ from $\text{fib}(n - 2)$ with one addition as in the previous algorithm. In fact, the evaluation of $\text{fib}(n)$ requires $f_n \approx 1.6^n$ operations, so the recursive algorithm is exponential in cost versus the linear cost of the first algorithm. It is possible to compute f_n with only logarithmic cost. The idea is to write

$$\begin{bmatrix} f_n \\ f_{n-1} \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix} \begin{bmatrix} f_{n-1} \\ f_{n-2} \end{bmatrix} = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}^2 \begin{bmatrix} f_{n-2} \\ f_{n-3} \end{bmatrix} = \cdots = \begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}^{n-1} \begin{bmatrix} f_1 \\ f_0 \end{bmatrix}.$$

The matrix $\begin{bmatrix} 1 & 1 \\ 1 & 0 \end{bmatrix}^{n-1}$ can be computed in $O(\log_2 n)$ operations using the analogue for matrices of algorithm 3.

A divide and conquer algorithm can break the problem into more than two subproblems. An example is the Karatsuba algorithm for multiplying two n -digit integers x and y . Suppose n is a power of 2 and write $x = x_1 10^{n/2} + x_2$, $y = y_1 10^{n/2} + y_2$, where x_1, x_2, y_1 , and y_2 are $n/2$ -digit integers. Then

$$xy = x_1y_1 10^n + (x_1y_2 + x_2y_1)10^{n/2} + x_2y_2.$$

Computing xy has been reduced to computing three half-sized products because $x_1y_2 + x_2y_1 = (x_1 + x_2)(y_1 + y_2) - x_1y_1 - x_2y_2$. This procedure can be applied recursively. Denoting by C_n the number of arithmetic operations (on single-digit numbers) to form the product of two n -digit integers by this algorithm, we have $C_n = 3C_{n/2} + kn$ and $C_1 = 1$, where kn is the cost of the additions. Then

$$\begin{aligned} C_n &= 3(3C_{n/4} + kn/2) + kn \\ &= 3(3(3C_{n/8} + kn/4) + kn/2) + kn \\ &= kn(1 + 3/2 + (3/2)^2 + \dots + (3/2)^{\log_2 n}) \\ &\approx 3kn^{\log_2 3} \approx 3kn^{1.58}, \end{aligned}$$

where the approximation is obtained by assuming that n is a power of 2. The cost is asymptotically less than the $O(n^2)$ cost of forming xy by the usual long multiplication method taught in school.

4 Computational Complexity

The computational cost of an algorithm is usually defined as the total number of arithmetic operations it requires, though it can also be defined as the execution time, under some assumption on the time required for each arithmetic operation. The cost is usually a function of the problem size, n say, and since the growth with n is of particular interest, the cost is usually approximated by the highest-order term, with lower-order terms ignored.

The algorithms considered so far all have the property that their computational cost is straightforward to evaluate and essentially independent of the data. For many algorithms the cost can vary greatly with the data. For example, an algorithm to sort a list of numbers might run more quickly when the list is nearly sorted. In this case it is desirable to find a bound that applies in all cases (a worst-case bound)—preferably one that is attainable for some set of data. It is also useful to have estimates of cost under certain assumptions on the distribution of the data. In *average-case analysis*, a probability distribution is assumed for the data and the expected cost is determined. *Smoothed analysis*, developed since 2000, interpolates between worst-case analysis and average-case analysis by measuring the expected performance of algorithms under small random perturbations of worst-case inputs. A number of algorithms are known for which the worst-case cost is exponential in the problem dimension n whereas the smoothed cost is polynomial in n , a prominent exam-

ple being the **SIMPLEX METHOD** [IV.11 §3.1] for linear programming.

A good example of a problem for which different algorithms can have widely varying cost is the solution of a linear system $Ax = b$, where A is an $n \times n$ matrix. Cramer's rule states that $x_i = \det(A_i(b)) / \det(A)$, where $A_i(b)$ denotes A with its i th column replaced by b . If the determinant is evaluated from the usual textbook formula involving EXPANSION BY MINORS [I.2 §18], the cost of computing x is about $(n+1)!$ operations, making this method impractical unless n is very small. By contrast, Gaussian elimination solves the system in $2n^3/3 + O(n^2)$ operations, with mere polynomial growth of the operation count with n . However, Gaussian elimination is by no means of optimal complexity, as we now explain.

The complexity of matrix inversion can be shown to be the same as that of matrix multiplication, so it suffices to consider the matrix multiplication problem $C = AB$ for $n \times n$ matrices A and B . The usual formula for matrix multiplication yields C in $2n^3$ operations. In a 1969 paper Volker Strassen showed that when $n = 2$ the product can be computed from the formulas

$$\begin{aligned} p_1 &= (a_{11} + a_{22})(b_{11} + b_{22}), \\ p_2 &= (a_{21} + a_{22})b_{11}, \quad p_3 = a_{11}(b_{12} - b_{22}), \\ p_4 &= a_{22}(b_{21} - b_{11}), \quad p_5 = (a_{11} + a_{12})b_{22}, \\ p_6 &= (a_{21} - a_{11})(b_{11} + b_{12}), \\ p_7 &= (a_{12} - a_{22})(b_{21} + b_{22}), \\ C &= \begin{bmatrix} p_1 + p_4 - p_5 + p_7 & p_3 + p_5 \\ p_2 + p_4 & p_1 + p_3 - p_2 + p_6 \end{bmatrix}. \end{aligned}$$

The evaluation requires seven multiplications and eighteen additions instead of eight multiplications and eight additions for the usual formulas. At first sight, this does not appear to be an improvement. However, these formulas do not rely on commutativity so are valid when the a_{ij} and b_{ij} are matrices, in which case for large dimensions the saving of one multiplication greatly outweighs the extra ten additions. Assuming n is a power of 2, we can partition A and B into four blocks of size $n/2$, apply Strassen's formulas for the multiplication, and then apply the same formulas recursively on the half-sized matrix products. The resulting algorithm requires $O(n^{\log_2 7}) = O(n^{2.81})$ operations. Strassen's work sparked interest in finding matrix multiplication algorithms of even lower complexity. Since there are $O(n^2)$ elements of data, which must each participate in at least one operation, the

Table 1 The cost of solving an $n \times n$ linear system obtained by discretizing the two-dimensional Poisson equation.

Year	Method	Cost	Type
1948	Banded Cholesky	n^2	Direct
1948	Jacobi, Gauss-Seidel	n^2	Iterative
1950	SOR (optimal parameter)	$n^{3/2}$	Iterative
1952	Conjugate gradients	$n^{3/2}$	Iterative
1965	Fast Fourier transform	$n \log n$	Direct
1965	Block cyclic reduction	$n \log n$	Direct
1977	Multigrid	n	Iterative

exponent of n must be at least 2. The current world record upper bound on the exponent is 2.3728639, proved by François Le Gall in 2014. However, all existing algorithms with exponent less than that of Strassen's algorithm are extremely complicated and not of practical interest.

An area that has undergone many important algorithmic developments over the years is the solution of linear systems arising from the discretization of partial differential equations (PDEs). Consider the POISSON EQUATION [III.18] on a square with the unknown function specified on the boundary. When discretized on an $N \times N$ grid by centered differences, a system of $n = N^2$ equations in n unknowns is obtained with a banded, symmetric positive-definite coefficient matrix containing $O(n)$ nonzeros. Table 1 gives the dominant term in the operation count (ignoring the multiplicative constant) for different methods, some of which are described in NUMERICAL LINEAR ALGEBRA AND MATRIX ANALYSIS [IV.10]. For the iterative algorithms it is assumed that the iteration is terminated when the error is of order 10^{-6} . The year is the year of first publication, or, for the first two methods, the year that the first stored-program computer was operational. Since there are n elements in the solution vector and at least one operation is required to compute each element, a lower bound on the cost is $O(n)$, and this is achieved by the multigrid method. The algorithmic speedups shown in the table are of a similar magnitude to the speedups in computer hardware over the same period.

4.1 Complexity Classes

The algorithms we have described so far all have a cost that is bounded by a polynomial in the problem dimension, n . For some problems the existence of algorithms with polynomial complexity is unclear. In analyzing this

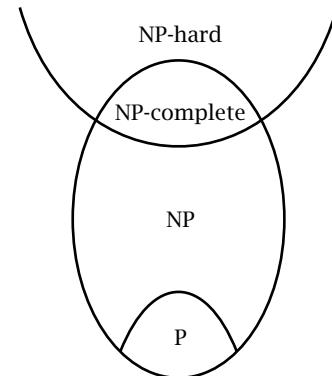

Figure 2 Complexity classes. It is not known whether the classes P and NP are equal.

question mathematicians and computer scientists use a classification of problems that makes a distinction finer than whether there is or is not an algorithm of polynomial run time. This classification is phrased in terms of decision problems: ones that have a yes or no answer. The problem class P comprises those problems that can be solved in polynomial time in the problem dimension. The class NP comprises those problems for which a yes answer can be verified in polynomial time. An example of a problem in NP is a jigsaw puzzle: it is easy to check that a claimed solution is a correctly assembled puzzle, but solving the puzzle in the first place appears to be much harder.

A problem is *NP-complete* if it is in NP and it is possible to reduce any other NP problem to it in polynomial time. Hence if a polynomial-time algorithm exists for an NP -complete problem then all NP problems can be solved in polynomial time. Many NP -complete problems are known, including Boolean satisfiability, graph coloring, choosing optimal page breaks in a document, and the Battleship game or puzzle.

A problem (not necessarily a decision problem) is *NP-hard* if it is at least as hard as any NP problem, in the sense that there is an NP -complete problem that is reducible to it in polynomial time. Thus the NP -hard problems are even harder than the NP -complete problems. Examples of NP -hard problems are the TRAVELING SALESMAN PROBLEM [VI.18], SPARSE APPROXIMATION [VII.10], and nonconvex QUADRATIC PROGRAMMING [IV.11 §1.3]. Figure 2 shows the relation among the classes.

An excellent example of the subtleties of computational complexity is provided by the determinant and the permanent of a matrix. The permanent of an $n \times n$

matrix A is

$$\text{perm}(A) = \sum_{\sigma} \prod_{i=1}^n a_{i,\sigma_i},$$

where the vector σ ranges over all permutations of the set of integers $\{1, 2, \dots, n\}$. The determinant has a similar expression differing only in that the product term is multiplied by the sign (± 1) of the permutation. Yet while the determinant can be computed in $O(n^3)$ operations, by Gaussian elimination, no polynomial-time algorithm has ever been discovered for computing the permanent. Leslie Valiant gave insight into this disparity when he showed in 1979 that the problem of computing the permanent is complete for a complexity class of counting problems called #P that extends NP.

The most famous open problem in computer science is “is P equal to NP?” It was posed by Stephen Cook in 1971 and is one of the seven Clay Institute Millennium Problems, for each of which a \$1 million prize is available for a solution. Informally, the question is whether the “easy to solve” problems are equal to the “easy to check” problems. It is known that $P \subseteq NP$, so the question is whether or not the inclusion is strict.

5 Trade-off between Speed and Accuracy

In designing algorithms that run in floating-point arithmetic it frequently happens that an increase in speed is accompanied by a decrease in accuracy. A classic example is the computation of the *sample variance* of n numbers x_1, \dots, x_n , which is defined as

$$s_n^2 = \frac{1}{n-1} \sum_{i=1}^n (x_i - \bar{x})^2, \quad (2)$$

where the sample mean

$$\bar{x} = \frac{1}{n} \sum_{i=1}^n x_i.$$

Computing s_n^2 from this formula requires two passes through the data, one to compute \bar{x} and the other to accumulate the sum of squares. A two-pass computation is undesirable for large data sets or when the sample variance is to be computed as the data is generated. An alternative formula, found in statistics textbooks (and implemented on many pocket calculators and spreadsheets over the years), uses about the same number of operations but requires only one pass through the data:

$$s_n^2 = \frac{1}{n-1} \left(\sum_{i=1}^n x_i^2 - \frac{1}{n} \left(\sum_{i=1}^n x_i \right)^2 \right). \quad (3)$$

However, this formula behaves badly in floating-point arithmetic. For example, if $n = 3$ and $x_1 = 10000$, $x_2 = 10001$, and $x_3 = 10002$, then, in IEEE single-precision arithmetic (with unit roundoff $u \approx 6 \times 10^{-8}$), the sample variance is computed as 1.0 by the two-pass formula (relative error 0) but 0.0 by the one-pass formula (relative error 1). The reason for the poor accuracy of the one-pass formula is that there is massive SUBTRACTIVE CANCELLATION [II.13] in (3). The original formula (2) always yields a computed result with error $O(nu)$. Is there a way of combining the speed of the one-pass formula with the accuracy of the two-pass one? Yes: the recurrence

$$\left. \begin{aligned} M_1 &= x_1, & Q_1 &= 0, \\ M_k &= M_{k-1} + \frac{x_k - M_{k-1}}{k} \\ Q_k &= Q_{k-1} + \frac{(k-1)(x_k - M_{k-1})^2}{k} \end{aligned} \right\} \quad k = 2:n$$

calculates Q_n , which yields $s_n^2 = Q_n/(n-1)$ and produces an accurate result in floating-point arithmetic.

6 Choice of Algorithm

Much research in numerical analysis and scientific computing is about finding the best algorithm for solving a given problem, and for classic problems such as solving a PDE or finding the eigenvalues of a matrix there are many possibilities, with improvements continually being developed. However, even for some quite elementary problems there are several possible algorithms, some of which are far from obvious.

A first example is the evaluation of a polynomial $p(x) = a_0 + a_1x + \dots + a_nx^n$. The most obvious way to evaluate the polynomial is by directly forming the powers of x .

```

1  p = a_0 + a_1x, w = x
2  for i = 2:n
3      w = wx
4      p = p + a_iw
5  end
```

This algorithm requires $2n$ multiplications and n additions (ignoring the constant term in the operation count).

An alternative method is *Horner's method* (nested multiplication). It is derived by writing the polynomial in nested form:

$$p(x) = (\dots ((a_nx + a_{n-1})x + a_{n-2})x + \dots + a_1)x + a_0.$$

Horner's method is

```

1  p = a_n
2  for i = n - 1:-1:0 % i goes down in steps of -1
3      p = px + a_i
4  end

```

Horner's method requires n multiplications and n additions, so is significantly less expensive than the first method.

However, even Horner's method is not optimal. For example, it requires eight multiplications for $p(x) = x^8$, but this polynomial can be evaluated in just three multiplications using algorithm 3 in section 3. Moreover, for general polynomials of degree $n > 4$ there exist evaluation schemes that require strictly less than the $2n$ total additions and multiplications required by Horner's rule; the catch is that the operation count excludes some precomputation of coefficients that, once computed, can be reused for every subsequent polynomial evaluation. This latter example emphasizes that if one wishes to investigate optimality of schemes for polynomial evaluation it is important to be precise about what is included in the operation count.

A second example concerns the continued fraction

$$r_n(x) = b_0 + \cfrac{a_1x}{b_1 + \cfrac{a_2x}{b_2 + \cfrac{a_3x}{b_3 + \cdots + \cfrac{a_{n-1}x}{b_{n-1} + \cfrac{a_nx}{b_n}}}}. \quad (4)$$

This continued fraction represents a rational function $r_n(x) = p_n(x)/q_n(x)$, where p_n and q_n are polynomials of degrees $\lceil n/2 \rceil$ and $\lfloor n/2 \rfloor$, respectively. Such continued fractions arise in the approximation of transcendental functions by PADÉ APPROXIMANTS [IV.9 §2.4].

Probably the most obvious way to evaluate the continued fraction is by the following bottom-up procedure.

Algorithm 5 (continued fraction, bottom-up). *This algorithm evaluates the continued fraction (4) in bottom-up fashion.*

```

1  y_n = (a_n/b_n)x
2  for j = n - 1:-1:1
3      y_j = a_jx/(b_j + y_{j+1})
4  end
5  r_n = b_0 + y_1

```

Cost. The total number of operations is $n(D + M + A)$, where A , D , and M denote an addition, a division, and a multiplication, respectively.

The bottom-up evaluation requires us to know the value of n in advance and is not well suited to evaluating the sequence $r_1(x), r_2(x), \dots$, since it needs to start afresh each time. Top-down evaluation is better in this case. The following recurrence dates back to John Wallis in 1655.

Algorithm 6 (continued fraction, top-down). *This algorithm evaluates the continued fraction (4) in top-down fashion.*

```

1  p_{-1} = 1, q_{-1} = 0, p_0 = b_0, q_0 = 1
2  for j = 1:n
3      p_j = b_j p_{j-1} + a_j x p_{j-2}
4      q_j = b_j q_{j-1} + a_j x q_{j-2}
5  end
6  r_n = p_n q_n^{-1}

```

Cost. $5nM + 2nA + D$.

It is not obvious that algorithm 6 does actually evaluate $r_m(x)$, but this can be proved inductively. Note that top-down evaluation is substantially more expensive than bottom-up evaluation.

These are not the only possibilities. For example, when $n = 2m$ one can write r_n in partial fraction form $r_n(x) = \sum_{j=1}^m \alpha_j x / (x - \beta_j)$, where the β_j (assumed to be distinct) are the roots of q_n , which permits evaluation at a cost of $m(2M + A + D)$.

In practice, one needs to consider the effect of rounding errors on the evaluation, and this is in general dependent on the particular coefficients a_i and b_i and on the range of x of interest.

When there are several algorithms for solving a problem one may need a *polyalgorithm*, which is a set of algorithms with rules for choosing between them. A good example of a polyalgorithm is the MATLAB backslash operator, which enables a solution to a linear system $Ax = b$ to be computed using the syntax $A \backslash b$. The matrix A may be square or rectangular; diagonal, triangular, full, or sparse; and symmetric, symmetric positive-definite, or completely general. Underlying the backslash operator is an algorithm for identifying which of these properties hold and choosing the appropriate matrix factorization and solution process to apply.

7 Randomized Algorithms

All the algorithms described so far in this article are deterministic: if they are run repeatedly on the same data, they produce the same result every time. Some algorithms make random choices and so generally produce a different result every time they are run. For example, we might approximate

$$\int_0^1 f(x) dx \approx \frac{1}{n} \sum_{i=1}^n f(x_i),$$

where the x_i are independent random numbers uniformly distributed in $[0, 1]$. The standard deviation of the error in this approximation is of order $n^{-1/2}$. This is an example of a *Monte Carlo algorithm*; such algorithms have a deterministic run time and produce an output that is correct (or has a given accuracy) with a certain probability. Of course, there are much more efficient ways to estimate a one-dimensional integral, but Monte Carlo algorithms come into their own for multidimensional integrals over complicated domains.

A *Las Vegas algorithm* always produces a correct result, but its run time is nondeterministic. A classic example is the quicksort algorithm for sorting a list of numbers, for which a randomized choice of the partition element makes the algorithm much faster on average than in the worst case ($O(n \log n)$ running time versus $O(n^2)$, for n numbers).

Randomized algorithms can be much simpler than deterministic alternatives, they may be more able to exploit modern computing architectures, and they may be better suited to large data sets. There is a wide variety of randomized algorithms, and they are studied in mathematics, computer science, statistics, and other areas.

One active area of research is randomized algorithms for numerical linear algebra problems, based on random sampling and random projections. For example, fast algorithms exist for computing low-rank approximations to a given matrix. The general framework is that random sampling is used to identify a subspace that captures most of the action of the matrix, the matrix is then compressed to this subspace, and a low-rank factorization is computed from the reduced matrix.

Examples of randomized algorithms mentioned in this book are the Google PAGERANK ALGORITHM [VI.9], with its use of a random surfer, the *k*-MEANS ALGORITHM [IV.17 §5.3] for clustering, and MARKOV CHAIN MONTE CARLO ALGORITHMS [V.11 §3].

8 Some Key Algorithms in Applied Mathematics

Table 2 lists a selection of algorithms mentioned in this book. Very general methods such as preconditioning and the finite-element method, which require much more information to produce a particular algorithm, are omitted. The table illustrates the wide variety of important algorithms in applied mathematics, ranging from the old to the relatively new.

A notable feature of some of the algorithms is that they are iterative algorithms, which in principle take an infinite number of steps, for solving problems that can be solved directly, that is, in a finite number of operations. The conjugate gradient and multigrid methods are iterative methods for solving a linear system of equations, and for suitably structured systems they can provide a given level of accuracy much faster than Gaussian elimination, which is a direct method. Similarly, interior point methods are iterative methods for linear programming, competing with the simplex method, which is a direct method.

Further Reading

A classic reference for algorithms and their analysis is Donald Knuth's *The Art of Computer Programming*. The first volume appeared in 1968 and the development is ongoing. Current volumes are *Fundamental Algorithms* (volume 1), *Seminumerical Algorithms* (volume 2), *Sorting and Searching* (volume 3), and *Combinatorial Algorithms* (volume 4), all published by Addison-Wesley (Reading, MA).

existing mathematical ideas to practical problems: new results are continually being developed, usually building on old ones. Applied mathematicians are always innovating, and the constant arrival of new or modified problems provides direction and motivation for their research.

In this article we describe some goals of research in applied mathematics from the perspectives of the ancient problem of solving equations, the more contemporary theme of exploiting structure, and the practically important tasks of modeling and prediction. We also discuss the strategy behind research.

1 Solving Equations

A large proportion of applied mathematics research papers are about analyzing or solving equations. The

equations may be algebraic, such as linear or nonlinear equations in one or more variables. They may be ordinary differential equations (ODEs), partial differential equations (PDEs), integral equations, or differential-algebraic equations.

The wide variety of equations reflects the many different ways in which one can attempt to capture the behavior of the system being modeled. Whatever the equation, an applied mathematician is interested in answering a number of questions.

1.1 Does the Equation Have a Solution?

We are interested in whether there is a unique solution and, if there is more than one solution, how many there are and how they are characterized. Existence of solutions may not be obvious, and one occasionally

hears tales of mathematicians who have solved equations for which a proof is later given that no solution exists. Such a circumstance may sound puzzling: is it not easy to check that a putative solution actually is a solution? Unfortunately, checking satisfaction of the equation may not be easy, especially if one is working in a function space. Moreover, the problem specification may require the solution to have certain properties, such as existence of a certain number of derivatives, and the claimed solution might satisfy the equation but fail to have some of the required properties. Instead of analyzing the problem in the precise form in which it is given, it may be better to investigate what additional properties must be imposed for an equation to have a unique solution.

1.2 Is the Equation Well-Posed?

A problem is *well-posed* if it has a unique solution and the solution changes continuously with the data that define the problem. A problem that is not well-posed is *ill-posed*. For an ill-posed problem an arbitrarily small perturbation of the data can produce an arbitrarily large change in the solution, which is clearly an unsatisfactory situation.

An example of a well-posed problem is to determine the weight supported by each leg of a three-legged table. Assuming that the table and its legs are perfectly symmetric and the ground is flat, the answer is that each leg carries one-third of the total weight. For a table with four legs each leg supports one-quarter of the total weight, but if one leg is shortened by a tiny amount then it leaves the ground and the other three legs support the weight of the table (a phenomenon many of us have experienced in restaurants). For four-legged tables the problem is therefore ill-posed.

For finite-dimensional problems, uniqueness of the solution implies well-posedness. For example, a linear system $Ax = b$ of n equations in n unknowns with a nonsingular coefficient matrix A is well-posed. Even so, if A is nearly singular then a small perturbation of A can produce a large change in the solution, albeit not arbitrarily large: the CONDITION NUMBER [I.2 §22] $\kappa(A) = \|A\| \|A^{-1}\|$ bounds the relative change. But for infinite-dimensional problems the existence of a unique solution does not imply that the problem is well-posed; examples are given in the article on INTEGRAL EQUATIONS [IV.4 §6].

The notion of well-posedness was introduced by Jacques Hadamard at the beginning of the twentieth

century. He believed that physically meaningful problems should be well-posed. Today it is recognized that many problems are ill-posed, and they are routinely solved by reformulating them so that they are well-posed, typically by a process called REGULARIZATION [IV.15 §2.6] (see also INTEGRAL EQUATIONS [IV.4 §7]).

An important source of ill-posed problems is INVERSE PROBLEMS [IV.15]. Consider a mathematical model in which the inputs are physical variables that can be adjusted and the output variables are the result of an experiment. The *forward problem* is to predict the outputs from a given set of inputs. The *inverse problem* is to make deductions about the inputs that could have produced a given set of outputs. In practice, the measurements of the outputs may be subject to noise and the model may be imperfect, so UNCERTAINTY QUANTIFICATION [II.34] needs to be carried out in order to estimate the uncertainty in the predictions and deductions.

1.3 What Qualitative Properties Does a Solution Have?

It may be of more interest to know the behavior of a solution than to know the solution itself. One may be interested in whether the solution, $f(t)$ say, decays as $t \rightarrow \infty$, whether it is monotonic in t , or whether it oscillates and, if so, with what fixed or time-varying frequency. If the problem depends on parameters, it may be possible to answer these questions for a range of values of the parameters.

1.4 Does an Iteration Converge?

As we saw in METHODS OF SOLUTION [I.3], solutions are often computed from iterative processes, and we therefore need to understand these processes. Various facets of convergence may be of interest.

- Is the iteration always defined, or can it break down (e.g., because of division by zero)?
- For what starting values, and for what class of problems, does the iteration converge?
- To what does the iteration converge, and how does this depend on the starting value (if it does at all)?
- How fast does the iteration converge?
- How are errors (in the initial data, or rounding errors introduced during the iteration) propagated? In particular, are they bounded?

To illustrate some of these points we consider the iteration

$$x_{k+1} = \frac{1}{p}[(p-1)x_k + x_k^{1-p}a], \quad (1)$$

with p a positive integer and $a \in \mathbb{C}$, which is Newton's method for computing a p th root of a . We ask for which a and which starting values x_0 the iteration converges and to what root it converges. The analysis is simplified by defining $y_k = \theta^{-1}x_k$, where θ is a p th root of a , as the iteration can then be rewritten

$$y_{k+1} = \frac{1}{p}[(p-1)y_k + y_k^{1-p}], \quad y_0 = \theta^{-1}x_0, \quad (2)$$

which is Newton's method for computing a p th root of unity. The original parameters a and x_0 have been combined into the starting value y_0 .

Figure 1 illustrates the convergence of the iteration for $p = 2, 3, 5$. For y_0 ranging over a 400×400 grid with $\operatorname{Re} y_0, \operatorname{Im} y_0 \in [-2.5, 2.5]$, it plots the root to which y_k from (2) converges, with each root denoted by a different grayscale from white (the principal root, 1) to black. Convergence is declared if after fifty iterations the iterate is within relative distance 10^{-13} of a root; the relatively small number of points for which convergence was not observed are plotted white. For $p = 2$ the figure suggests that the iteration converges to 1 if started in the open right half-plane and -1 if started in the open left half-plane, and this can be proved to be true. But for $p = 3, 5$ the regions of convergence have a much more complicated structure, involving sectors with petal-like boundaries.

The complexity of the convergence for $p \geq 3$ was first noticed by Arthur Cayley in 1879, and an analysis of convergence for all starting values requires the theory of Julia sets of rational maps. However, for practical purposes it is usually principal roots that need to be computed, so from a practical viewpoint the main implication to be drawn from the figure is that for $p = 3, 5$ Newton's method converges to 1 for y_0 sufficiently close to the positive real axis—and it can be proved that this is true.

We see from this example that the convergence analysis depends very much on the precise question that is being asked. The iteration (1) generalizes in a natural way to matrices and operators, for which the convergence results for the scalar case can be exploited.

2 Preserving Structure

Many mathematical problems have some kind of structure. An example with explicit structure is a linear system $Ax = b$ in which the $n \times n$ matrix A is a TOEPLITZ

MATRIX [I.2 §18]. This system has $n^2 + n$ numbers in A and b but only $3n - 1$ independent parameters. On the other hand, if for the vector ODE $y' = f(t, y)$ there is a vector v such that $v^T f(t, y) = 0$ for all t and y , then $(d/dt)v^T y(t) = v^T f(t, y) = 0$, so $v^T y(t)$ is constant for all t . This conservation or invariance property is a form of structure, though one more implicit than for the Toeplitz system.

An example of a nonlinear conservation property is provided by the system of ODEs

$$\begin{aligned} u'(t) &= v(t), \\ v'(t) &= -u(t). \end{aligned}$$

For this system,

$$\frac{d}{dt}(u^2 + v^2) = 2(u'u + v'v) = 2(vu - uv) = 0,$$

so there is a quadratic invariant. In particular, for the initial values $u(0) = 1$ and $v(0) = 0$ the solution is $u(t) = \cos t$ and $v(t) = -\sin t$, which lies on the unit circle centered at the origin in the uv -plane. If we solve the system using a numerical method, we would like the numerical solution also to lie on the circle. In fact, one potential use of this differential equation is to provide a method for plotting circles that avoids the relatively expensive evaluation of sines and cosines. Consider the following four standard numerical methods applied to our ODE system. Here, $u_k \approx u(kh)$ and $v_k \approx v(kh)$, where h is a given step size, and $u_0 = 1$ and $v_0 = 0$:

$$\begin{aligned} \text{Forward Euler} \quad &\begin{cases} u_{k+1} = u_k + hv_k, \\ v_{k+1} = v_k - hu_k, \end{cases} \\ \text{Backward Euler} \quad &\begin{cases} u_{k+1} = u_k + hv_{k+1}, \\ v_{k+1} = v_k - hu_{k+1}, \end{cases} \\ \text{Trapezium method} \quad &\begin{cases} u_{k+1} = u_k + h(v_k + v_{k+1})/2, \\ v_{k+1} = v_k - h(u_k + u_{k+1})/2, \end{cases} \\ \text{Leapfrog method} \quad &\begin{cases} u_{k+1} = u_k + hv_k, \\ v_{k+1} = v_k - hu_{k+1}. \end{cases} \end{aligned}$$

Figure 2 plots the numerical solutions computed with 32 steps of length $h = 2\pi/32$. We see that the forward Euler solution spirals outward while the backward Euler solution spirals inward. The trapezium method solution stays nicely on the unit circle. The leapfrog method solution traces an ellipse. This behavior is easy to explain if we write each method in the form

$$z_{k+1} = Gz_k, \quad z_k = \begin{bmatrix} u_k \\ v_k \end{bmatrix},$$

where $G = \begin{bmatrix} 1 & h \\ -h & 1 \end{bmatrix}$ for the Euler method, for example. Then the behavior of the sequence z_k depends on the

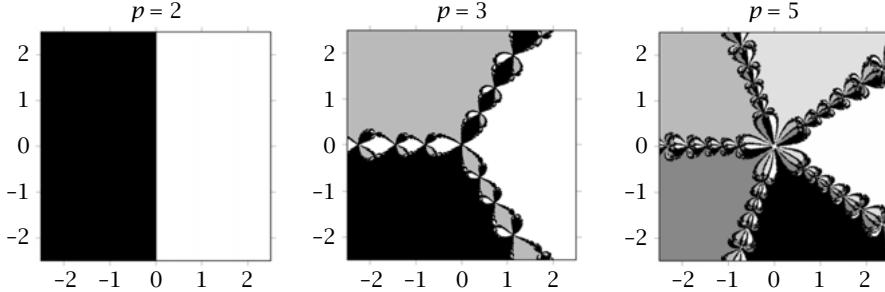

Figure 1 Newton iteration for a p th root of unity. Each point y_0 in the region is shaded according to the root to which the iteration converges, with white denoting the principal root, 1.

eigenvalues of the matrix G . It turns out that the spectral radius of G is greater than 1 for forward Euler and less than 1 for backward Euler, which explains the spiraling. For the trapezium rule G is orthogonal, so $\|z_{k+1}\|_2 = \|z_k\|_2$ and the trapezium solutions stay exactly on the unit circle. For the leapfrog method the determinant of G is 1, which means that areas are preserved, but G is not orthogonal so the leapfrog solution drifts slightly off the circle.

The subject of GEOMETRIC INTEGRATION [IV.12 §5] is concerned more generally with methods for integrating nonlinear initial-value ODEs and PDEs in a way that preserves the invariants of the system, while also providing good accuracy in the usual sense. This includes, in particular, SYMPLECTIC INTEGRATORS [IV.12 §1.3] for Hamiltonian systems.

3 Modeling and Prediction

As WHAT IS APPLIED MATHEMATICS? [I.1 §1] explains, modeling is the first step in solving a physical problem. Models are necessarily simplifications because it is impractical to incorporate every detail. But simple models can still be useful as tools to explore the broad consequences of physical laws. Moreover, the more complex a model is the more parameters it has (all of which need estimating) and the harder it is to analyze.

In their 1987 book *Empirical Model-Building and Response Surfaces*, Box and Draper ask us to

Remember that all models are wrong; the practical question is how wrong do they have to be to not be useful.

Road maps illustrate this statement. They are always a simplified representation of reality due to representing a three-dimensional world in two dimensions and displaying wiggly roads as straight lines. But road maps

are very useful. Moreover, there is no single “correct” map but rather many possibilities depending on resolution and purpose. Another example is the approximation of π . The approximation $\pi \approx 3.14$ is a model for π that is wrong in that it is not exact, but it is good enough for many purposes.

It is difficult to give examples of the modeling process because knowledge of the problem domain is usually required and derivations can be lengthy. We will use for illustration a very simple model of population growth, based on the *logistic equation*

$$\frac{dN}{dt} = rN \left(1 - \frac{N}{K}\right).$$

Here, $N(t)$ is a representation in a continuous variable of the number of individuals in a population at time t , $r > 0$ is the growth rate of the population, and $K > 0$ is the carrying capacity. For $K = \infty$, the model says that the rate of change of the population, dN/dt , is rN ; that is, it is proportional to the size of the population through the constant r , so the population grows exponentially. For finite K , the model attenuates this rate of growth by a subtractive term rN^2/K , which can be interpreted as representing the increasing effects of competition for food as the population grows. The logistic equation can be solved exactly for $N(t)$ (see ORDINARY DIFFERENTIAL EQUATIONS [IV.2 §2]). Laboratory experiments have shown that the model can predict reasonably well the growth of protozoa feeding on bacteria. However, for some organisms the basic logistic equation is not a good model because it assumes instant responses to changes in population size and so does not account for gestation periods, the time taken for young to reach maturity, and other delays. A more realistic model may therefore be

$$\frac{dN(t)}{dt} = rN(t) \left(1 - \frac{N(t-\tau)}{K}\right),$$

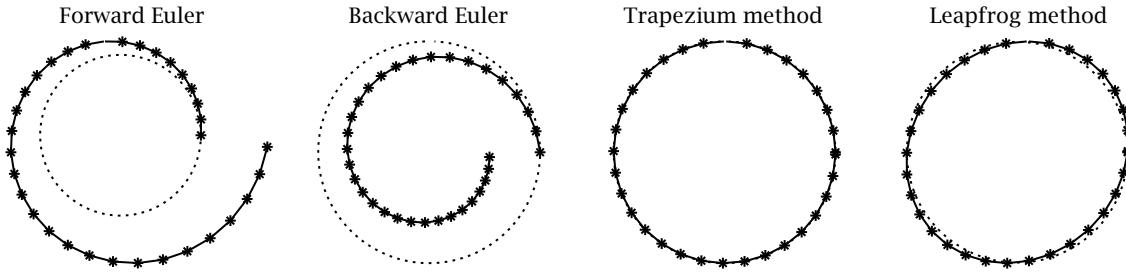

Figure 2 Approximations to the unit circle computed by four different numerical integrators with step size $h = 2\pi/32$. The dotted line is the unit circle; asterisks denote numerical approximations.

where $\tau > 0$ is a delay parameter. At time t , part of the quadratic term is now evaluated at an earlier time, $t - \tau$. This delay differential equation has oscillatory solutions and has been found to model well the population of lemmings in the Arctic. Note that in contrast to the PREDATOR-PREY MODEL [I.2 §10], the delayed logistic model can produce oscillations in a population without the need for a second species acting as predator. There is no suggestion that either of these logistic models is perfect, but with appropriate fitting of parameters they can provide useful approximations to actual populations and can be used to predict future behavior.

3.1 Errors

A lot of research is devoted to understanding the errors that arise at the different stages of the modeling process. These can broadly be categorized as follows.

Errors in the mathematical model. Setting up the model introduces errors, since the model is never exact. These are the hardest errors to estimate.

Approximation errors. These are the errors incurred when infinite-dimensional equations are replaced by a finite-dimensional system (that is, a continuous problem is replaced by a discrete one: the process of discretization), or when simpler approximations to the equations are developed (e.g., by MODEL REDUCTION [II.26]). These errors include errors in replacing one approximating space by another (e.g., replacing continuous functions by polynomials), errors in FINITE-DIFFERENCE [II.11] approximations, and errors in truncating power series and other expansions.

Rounding errors. Once the problem has been put in a form that can be solved by an algorithm implemented in a computer program, the effects of the rounding errors introduced by working in finite-precision arithmetic need to be determined.

Analysis of errors may include looking at the effects of uncertainties in the model data, including in any parameters in the model that must be estimated. This might be tackled in a statistical sense using techniques from UNCERTAINTY QUANTIFICATION [II.34]—indeed, if the model has incompletely known data then probabilistic techniques may already be in use to estimate the missing data. Sensitivity of the solution of the model may also be analyzed by obtaining worst-case error bounds with the aid of CONDITION NUMBERS [I.2 §22].

3.2 Multiphysics and Multiscale Modeling

Scientists are increasingly tackling problems with one or both of the following characteristics: (a) the system has multiple components, each governed by its own physical principles; and (b) the relevant processes develop over widely different time and space scales. These are called *multiphysics* and *multiscale* problems, respectively. An example of both is the problem of modeling how *space weather* affects the Earth, and in particular modeling the interaction of the solar wind (the flow of charged particles emitted by the sun) with the Earth's magnetic field. Different physical models describe the statistical distribution of the plasma, which consists of charged particles, and the evolution of the electric and magnetic fields, and these form a coupled nonlinear system of PDEs. The length scales range from millions of kilometers (the Earth-sun distance) to hundreds of meters, and the timescales range from hours down to 10^{-5} seconds. Problems such as this pose challenges both for modeling and for computational solution of the models. The computations require HIGH-PERFORMANCE COMPUTERS [VII.12], and a particular task is to present the vast quantities of data generated in such a way that users, such as forecasters of space

weather, can explore and interpret them. More on the issues of this section can be found in the articles on COMPUTATIONAL SCIENCE [IV.16] and VISUALIZATION [VII.13].

3.3 Computational Experiments

The step in the problem solution when computational experiments are carried out might seem to be the easiest, but it can in fact be one of the hardest and most time-consuming, for several reasons. It can be hard to decide what experiments to carry out, and it may be necessary to refine the experiments many times until useful or satisfactory results are obtained. The computations may have a long run time, even if executed on a high-performance computer.

Many pitfalls can be avoided by working to modern standards of REPRODUCIBLE RESEARCH [VIII.5], which require that programs, data, and results be recorded, documented, and made available in such a way that the results can be reproduced by an independent researcher and, just as importantly, by the original author.

3.4 Validation

The process of *validation* involves asking the question, “Have we solved the right equations?” This is not to be confused with *verification*, which asks whether the equations in the model have been solved correctly. Whereas verification is a purely mathematical question, validation intimately involves the underlying physical problem. A classic way to validate results from a model is to compare them with experimental results. However, this is not always feasible, as we may be modeling a device or structure that is still in the design phase or on which experiments are not possible (e.g., the Earth’s climate).

Validation may not produce a yes or no answer but may instead indicate a range of parameters for which the model is a good predictor of actual behavior.

Validation may be the first step of an iterative refinement procedure in which the steps in figure 1 are repeated, with the second and subsequent invocations of the first step now comprising adjustments to the current model. Assuming it is feasible to carry out refinement, there is much to be said for starting with the simplest possible model and building gradually toward an effective model of minimal complexity.

4 Strategies for Research and Publishing

Analysis of the research literature in applied mathematics reveals some common features that can be built into a list of strategies for doing research.

- (i) Solve an open problem or prove the truth or falsity of a conjecture that has previously been stated in the literature.
- (ii) Derive a method for solving a problem that occurs in practice and has not been effectively solved previously. Problems of very large dimension, for which existing techniques might be impractical, are good hunting grounds.
- (iii) Prove convergence of a method for which the existing convergence theory is incomplete.
- (iv) Spot some previously unnoticed phenomenon and explain it.
- (v) Generalize a result or algorithm to a wider class of problems, obtaining new insight in doing so.
- (vi) Provide a new derivation of an existing result or algorithm that yields new insight.
- (vii) Develop a new measure of cost or error for a problem and then derive a new algorithm that is better than existing algorithms with respect to that metric. For example, instead of measuring computational cost in the traditional way by the number of elementary arithmetic operations, also include the cost of data movement when the algorithm is implemented on a parallel computer.
- (viii) Find hidden assumptions in an existing method and remove them. For example, it may seem obvious that multiplying two 2×2 matrices requires eight multiplications, but Strassen showed that only seven multiplications are needed (see [I.4 §4] for the relevant formulas), thereby deriving an asymptotically fast method for matrix multiplication.
- (ix) Rehabilitate an out-of-favor method by showing that it can be made competitive again by exploiting new research results, problem requirements, or hardware developments.
- (x) Use mathematical models to gain new insight into complex physical processes.
- (xi) Use mathematical models to make quantitative predictions about physical phenomena that can lead to new procedures, standards, etc., in the target field. Here it will probably be necessary to work with researchers from other disciplines.

Nowadays, publishing the results of one's research is more important than ever. Funding bodies expect to see publications, as they provide evidence that the research has been successful and they help to disseminate the work. Assessment of researchers and their institutions increasingly makes use of metrics, some of which relate to publications, such as the number of citations a paper receives and the ranking of the journal in which it is published. There is therefore a tension between publishing prolifically (which, taken to the extreme, leads to breaking research up into "least publishable units") and publishing fewer, longer, more-considered papers.

In addition to the traditional journals and conference proceedings that publish (usually) refereed articles, nowadays there are many outlets for unrefereed manuscripts, including institutional eprint servers, the global arXiv eprint service, and personal Web pages. Blogs provide yet another venue for publishing research, usually in the form of shorter articles presented in a more accessible form than in a regular paper. The nonjournal outlets provide for instant publication but have varying degrees of visibility and permanence.

The balance between publication of journals and books in print only, in both print and electronic form, and purely in electronic form has been changing for the past decade or more, and the advent of handheld devices such as smartphones and tablets has accelerated developments. Equally disruptive is the movement toward open-access publishing. Traditionally, the publishers of mathematics journals did not charge an author to publish an article but did charge institutions to subscribe to the journal. In recent years a new model has been introduced in which the author pays to publish an article in a journal and the article is freely available to all.

While we can be sure that there will always be outlets for publishing research, it is difficult to predict how the forms that these outlets take will evolve in the future.

I.6 The History of Applied Mathematics

*June Barrow-Green and Reinhard
Siegmund-Schultze*

And as for the Mixt Mathematikes I may only make this prediction, that there cannot faile to bee more kinds of them, as Nature growes furder disclosed.

Francis Bacon: *Of the Proficience and Advancement of Learning* (1605)

Figure 1 Detail from a pictorial representation of J. le R. d'Alembert's "Système des Connoissances Humaines" in the supplement to volume 2 of *l'Encyclopédie* (1769), mentioning "mixed mathematics," for which Francis Bacon had predicted a great future.

1 Introduction

What is applied mathematics? This is a difficult question—one to which there is no simple answer. The massive growth in applications of mathematics within and outside the sciences, especially since World War II, has made this question even more problematic, the increasing overlap with other disciplines and their methods adding further to the difficulties, creating problems that border on the philosophical.

Given the fact that almost every part of mathematics is potentially applicable, there are mathematicians and historians who consider the term “applied mathematics” primarily as a term of social distinction or a matter of attitude. One such was William Bonnor, the mathematician and gravitational physicist, who in 1962 in a lecture on “The future of applied mathematics” said the following:

Applied mathematics, as I should like it to be understood, means the application of mathematics to *any* subject, physical or otherwise; with the proviso that the mathematics shall be interesting and the results nontrivial. An applied mathematician, on this view, is somebody who has been trained to make such applications, and who is always prepared to look for situations where fruitful application is possible. As such, he is not a physicist *manqué*. I therefore see applied mathematics as an activity, or attitude of mind, rather than as a body of knowledge.

Not everyone will agree with Bonnor. Some take a more methodological approach and almost equate applied mathematics with “mathematical modeling.” Others are of a more concrete, mathematical mind and insist that there are parts of mathematics that are *per se* more or less applicable than others. We find Bonnor’s definition appealing because it stresses the social dimension of the mathematical working process and allows a historical understanding of the notion of applied mathematics.

The importance of “attitudes” notwithstanding, by any definition applied mathematics has to be “genuine” mathematics in the sense that it aims at and/or uses general statements (theorems) even if the piece of mathematics in question has not yet been fully logically established. In fact, the applicability of mathematics is mainly based on its “generality,” which in relation to fields of application often appears as “abstractness.” This applies even to relatively elementary applications such as the use of positional number systems.

Applications of mathematics, even on a nonelementary level, have been possible because certain practices and properties, such as algorithms for approximations or geometrical constructions, have always existed within mathematics itself and have led to spontaneous or deliberate applications. While, as the universal mathematician John von Neumann observed in 1947, in pure mathematics many problems and methods are selected for aesthetic reasons, in applied mathematics, problems considered at the time as urgent have priority, and the choice of methods often has to be subordinated to the goals in question. However, attitudes and values, which often had and continue to have strong political and economic overtones, have always been instrumental in deciding exactly which parts of mathematics should be emphasized and developed. Since attitudes have to be promoted through education, this puts a great responsibility on teaching and training and makes developments in that area an important topic for a history of applied mathematics.

Of course, many modern and recent applications rely on older mathematical ideas in differential equations, topology, and discrete mathematics and on established notation and symbolism (matrices, quaternions, Laplace transforms, etc.), while important new developments in INTEGRAL EQUATIONS [IV.4], measure theory, vector and tensor analysis, etc., at the turn of the twentieth century have added to these ideas.

However, in the twentieth century, three major scientific and technical innovations both changed and

enlarged the notion of applied mathematics. In rough chronological order, these are mathematical *modeling* in a broad, modern sense, *stochastics* (modern probability and statistics), and the *digital computer*. These three innovations have, through their interactions, restructured applied mathematics. They were principally established after World War II, and it was also only then that the term “mathematical modeling” came to be more frequently used for activities that had hitherto usually been expressed by less concise words such as “problem formulation and evaluation.” In addition to these innovations, which are essentially concerned with methodology, several totally new fields of application, such as electrical engineering, economics, biology, meteorology, etc., emerged in the twentieth century.

While in 1914 one of the pioneers of modern applied mathematics, Carl Runge, still doubted whether “the name of ‘applied mathematics’ was chosen appropriately, because when applied to empirical sciences it still remains pure mathematics,” the three major innovations listed above would radically alter and extend the notion of mathematics and, in particular, that of applied mathematics. Due to these innovations, the modern disciplines at the interface of mathematics and engineering, such as cybernetics, control theory, computer science, and optimization, were all able to emerge in the 1940s and 1950s in the United States (Wiener, Shannon, Dantzig) and the Soviet Union (Andronov, Kolmogorov, Pontryagin, Kantorovich) independently, and to a somewhat lesser degree in England (Turing, Southwell, Wilkinson), France (Couffignal), and elsewhere. These innovations also gradually changed “hybrid disciplines,” such as electrical engineering and aerodynamics, that had originated at the turn of the century. In the case of aerodynamics, not only were statistical explanations of TURBULENCE [V.21] increasingly proposed after World War II, but also CONFORMAL MAPPINGS [II.5] gradually lost importance in favor of computational FLUID DYNAMICS [IV.28]. Within operations research, with its various approaches and techniques (linear programming, optimization methods, statistical quality control, inventory control, queuing analysis, network flow analysis), mathematical concepts, especially mathematical models, acquired an even stronger foothold than in the more traditional industrial engineering.

One typical modern mathematical discipline that intimately combines pure and applied aspects of the subject and that is intertwined with various other scientific (physical and biological) and engineering disciplines

is the theory of DYNAMICAL SYSTEMS [IV.20]. After initial work in the field by Poincaré, Lyapunov, and Birkhoff, the theory fell into oblivion until the 1960s. This falling away can be explained by fashion (such as the trend toward the mathematics of Bourbaki), by new demands in applications connected to dissipative systems, and by the partial invisibility of the Russian school in the West. With the advent of modern computing devices, the shape of the discipline changed dramatically. Mathematicians were empowered computationally and graphically, the visualization of new objects such as fractals was made possible, and applications in fields such as CONTROL THEORY [IV.34] and meteorology—quantitative applications as well as qualitative ones—began to proliferate. The philosophical discussion about mathematics and applications has also been enriched by this discipline, with the public being confronted by catchwords such as CHAOS [II.3], catastrophe, and self-organization. However, the process whereby the various streams of problems converged and led to the subject's modern incarnation is complex:

In the 1930s, for example, what could the socio-professional worlds of the mathematician Birkhoff (professor at Harvard), the “grand old man of radio” van der Pol (at the Philips Research Lab), and the Soviet “physico [engineer] mathematician” Andronov at Gorki have had in common? What, in the 1950s, had Kolmogorov’s school in common with Lefschetz’s? It is precisely this manifold character of social and epistemic landscapes that poses problem[s] in this history.

Aubin and Dahan (2002)

The role played by the three major innovations continues largely unabated today, as is evident, for instance, from a 2012 report from the Society for Industrial and Applied Mathematics (SIAM) on industrial mathematics:

Roughly half of all mathematical scientists hired into business and industry are statisticians. The second-largest group by academic specialty is applied mathematics. Compared to the 1996 survey, fewer graduates reported “modeling and simulation” as an important academic specialty for their jobs, and more reported “statistics.” Programming and computer skills continue to be the most important technical skill that new hires bring to their jobs.

By separating statistics from applied mathematics, the SIAM report follows a certain tradition, caused in

part by institutional boundaries, such as the existence of separate statistics departments in universities. This distinction is also partly followed in the present volume and in this article, although there is no doubt about the crucial role of probability and statistics in applications. For example, one need only consider the Monte Carlo method—notably developed at Los Alamos in the 1940s by Stanislaw Ulam and von Neumann, and continued by Nicholas Metropolis—which is now used in a wide variety of different contexts including numerical integration, optimization, and inverse problems. In addition, the combination of stochastics and modeling in biological and physical applications has had a philosophical dimension, contributing to the abandonment of rigid causality in science, e.g., through Karl Pearson’s correlation coefficient and Werner Heisenberg’s uncertainty principle. However, by the end of the 1960s the limitations of stochastics in helping us to understand the nature of disorder had become apparent, particularly in connection with the study of complex (“chaotic”) dynamical systems. Nevertheless, stochastics continues to play an important role in the development of big theories with relevance for applications, including statistical models for weather forecasting.

1.1 Further Themes and Some Limitations

Putting stochastics on the sidelines is but one of several limitations of this article—limitations that are the result of a lack of space, a lack of distance, and more general methodological considerations. A further thematic restriction concerns industrial mathematics, which figures separately from applied mathematics in the very name of SIAM, although there are obvious connections between the two, in particular with respect to training and in developing attitudes toward applications. Knowing that industrial mathematics has changed, and above all expanded, from its origins in the early twentieth century to move beyond its purely industrial context, these connections become even clearer. Industrial mathematics is, today, an established subdiscipline, loosely described as the modeling of problems of direct and immediate interest to industry, performed partly in industrial surroundings and partly in academic ones.

The history of mathematical instruments, including both numerical and geometrical devices, and their underlying mathematical principles is another topic we have had to leave out almost completely. Some discussion of the history of mathematical table projects

is the farthest we reach in this respect. This limitation also applies to the technological basis of modern computing and the development of software technology (covered by Cortada's excellent bibliography), which has provided, and continues to provide, an important stimulus for the development (and funding) of applied mathematics. In 2000, in the *Journal of Computational and Applied Mathematics*, it was estimated that of the increase in computational power, half should be attributed to improved algorithms and half should be attributed to the increase in computational hardware speeds. Computing technology has continued to advance rapidly, and companies are making more and more aggressive use of HIGH-PERFORMANCE COMPUTING [VII.12]

A detailed discussion of the fields of application of mathematics themselves—be it in (pure) mathematics, the sciences, engineering, economics and finance, industry, or the military—is absent from this article for a number of reasons, both practical and methodological, above all the huge variation of specific conditions in these fields.

This particularly affects the role of mathematics in the military, to which we will devote only scattered remarks and no systematic discussion. While there are still considerable lacunae in the literature on mathematics during World War I (although some of these have been filled by publications prepared for the centenary), there is more to be found in print about mathematics in World War II, not least because of the increased role of that discipline in it. (We recommend Bool-Bavnbek and Høyrup (2003) as a good place to start to find out more than is covered in our article.)

Another topic that deserves broader coverage than is possible here is the history of philosophical reflection about mathematical applications. This is particularly true for the notion of “mathematical modeling” taken in the sense of problem formulation. According to the *Oxford Encyclopedic Dictionary* (1996), the new notion of a mathematical model was used first in a statistical context in 1901. At about the same time, the French physicist and philosopher Pierre Duhem accused British physicists of still using the term “model” only in the older and narrower sense of material, mechanical, or visualizable models. Duhem therefore preferred the word “analogy” for expressing the relationship between a theory and some other set of statements. Particularly with the upswing of “mathematical modeling” since the 1980s, a broad literature, often with a philosophical bent, has discussed

the specificity of mathematics as a language, as an abstract unifier and a source of concepts and principles for various scientific and societal domains of application. Another (though not unrelated) development in the philosophy of applied mathematics concerns the growing importance of algorithmic aspects within mathematics as a whole. It was no coincidence that in the 1980s, with the rise of scientific computing, several “maverick” philosophers of mathematics, such as Philip Kitcher and Thomas Tymoczko, entered the scene. They introduced the notion of “mathematical practice,” by which they meant more than simply applications. One of the features of the maverick tradition was the polemic against the ambitions of mathematical logic to be a canon for the philosophy of mathematics, ambitions that have dominated much of the philosophy of mathematics in the twentieth century. The change was inspired by the work of both those mathematicians (such as Philip Davis and Reuben Hersh) and those philosophers (including Imre Lakatos and David Corfield) who were primarily interested in the actual working process of mathematicians, or what they sometimes called “real mathematics.” Meanwhile, the philosophical discussion of mathematical practice has been professionalized and reconnected to the foundationalist tradition. It usually avoids premature discussion of “big questions” such as “Why is mathematics applicable?” or “Is the growth of mathematics rational?” restricting its efforts to themes of mathematical practice in a broader sense, like visualization, explanation, purity of methods, philosophical aspects of the uses of computer science in mathematics, and so on. An overview of the more recent developments in the philosophy of mathematical practice is given in the introduction to Mancosu (2008).

Unfortunately, there is also little space for biographical detail in this article, and thus no bow can be given to the great historical heroes of applied mathematics, such as Archimedes, Ptolemy, Newton, Euler, Laplace, and Gauss. Nor is there room to report on the conversions of pure mathematicians into applied mathematicians, such as those undergone by Alexander Ostrowski, John von Neumann, Solomon Lefschetz, Ralph Fowler, Garrett Birkhoff, and David Mumford, all personal trajectories that paralleled the global development of mathematics. In any case, any systematic inclusion of biographies could not be restricted to mathematicians, considering the term in its narrowest sense. In an influential report on industrial mathematics in the *American Mathematical Monthly* of

1941, Thornton Fry spoke about a “contrast between the ubiquity of mathematics and the fewness of the mathematicians.” Indeed, historically, engineers such as Theodore von Kármán, Richard von Mises, Ludwig Prandtl, and Oliver Heaviside; physicists such as Walter Ritz, Aleksandr Andronov, Cornelius Lanczos, and Werner Romberg; and industrial mathematicians such as Balthasar van der Pol have, by any measure, made significant contributions to applied mathematics. In addition, several pioneers of applied mathematics, such as Gaspard Monge, Felix Klein, Mauro Picone, Vladimir Steklov, Vannevar Bush, and John von Neumann, actively used political connections. The actions of nonscientists, and particularly politicians, have also therefore played a part in the development of the subject. For a full history of applied mathematics the concrete interplay of the interests of mathematicians, physicists, engineers, the military, industrialists, politicians, and other appliers of mathematics would have to be analyzed, but this is a task that goes well beyond the scope of this article.

In general, the historical origin of individual notions or methods of applied mathematics, which often have a history spanning several centuries, will not be traced here; pertinent historical information is often included in the specialized articles elsewhere in this volume. By and large, then, this article will focus on the broader methodological trends and the institutional advances that have occurred in applied mathematics since the early nineteenth century.

1.2 Periodization

From the point of view of applications, the history of mathematics can be roughly divided into five main periods that reveal five qualitatively different levels of applied mathematics, the first two of which can be considered as belonging to the prehistory of the subject.

- (1) **ca. 4000 B.C.E.–1400 C.E.** Emergence of mathematical thinking, and establishment of theoretical mathematics with spontaneous applications.
- (2) **ca. 1400–1800.** Period of “mixed mathematics” centered on the Scientific Revolution of the seventeenth century and including “rational mechanics” of the eighteenth century (dominated by Euler).
- (3) **1800–1890.** Applied mathematics between the Industrial Revolution and the start of what is often called the second industrial (or scientific-technical) revolution. Gradual establishment of both the term

and the notion of “applied mathematics.” France and Britain dominate applied mathematics, while Germany focuses more on pure.

- (4) **1890–1945.** The so-called resurgence of applications and increasing internationalization of mathematics. The rise of new fields of application (electrical communication, aviation, economics, biology, psychology), and the development of new methods, particularly those related to mathematical modeling and statistics.
- (5) **1945–2000.** Modern internationalized applied mathematics after World War II, inextricably linked with industrial mathematics and high-speed digital computing, led largely by the United States and the Soviet Union, the new mathematical superpowers.

Arguably, one could single out at least two additional subperiods of applied mathematics: the eighteenth century, with Euler’s “rational mechanics,” and the technological revolution of the present age accompanied by the rise of computer science since the 1980s. However, in the first of these subperiods, which will be described in some detail below, mathematics as a discipline was still not yet fully established, either institutionally or with respect to its goals and values, so distinguishing between her pure and applied aspects is not straightforward. As to the second of the two subperiods, we believe that these events are so recent that they escape an adequate historical description. Moreover, World War II had such strong repercussions on mathematics as a whole—particularly on institutionalization (journals, institutes, professionalization), on material underpinning (state funding, computers, industry), and not least on the massive migration of mathematicians to the United States—that it can be considered a watershed in the worldwide development of both pure and applied mathematics. However, the dramatic prediction by James C. Frauenthal—in an editorial of *SIAM News* in 1980 on what he considered the “revolutionary” change in applied mathematics brought about by the invention of the computer—that by 2025 “in only a few places will there remain centers for research in pure mathematics as we know it today” seems premature.

2 Mathematics before the Industrial Revolution

Since the emergence of mathematical thinking around 4000 B.C.E., through antiquity and up to the start of the Renaissance (ca. 1400 C.E.), and embracing the cultures

of Mesopotamia, Egypt, and ancient Greece, as well as those of China, India, the Americas, and the Islamic-Arabic world, applications arose as a result of various societal, technical, philosophical, and religious needs. Well before the emergence of the Greek notion of a mathematical proof around 500 B.C.E., areas of application of mathematics in various cultures included accountancy, agricultural surveying, teaching at scribal schools, religious ceremonies, and (somewhat later) astronomy. Among the methods used were practical arithmetic, basic geometry, elementary combinatorics, approximations (e.g., π), and solving quadratic equations. Instruments included simple measuring and calculation devices: measuring rods, compasses, scales, knotted ropes, counting rods, abaci, etc.

The six classical sciences—geometry, arithmetic, astronomy, music, statics, and optics—existed from the time of Greek antiquity and were based on mathematical theory, with the Greek word “mathemata” broadly referring to anything teachable and learnable. The first four of the classical sciences constituted the quadrivium within the Pythagorean-Platonic tradition. The theories of musical harmony (as applied arithmetic) and astronomy (as applied geometry) can thus be considered the two historically earliest branches of applied mathematics. The two outstanding applied mathematicians of Greek antiquity were Archimedes (statics, hydrostatics, mechanics) and Ptolemy (astronomy, optics, geography). Since the early Middle Ages, the Computus (Latin for computation)—the calculation of the date of Easter in terms of first the Julian calendar and later the Gregorian calendar—was considered to be the most important computation in Europe. In medieval times, particularly from the seventh century, the development of algebraic and calculative techniques and of trigonometry in the hands of Islamic and Indian mathematicians constituted considerable theoretical progress and a basis for further applications, with significant consequences for European mathematics. Particularly notable was the *Liber Abaci* (1202) of Leonardo of Pisa (Fibonacci), which heralded the gradual introduction of the decimal positional system into Europe, one of the broadest and most important applications of mathematics during the period. Chinese mathematics remained more isolated from other cultures at the time and is in need of further historical investigation, as are some developments within Christian scholastics. In spite of their relative fewness and their thematic restrictions, we consider the early applications to be a deep and historically important root for the emergence

of theoretical mathematics and not as a mere follow-up of the latter.

From the beginning of the fifteenth century to the end of the eighteenth century, applications of mathematics were successively based on the dissemination of the decimal system, the rise of symbolic algebra, the theory of perspective, functional thinking (Descartes's coordinates), the calculus, and natural philosophy (physics). The teaching of practical arithmetic, including the decimal system, by professional “reckoning masters,” such as the German Adam Ries in the sixteenth century, remained on the agenda for several centuries. Meanwhile, the first systematic discussion of decimal fractions appeared in a book by the Dutch engineer Simon Stevin in 1585.

During this period, and connected to the new demands of society, there emerged various hybrid disciplines combining elements of mathematics and engineering: architecture, ballistics, navigation, dynamics, hydraulics, and so on. Their origins can be traced back, at least in part, to medieval times. For example, partly as a result of fourteenth-century scholastic analysis, the subject of local motion was separated from the traditional philosophical problem of general qualitative change, thus becoming a subject of study in its own right.

The term “mixed mathematics” as a catch-all for the various hybrid disciplines seems to have been introduced by the Italian Marsilio Ficino during the fifteenth century in his commentary on Plato's *Republic*. It was first used in English by Francis Bacon in 1605. In his *Mathematicall Praeface* to the first English translation of Euclid's *Elements* (1570), John Dee set out a “ground-plat” or plan of the “sciences and artes mathematicall,” which included astronomy and astrology. Due to the broad meaning of the original Greek word, the Latin name “mathematicus” was used for almost every European practitioner or artisan within one of these hybrid disciplines. As late as 1716, the loose use of “mathematicus” was deplored by the philosopher Christian Wolff (a follower of Leibniz) in his *Mathematisches Lexicon*, an influential dictionary of mathematics, because in his opinion it diminished the role of mathematics.

The emergence of the new Baconian sciences (magnetism, electricity, chemistry, etc.)—which went beyond mixed mathematics and were even partially opposed to the mathematical spirit of the classical sciences (Bacon's acknowledgment of the future of mixed mathematics, as expressed in the epigraph, was coupled with a certain distrust of pure mathematics)—signaled

the rise of systematic experimental methods. The latter reached a symbiosis with mixed mathematics in the hands of Galileo, Descartes, Huygens, Newton, and other pioneers of the Scientific Revolution. In their work, the guiding thought was of a fundamental connection between mathematical and mechanical exactness. However, a certain division between the tradition of mathematics and of the Baconian sciences remained palpable until the nineteenth century.

While talk about “applications of mathematics” was common in the English language from at least the seventeenth century (in, for example, the work of Isaac Barrow and others), the term “applied mathematics” (with “applied” as an adjective), as the successor to “mixed mathematics,” was apparently not introduced prior to the eighteenth century. The name seems to have appeared first in German as “angebrachte Mathematik” (“angebracht” having roughly the meaning of “applied,” if a bit more in the sense of “attached”) in Wolff’s dictionary of 1716. In Latin it appeared two years later, in Johann Friedrich Weidler’s textbook *Institutiones mathematicae* (1718), as “Mathesis applicata quam nonnulli mixta appellant.” In his *Universallexicon* (1731–54), Johann Heinrich Zedler followed

Figure 3 A. G. Kästner, *Anfangsgründe der Angewandten Mathematik* (1759).

Wolff and gave a detailed classification of the parts of “angebrachte Mathematik” (figure 2).

Finally, “applied mathematics” figures for the first time on the title page of a book as “Angewandte Mathematik” in the second volume of Abraham Gotthelf Kästner’s mathematical textbook *Mathematische Anfangsgründe* (“mathematical elements”) of 1759 (figure 3). The German philosopher Kant used the term “applied mathematics” in his Berlin *Preisschrift* of 1763/64. The latter was translated into English in 1798 and, according to the *Oxford English Dictionary*, it is in this translation that the term makes its first appearance in English. Meanwhile, “mixed mathematics” (“mathématiques mixtes”) was still in use in French, appearing in the famous *Encyclopédie* of Diderot and d’Alembert (1750) (figure 1), and even in the second edition of J.-E. Montucla’s *Histoire des Mathématiques* (1798–1802).

There is no doubt that the period of the Enlightenment of the eighteenth century deserves a special place in a history of applied mathematics, particularly as a bridge—via so-called rational mechanics,

which uses the invention of the calculus (Newton/Leibniz)—between the natural philosophy of the seventeenth century and the mathematical engineering and physics of the nineteenth and twentieth centuries. There are six principal actors here: three from the famous Swiss Bernoulli family (the brothers Jakob (James) and Johann (John), and Daniel, the son of the latter), Alexis-Claude Clairaut, Jean d'Alembert, and, by far the most prolific of all, Leonhard Euler. The dominating role of applied mathematics at the time is perhaps most convincingly illustrated in the themes of the prize competitions run by the prominent academies of science, especially the Paris Academy. The topics set in Paris included the optimum arrangement of ship masts (1727), the motion of the moon (1764/68), the motion of the satellites of Jupiter (1766), the three-body problem (1770/72), the secular perturbations of the moon (1774), the perturbations of comet orbits (1776/78/80), the perturbation of the orbit of Pallas (in the beginning of the nineteenth century), the question of heat conduction (1810/12), and the propagation of sound waves in liquids (1816). Only occasionally, and mostly in a later period, would questions of pure mathematics be posed in these competitions, examples being questions on the theory of polyhedra (1810) and the Fermat problem (1816). Euler himself, who won the Paris prize twelve times, subscribed to the utilitarian mood of Enlightenment when in 1741 he wrote his essay "On the utility of higher mathematics," first published only in 1847. According to Goldstine (a pioneer and historian of numerical analysis):

Euler did at least the ground work on virtually every topic in modern numerical analysis. This work included the basic notions for the numerical integration of differential equations. Moreover, his development of lunar theory made possible the accurate calculation of the moon's position and the founding of the Nautical Almanac in Great Britain.

Goldstine (1977)

A typical example of Euler's influence can be found in Carl Runge's first two articles on the numerical solution of differential equations, which appeared in the *Mathematische Annalen* in 1894 and 1895. The second article connects explicitly to Euler's *Introductio in Analysis Infinitorum* (1748), in which one finds the first example of an approximation by a polygonal chain. Of Euler's more than 800 publications, two-thirds belong to mechanics of a varying degree of abstractness. The noted and controversially discussed continuum mechanist and historian Clifford Truesdell has traced and

described the innovations that Euler, d'Alembert, and the Bernoullis brought into Newtonian mechanics, in terms of both modeling and mathematical methods, relying on experience but not undertaking systematic experiments. In an apparent allusion to the philosophical age of reason, he called these innovations "rational mechanics," a term that was occasionally used at the time in a broader sense but by which Truesdell meant more specifically mathematical mechanics (Truesdell 1960). Rational mechanics, as Newton had used the term in the preface to his *Principia* (1687), was one of two traditions of mechanics already known in Greek antiquity, namely the one that "proceeds accurately by demonstration" (the other being practical mechanics). For Newton, rational mechanics in this sense was the core of natural philosophy. Truesdell opposed the view (propounded, for instance, by the positivist philosopher Ernst Mach) that Euler and like-minded mathematicians simply systematically applied the new calculus of Newton and Leibniz to mechanic and thus did not contribute anything substantial to theoretical mechanics itself. Today, historians usually stress the conceptual progress both in mathematics (e.g., by removing certain geometric elements from the Leibnizian calculus) and physics (e.g., exploring in detail the relation between force and motion) accomplished in the work of Euler. It is probably this role of Euler as a "mathematical physicist," combined with the lack of immediate usefulness of Euler's rational mechanics, that caused Truesdell in 1960 to declare that the latter was not applied mathematics.

Among the new fields of mathematics was, for instance, partial differential equations (of which the first example appears in a work by Euler of 1734), which were successfully applied by Euler and d'Alembert in the second half of the 1740s in the analysis of the vibrating string. In his *Methodus inveniendi* of 1744, Euler picked up on the tradition of solving the PROBLEM OF THE BRACHISTOCHRONE [IV.6 §1] in the work of the Bernoulli brothers. He set standards in the calculus of variations developed later by Joseph Louis Lagrange and others. As an extension of Daniel Bernoulli's *Hydrodynamica* of 1738, and partly influenced by d'Alembert, Euler's equations of fluid dynamics (1755), which did not yet have a term for viscosity, remained a challenge for generations of mathematicians to come, not least due to their nonlinearity. Euler, like d'Alembert before him, was unable to produce from his equations of fluid dynamics a single new result fit for comparison with experiment.

In our opinion (deviating slightly from Truesdell), rational mechanics, in hindsight, bears almost all the characteristics of applied mathematics in the modern sense. At the time, however, in a predominantly utilitarian environment, it was the pinnacle of mathematics. It was then rarely counted as mixed mathematics, notwithstanding some occasional remarks by d'Alembert. The term mixed mathematics was more frequently used for the mathematically less advanced engineering mechanics (Bernard Forest de Bélidor and Charles-Augustin de Coulomb, etc.) of the time and for other fields of application.

Toward the end of the eighteenth century rational mechanics was somewhat narrowed down, both thematically and with respect to possible applications (although still including continuum mechanics), by further mathematical formalization, particularly at the hands of Lagrange, Euler's successor in Berlin, whose *Méchanique Analytique* first appeared in 1788. The towering figure of Pierre Simon Laplace in Paris—with his pioneering work since the late 1770s in celestial and terrestrial mechanics and in probability theory—foreshadowed much of the important French work in applied mathematics, such as that done by Poisson, Fourier, Cauchy, and others in the century that followed. To Laplace (generating functions, difference equations) and to his great younger contemporary Carl Friedrich Gauss in Göttingen (numerical integration, elimination, least-squares method) we owe much of the foundations of future numerical analysis. Parts of their work overlapped (interpolation), while parts were supplemented by Adrien-Marie Legendre (least-squares method), details of which can be traced from Goldstine's *A History of Numerical Analysis*.

3 Applied Mathematics in the Nineteenth Century

Around 1800, in the age of the Industrial Revolution and of continued nation building, state funding and political and ideological support (revolution in France, Neo-Humanism in Germany) led (mainly through teaching and journals) to a new level of recognition for mathematics as a discipline. The older bifurcation of pure/mixed mathematics was replaced in France and Germany (although not yet in England) by that of pure/applied. The difference was mainly that before 1800 only mixed mathematics together with rational mechanics had the support of patrons, while now, around 1800, the whole of mathematics was beginning

to be supported and recognized. Somewhat paradoxically, then, in spite of the general importance of the Industrial Revolution as a historical background, it is pure mathematics that increasingly gets systematic public support for the first time. Indeed, for most of the nineteenth century, mathematics would not be strongly represented in either engineering or industrial environments.

The foundation of the École Polytechnique (EP) in Paris in 1794 is a good point of reference for the beginning of our third period. The EP, where military and civil engineers were trained, became the leading and “most mathematical” institution within a system of technical education. This included several “schools of applications,” such as the École des Mines and the École Nationale des Ponts et Chaussées, to which the students of the EP proceeded. The EP became an example to be emulated by many technical colleges, particularly in German-speaking regions, throughout the nineteenth century. The most influential mathematician in the early history of the EP was Gaspard Monge, and it was in accordance with his ideas that mathematics became one of the bases of the EP curriculum. In 1795, in the introduction to his lectures on descriptive geometry, the theory that became the “language of the engineer” for more than a century, Monge wrote:

In order to reduce the dependence of the French nation on foreign industry one has to direct public education to those subjects which require precision.

Monge's aspirations for a use of higher mathematics in industrial production remained largely unfulfilled at the time, except for the use of descriptive geometry. However, developments in industry and in educational systems led to a stronger focus on the criteria for precision and exactitude in the sciences (most notably in academic physics) and in engineering, preparing the ground for an increased use of mathematics in these fields of application at the beginning of the twentieth century. In fact, it could be argued that it required a logical consolidation and a more theoretical phase of the development of mathematical analysis before a new phase of more sophisticated applied mathematics could set in.

The first concrete institutional confirmation of the notion of “applied mathematics” was the appearance of the term in the names of journals. Again, the Germans were quicker than the French here. Two short-lived journals cofounded by the influential combinatorialist Carl Friedrich Hindenburg were the *Leipziger*

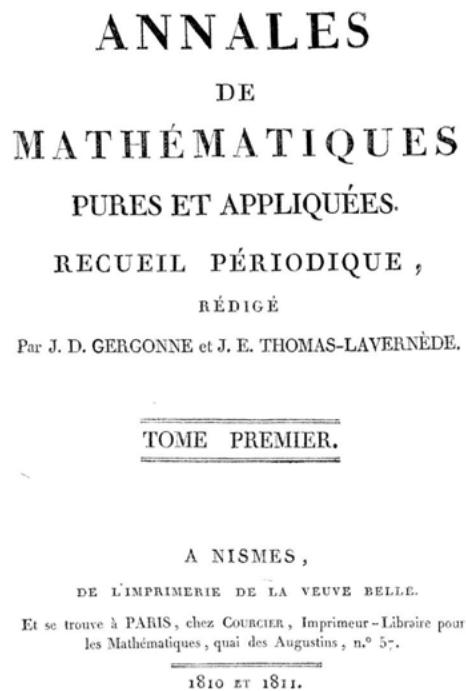

Figure 4 Gergonne's *Annales de Mathématiques Pures et Appliquées* (1810–11).

Magazin für reine und angewandte Mathematik (1786–89) and the *Archiv für reine und angewandte Mathematik* (1795–99). A somewhat longer career was had by *Annales de Mathématiques Pures et Appliquées*, founded by Joseph Diaz Gergonne in 1810 (figure 4). While this journal survived only until 1832, the German *Journal für die reine und angewandte Mathematik* (which, according to the preface by its founder August Leopold Crelle in 1826, was largely modeled after Gergonne's journal) is still extant today. This is true too of the French *Journal de Mathématiques Pures et Appliquées*, founded by Joseph Liouville in 1836, and of the Italian *Annali di Matematica Pura ed Applicata*, launched by Francesco Brioschi and Barnaba Tortolini in Italy in 1858 as an immediate successor to the *Annali di Scienze Matematiche e Fisiche*. On the other hand, James Joseph Sylvester's *Quarterly Journal of Pure and Applied Mathematics*, which was founded in 1855, survived only until 1927.

The inclusion of “applied mathematics” in the names of these nineteenth-century journals did not necessarily guarantee a strong representation of applied topics,

however, either in the journals themselves or in the mathematical culture at large. But neither were these journals the only outlets for articles on applied topics. Journals associated with national academies, such as the *Philosophical Transactions of the Royal Society*, carried articles on applied topics, while the *Philosophical Magazine* (launched in 1798) was the journal of choice for several leading nineteenth-century British applied mathematicians.

This was also the period in which positions explicitly devoted to applications were created at universities. In Norway, which had just introduced a constitution and was emancipating itself from Danish rule, Christopher Hansteen's position as “lecturer for applied mathematics” (“Lector i den anvendte Mathematik”) at the newly founded university in Christiania was expressly justified in May 1814 by “the broad scope of applied mathematics and its importance for Norway.” In 1815 Hansteen was promoted to “Professor Matheseos applicatae.”

Throughout the nineteenth century, the mathematization of mechanics continued largely in the tradition of Lagrange's analytical mechanics, with a division of labor between physicists and mathematicians such as William Rowan Hamilton and Carl Jacobi, arguably neglecting some of the topics and insights of Euler's rational mechanics, particularly in continuum mechanics. However, from the 1820s, although the EP still gave preference to analytical mechanics in its courses, there were efforts among the professors there, and at the more practically oriented French engineering schools (“écoles d'application”), to develop a mechanics for the special needs of engineers, a discipline that would today be called technical mechanics. The latter drew strongly on traditions in mixed mathematics, such as the work of de Bélidor in hydraulics from the 1730s to the 1750s and that of de Coulomb in mechanics and electromagnetism from the 1780s onward. It found its first energetic proponents in Claude Navier, Jean Victor Poncelet, and Gaspard Gustave de Coriolis.

Around 1820, Poncelet separately developed his projective geometry, which became part of the mathematically rather sophisticated engineering education at several continental technical colleges. It led to methods such as graphical statics, founded by the German-Swiss Carl Culmann in the middle of the century, with applications in crystallography and civil engineering, the latter exemplified by the construction of the Eiffel Tower in 1889. Also in the 1820s, influenced by Euler's hydrodynamics and possibly by Navier's work in engineering,

Augustin-Louis Cauchy was the first to base the theory of elasticity on a general definition of internal stresses. The work of Cauchy, who was at the same time known for his efforts to introduce rigor into analysis, underscores the dominance of the French in both pure and applied mathematics during the early nineteenth century, with the singular work of Gauss in Göttingen being the only notable exception.

In England the development of both pure and applied mathematics during the nineteenth century showed marked differences from that in Continental Europe. One of the goals of the short-lived Analytical Society (1812–19), founded in Cambridge by Charles Babbage and others, was to promote Leibnizian calculus over Newtonian calculus, or, in Babbage's words, to promote "The Principles of pure D-ism in opposition to the Dotage of the University." The members of the Analytical Society were impressed by the new rigor in analysis achieved in France, especially in the work of Lagrange, and lobbied for a change in teaching and research in Cambridge mathematics, and in particular in the examinations of the Mathematical Tripos, which were very much based on traditional mixed and physical mathematics, as well as on Euclid's *Elements*. If anything, though, this aspect of the French influence led away from applications and toward a gradual purification of British mathematics.

Babbage was impressed by the French mathematical tables project directed by Gaspard de Prony at the end of the eighteenth century. In a similar vein to Monge before him, Babbage pointed to increased competition between nations in the age of industrialization, and he stressed the need for the development of calculating techniques. In *On the Economy of Machinery and Manufactures* (1832) he wrote:

It is the science of *calculation*,—which becomes continually more necessary at each step of our progress, and which must ultimately govern the whole of the applications of science to the arts of life.

Another (at least indirect) impact of the Industrial Revolution on mathematics was the Russian Pafnuty Lvovich Chebyshev's study of James Watt's steam engine, in particular of the "governor," the theory of which proved to be a stimulus for the notion of feedback in control theory, and the modern theory of servomechanisms. Chebyshev's interest in the technical mechanics of links was also one of the stimuli for his studies concerning mathematical approximation theory in the 1850s. In addition, he was impressed with

Poncelet's technical mechanics. As a result, and due to Chebyshev's great influence within Russian mathematics, applied mathematics remained much more part of mainstream mathematics in Russia during the latter half of the nineteenth century than it was in other parts of Europe, especially in Germany.

In the middle of the nineteenth century, the French engineering schools, in particular the EP, lost their predominant position in mathematics, due to slow industrial development in France and problems with the overcentralized and elitist educational system. The lead was taken by the German-speaking technical colleges ("Technische Hochschulen") in Prague, Vienna, Karlsruhe, and Zurich, in particular with respect to the mathematization of the engineering sciences. This was true for their emulation of the general axiomatic spirit of mathematics even more than for their concern for the actual mathematical details. Ferdinand Redtenbacher (in his analytical machine theory (1852)) and Franz Reuleaux (in his kinematics (1875)) aimed at "designing invention and construction deductively." So convinced of the important future role of mathematics were leading engineers at the Technische Hochschulen that they supported the appointment of academically trained mathematicians from the classical universities. In this way pure mathematicians, such as Richard Dedekind, Alfred Clebsch, and later Felix Klein, assumed positions at Technische Hochschulen in which they were responsible for the education of engineers.

In parallel, and also from the middle of the nineteenth century, mathematics at the leading German universities that did not have engineering departments increasingly developed into a pure science, detached from practical applications. Supported by the ideology of "Neo-Humanism" within a politically unmodernized environment, the discipline's educational goal (and its legitimization in society) was the training of high school teachers, who during their studies were often introduced to the frontiers of recent (pure) mathematical research. The result of this was that professors at the Technische Hochschulen who were hired from the traditional universities were not really prepared for training engineers. In the long run, the strategy of appointing university mathematicians backfired and this, together with general controversies about the social status of technical schools, led to the so-called anti-mathematical movement of engineers in Germany in the 1890s.

British and Irish applied mathematics, in the sense of mathematical physics, remained strong through the

nineteenth century, with work by George Green, George Stokes, William Rowan Hamilton, James Clerk Maxwell, William Thomson (Lord Kelvin), Lord Rayleigh, William Rankine, Oliver Heaviside, Karl Pearson, and others, while in the works of James Joseph Sylvester and Arthur Cayley in the 1850s, the foundations of modern matrix theory were laid. That being said, there was no systematic, state-supported technical or engineering education in the British system until late in the nineteenth century. What was taught in this respect at schools and traditional universities was increasingly questioned by engineers such as John Perry (see below), particularly with respect to the mathematics involved. In England the term “mixed mathematics” was occasionally used interchangeably with “applied mathematics” up until the end of the century, a prominent example of this being the tribute by Richard Walker (then president of the London Mathematical Society) to Lord Rayleigh on winning the society’s De Morgan Medal in 1890.

Applications of mathematics also featured among the activities of the British Association for the Advancement of Science, which, in 1871, formed a Mathematical Tables Committee for both cataloguing and producing numerical tables; the committee lasted, with varying levels of intensity, until 1948, when the Royal Society took over. A prime example of joint enterprise between pure and applied mathematicians—the original committee consisted of Cayley, Henry Smith, Stokes, and Thomson—the project catered for all tastes, its products including both factor tables and Bessel function tables, among others. As J. W. L. Glaisher, the project secretary, wrote in 1873: “one of the most valuable uses of numerical tables is that they connect mathematics and physics, and enable the extension of the former to bear fruit practically in aiding the advance of the latter.” The project was finally dissolved in 1965, with some of the greatest British mathematicians, both pure and applied, having been active in its work.

With the upswing of electrical engineering, more sophisticated mathematics (operational calculus, complex numbers, vectors) finally entered industry in around 1890, e.g., through the work of Heaviside in England and of the German immigrant Charles P. Steinmetz in the United States. Mechanical engineering, on the other hand, e.g., in the construction of turbines, remained free of advanced mathematics until well into the twentieth century.

It was also not until the end of the nineteenth century that applied mathematics finally began to lose its

almost exclusive bond to mathematical physics and mechanics; new fields of application, new methods such as statistics, and new professions such as actuarial and industrial mathematicians were largely matters for the twentieth century.

This change is nicely captured through the example of the English applied mathematician Karl Pearson. In his philosophical book *Grammar of Science* (1892), Pearson, who at the time was mainly known for his work on elasticity, defined as the “topic of Applied Mathematics . . . the process of analyzing inorganic phenomena by aid of ideal elementary motions.” At the time Pearson was already working on biometrics, the subject that would lead him to found, together with Francis Galton, the journal *Biometrika* in 1901. Therefore, although Pearson was effectively extending the realm of applications of mathematics to the statistical analysis of biological (i.e., organic) phenomena, he apparently did not consider what he was doing to be applied mathematics.

4 The “Resurgence of Applications” and New Developments up to World War II

From the 1890s, the University of Göttingen (pure) mathematician Felix Klein saw the importance of taking the diverging interests of the engineering professors at technical colleges and those of German university mathematicians into account. Not only did different professions (teaching and engineering) require different education, but the gradual emergence of industrial mathematics had to be considered as well. Klein recognized the need for reform, including in teaching at high school level, and he developed Göttingen into a center of mathematics and the exact sciences (figure 5). Chairs for applied mathematics and applied mechanics were created there in 1904, with Carl Runge and Ludwig Prandtl being the first appointees. Meanwhile, from 1901, and under the editorship of Runge, the transformation of *Zeitschrift für Mathematik und Physik* into a journal exclusively for applied mathematics had begun. These events in Germany, contrasting with those of the period before, led to talk about a “resurgence of applications” (“Wiederhervorkommen der Anwendungen”).

From 1898 and for several decades afterward, the famous German multivolume *Encyclopedia of the Mathematical Sciences including Their Applications* was edited by Klein together with Walther von Dyck and Arnold Sommerfeld, both from Munich, and others.

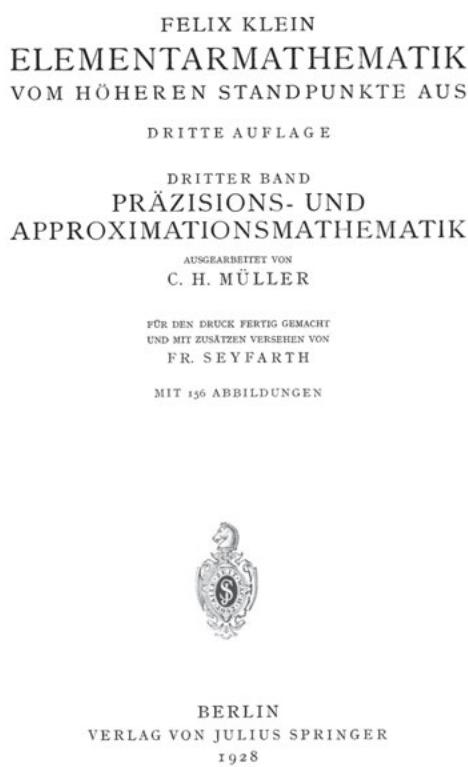

Figure 5 F. Klein, *Präzisions- und Approximationsmathematik* (1928). Posthumous publication of Klein's 1901 lectures in Göttingen where he tried to differentiate between a mathematics of precision and one of approximation.

The articles in it, all written in German but including authors from France and Britain, such as Paul Painlevé and Edmund Taylor Whittaker, contain valuable historical references that are still worth consulting today. “Applications” as emphasized in the title and in the program of the *Encyclopedia* meant areas of application, such as mechanics, electricity, optics, and geodesy. The articles were assigned to volumes IV–VI, which were in themselves divided into several voluminous books each. There were also articles on mechanical engineering, such as those by von Mises and von Kármán. However, topics that would today be classified as core subjects of applied mathematics—such as numerical calculation (Rudolph Mehmke), difference equations (Dmitri Seliwanoff), and interpolation and error compensation (both by Julius Bauschinger)—appeared as appendices within volume I, which was

devoted to pure mathematics (arithmetic, algebra, and probability). Runge's contribution on “separation and approximation of roots” (1899) was subsumed under “algebra.”

Klein also succeeded in introducing a state examination in applied mathematics for mathematics teachers, which focused on numerical methods, geodesy, statistics, and astronomy. In addition, he inspired educational reform of mathematics in high schools that he designed around the notions of “functional thinking” and “intuition,” thereby trying to counteract the overly logical and arithmetical tendencies that had until then permeated mathematics education. Klein and his allies insisted on taking into account international developments in teaching and research, for instance by initiating a series of comparative international reports on mathematical education; these reports in turn led to the creation of what has now become the International Commission on Mathematical Instruction (ICMI). The *Encyclopedia* also provided evidence of the increasing significance of the international dimension. In his “introductory report” in 1904, von Dyck stressed the importance for the project of securing foreign authors in applied mathematics. Later, a French translation of the *Encyclopedia* began to appear in a considerably enlarged version, although the project was never completed due to the outbreak of World War I.

Around 1900, reform movements reacting to problems in mathematics education similar to those in Germany existed in almost all industrialized nations. In England, the engineer John Perry had initiated a reform of engineering education in the 1890s, and this reform played into the ongoing critical discussions of the antiquated Cambridge Mathematical Tripos examinations and their traditional reliance on Euclid. The “Perry Movement” was noticed in Germany and in the United States. On the pages of *Science* in 1903, the founding father of modern American mathematics, Eliakim Hastings Moore, himself very much a pure mathematician, declared himself to be in “agreement with Perry” and proposed a “laboratory method of instruction in mathematics and physics.” At about the same time (1905), similar ideas “de créer de vrais laboratoires de Mathématiques” were proposed by Émile Borel in France. In Edinburgh, Whittaker instituted a “Mathematical Laboratory” in 1913 and later, together with George Robinson, published the influential *The Calculus of Observations: A Treatise on Numerical Mathematics* (1924), which derived from Whittaker's lectures given in the Mathematical Laboratory. In Germany, the

term “Mathematisches Praktikum” was most often used to describe laboratory work in mathematics. Common to these efforts was the aim to foster among students practical abilities in calculation and drawing, extending beyond mere theoretical mathematical knowledge.

Along with the German *Encyclopedia* and Whittaker and Robinson’s *Calculus of Observations*, several influential textbooks on applied mathematics, on both numerical and geometrical methods, appeared in various countries at the end of the nineteenth century and into the first decades of the new century, preparing the ground for future advances. Horace Lamb’s *Hydrodynamics* (1895), an expanded version of his 1879 text deriving from his Cambridge course, and Augustus Love’s *Elasticity* (1892) became staple fare for mathematicians in Britain, each running into several editions. In France Maurice d’Ocagne published his *Traité de Nomographie* (1899), which was initially developed for civil engineering (particularly railway and bridge construction) but was also used in the study of ballistics during World War I and thereafter. Carl Runge’s lectures at Columbia University in New York (1909/10) were published as *Graphical Methods* in the United States in 1912, and appeared in a German translation in 1914. Runge’s joint book with Hermann König *Vorlesungen über numerisches Rechnen* (1924), part of Springer’s *Grundlehren der mathematischen Wissenschaften* series, became a classic. Published that same year, and in the same series, *Differenzenrechnung* by the Dane Niels Erik Nörlund became “the standard treatise on new aspects of difference equations.” This was stated in a report to the American National Research Council on *Numerical Integration of Differential Equations* (1933), authored by Albert Bennett, William Milne, and Harry Bateman, which contains many valuable references. Cyrus Colton MacDuffee’s *The Theory of Matrices* (1933), also published by Springer in Germany, aimed, according to its preface, “to unify certain parts of the theory” because “many of the fundamental properties of matrices were first discovered in the notation of a particular application.” Some influential Russian textbooks such as L. V. Kantorovich’s and V. I. Krylov’s *Approximate Methods of Higher Analysis* (1941) became known in the West only much later through translations.

While it was certainly more a chemists’ and physicists’ war than one of mathematicians, World War I involved mathematicians on all sides. But politicians were slow to recognize the specific contribution that mathematics could offer to the war effort. France did

little to protect her most promising young mathematicians from the front, and about half of the science cohort studying at the École Normale Supérieure at the outbreak of the war was killed. Leading mathematicians such as Borel, however, gradually became involved as scientific advisors in warfare, while ballistics at the Gâvre proving ground was developed under Prosper Charbonnier, using graphical and numerical methods. In England Ralph Fowler, Edward Milne, and Herbert Richmond worked on the mathematics of anti-aircraft gunnery, while J. E. Littlewood applied his talents to more general ballistics and Karl Pearson interrupted his statistical research in biomathematics to oversee the production of the corresponding range tables. In Italy the experiences of Mauro Picone as an artillery officer working on ballistics research were influential with respect to the formation of the institute that was later set up under his lead (see below). Meanwhile, a key event in Germany was the foundation of the Aerodynamische Versuchsanstalt (“Aerodynamic Proving Ground”) in Göttingen in 1917, mainly financed by the military. This Proving Ground, together with the more theoretical Institute for Fluid Mechanics established in 1925 under the leadership of Ludwig Prandtl, would become the most advanced aerodynamic research installation in the world. In the United States systematic ballistics research was done in Washington under celestial mechanist Forest Ray Moulton and at the newly founded Aberdeen Proving Ground in Maryland under the geometer Oswald Veblen. In this context, finite-difference methods were introduced into ballistic computation by Moulton, as were higher methods of the calculus of variations by Gilbert Bliss in Aberdeen, which even in 1927 were described by Bliss as being “on the farther boundary of the explored mathematical domain of today.” From 1917 the new National Advisory Committee for Aeronautics, the predecessor of NASA, had its Langley Laboratory in Virginia, where Prandtl’s former student Max Munk was particularly influential in the 1920s when he explained the mathematics of aerodynamics to the laboratory’s engineers and built a variable-density wind tunnel.

More important for applied mathematics than the war itself, though, were its consequences.

The war led to the gradual recognition of the importance of the fundamental sciences (including mathematics), beyond mere technical inventions, for industrial and military applications. Science systems that were under close political control and received their main funding from government, such as those in

Germany, Italy, and Russia, had the potential to quickly recognize and respond to the importance of applied mathematics. There is of course nothing guaranteed about this relationship, as the example of the rather slow development in France shows. In the United States, new modes of industrial mass production during the war included scientific management (Taylorism). The superior strength of material resources, particularly in the electrical industry and in the development of calculating devices—IBM was founded in 1925—pointed to the future role of the United States in applied mathematics. Nevertheless, the predominantly private, but nonindustrial, sponsorship of the American university system before World War II slowed down the arrival of academic applied mathematics in the United States.

The foundation of the institute for applied mathematics at the University of Berlin (in 1920, under von Mises) can be partly explained against this backdrop of war and international competition. From 1921 von Mises edited the *Zeitschrift für angewandte Mathematik und Mechanik* (ZAMM), which had a clear engineering context, unlike the older *Zeitschrift für Mathematik und Physik*. In his programmatic article “On the tasks and goals of applied mathematics,” with which he started his new journal, von Mises gave his own definition of applied mathematics and added:

As a matter of course we put ourselves on the basis of the present, particularly on the standpoint of the scientifically minded engineer.

The foundation of the ZAMM was significantly ahead of the first Russian journal that expressly (and exclusively) referred to applications in its title, *Prikladnaya Matematika i Mekhanika*, which began in 1933; it is today regularly translated into English as the *Journal of Applied Mathematics and Mechanics*. The first American journal with “applied mathematics” in its title was the *Quarterly of Applied Mathematics*, edited at Brown University from 1943, which was partly modeled on von Mises’s ZAMM. However, the editors made a point in dropping “mechanics” from the title both in order to stress autonomy from the German example and to express the new level of independence of the field.

In spite of, or rather because of, increased economic competition after the war, internationalization remained the order of the day even in the applied sciences, as promoted by Felix Klein before the war. Indeed, the applied mathematician and fluid dynamics engineer von Kármán, who was closely connected to Göttingen, initiated the international congresses for

applied mechanics in 1924 (after organizing a successful conference on hydrodynamics and aerodynamics in Innsbruck in 1922) because he felt that the critical mass for discussion was not big enough on a national level and because postwar policies on each side threatened communication. Being Hungarian by origin, he was less skeptical about restoring international collaboration than von Mises and others who had stronger nationalist feelings. As von Kármán had hoped, the congresses attracted participants from across Europe, and by 1930, when the congress was held in Stockholm, there was also a strong delegation from the United States. However, the story of Russian participation is not so good. Politics did get in the way, and Russian mathematicians barely made an appearance.

Applied mathematics exhibited particular challenges for internationalization, not least because of its engineering context, which often bore traits of national idiosyncrasies, as is clear from the international efforts to unify terminology in vector calculus in around 1900. As late as 1935, at the Volta congress “High Velocities in Aviation” in Rome, terminology in ballistics and fluid mechanics was considered to be far from internationally standardized.

On the French side, the foundation of the Institut Henri Poincaré (1926), on the initiative of Borel and funded with American Rockefeller money, was a clear token of internationalization. Although the institute was less instrumental in the development of applied mathematics than its founder, with his broad view of “Borelian mathematics” (which stressed links between pure mathematics and applications, mainly based on mathematical physics and the theory of probability), had anticipated and wished for, it did provide the seeds for the development of French applied mathematics after the war.

In other European countries, such as Italy and Soviet Russia, new efforts to further work on applications were launched in the 1920s, partly motivated by experiences during the war and by political revolutions. The foundation in 1921 of the Institute of Physics and Mathematics of the Soviet Academy of Sciences by Vladimir Steklov (a former student of Aleksandr Lyapunov), which was supported by Lenin, was crucial for the further development of applied mathematics in the Soviet Union; the history of the institute has yet to be written. In Italy, under Mussolini, the central event concerning applications of mathematics in industry and the military was the creation in 1927–31 of the Italian

Research Council's National Institute for the Application of the Calculus under Mauro Picone in Naples and later in Rome.

In contrast, Britain created no new institutes for mathematics. Even G. H. Hardy, who had left Cambridge for Oxford shortly after the war, was unable to persuade his new university to build one. Nevertheless, the war left a tangible legacy for applied mathematics. Imperial College received a substantial grant to finance its Department of Aeronautics, while Cambridge established a new chair in aeronautical engineering. As a result of increased funding after the war, establishments such as the Royal Aircraft Establishment and the National Physical Laboratory were able to retain a number of their wartime staff, several of whom were mathematicians. Notable inclusions were Hermann Glauert, who made a career in aerodynamics at the Royal Aircraft Establishment, and Robert Frazer, who worked on wing flutter at the National Physical Laboratory. In the 1930s Frazer and his colleagues W. J. Duncan and A. R. Collar were "the first to use matrices in applied mathematics." In addition, theoreticians and practitioners who were brought together because of the war worked together afterward. Sometimes, as in the case of the Cambridge mathematician Arthur Berry and the aeronautical engineer Leonard Bairstow, the end of hostilities meant only the end of working in the same location, it did not mean the end of collaboration.

In the interwar period the degree of industrialization in a particular country was without doubt one of the defining factors in that country's support of applied mathematics. This is well exemplified by the solid development of applied mathematics in industrialized Czechoslovakia compared with the strong tradition in pure mathematics in less industrialized Poland.

Indeed, it became increasingly obvious after the war that engineering mathematics and insurance mathematics, both of which corresponded to the developing needs of the new professions and industries, had become legitimate parts of applied mathematics. Not only were they the most promising areas of the subject, but they were economically the most rewarding. Students trained at von Mises's institute in Berlin and at Prandtl's institute in Göttingen found jobs in various aerodynamic laboratories and proving grounds, as well as in industry. Von Mises himself both undertook governmental assignments and acted as an advisor for industry. At Siemens, AEG, and Zeiss (all in Germany), the General Electric Company (in Britain), Philips (in the Netherlands), and General Electric and Bell Laboratories

(in the United States) (Millman 1984), industrial laboratories (mainly in electrical engineering but also, for instance, in the optical and aviation industries) developed a demand for trained mathematicians. It was the study of the propagation of radio waves and of the electrical devices required to generate them that led in 1920 to the Dutchman van der Pol working out the equation that is to this day considered as the prototype of the nonlinear feedback oscillator. VAN DER POL'S EQUATION [IV.2 §10]) and his modeling approach have repeatedly been cited as exemplars for modern applied mathematics. Van der Pol's contribution, together with theoretical work by Henri Poincaré on limit cycles, strongly influenced Russian work on nonlinear mechanics. Its mathematical depth gained the approval (albeit somewhat reluctant approval) even of André Weil, a foremost member of the Bourbaki group of French mathematicians, who in 1950 called it "one of the few interesting problems which contemporary physics has suggested to mathematics." Van der Pol, who worked at the Philips Laboratories in Eindhoven from 1922, also contributed to the justification of the Heaviside operational calculus in electrical engineering. Around 1929 he used integral transformation methods similar to those developed before him by the English mathematician Thomas Bromwich and the American engineer John Carson at Bell Laboratories, who in 1926 wrote the influential book *Electric Circuit Theory and the Operational Calculus*. Somewhat later, the German Gustav Doetsch provided a more systematic justification of Heaviside's calculus based on the theory of the Laplace transform in his well-received book *Theorie und Anwendung der Laplace-Transformation* (1937). In another influential book, *Economic Control of Quality of Manufactured Product* (1931), the physicist Walter Shewhart, a colleague of Carson's at Bell Laboratories, was one of the first to promote statistics for industrial quality control using so-called control charts.

However, many of these developments in applied and industrial mathematics, both in Europe and America, occurred outside their national academic institutions, notwithstanding the beginnings of systematic academic training in applied mathematics in new institutes such as the one led by von Mises. A number of academically trained mathematicians and physicists were impressed by the spectacular and revolutionary ideas of relativity theory and quantum theory, but they were slow to recognize the importance of those new applications, often in engineering, that relied on classical mechanics.

This aloofness of academic scientists prevailed in the United States. The undisputed leader of American mathematicians, George Birkhoff, was aware of that when he addressed the American Mathematical Society at its semicentennial in 1938 with the following words:

The field of applied mathematics always will remain of the first order of importance inasmuch as it indicates those directions of mathematical effort to which nature herself has given approval.

Unfortunately, American mathematicians have shown in the last fifty years a disregard for this most authentically justified field of all.

There were exceptions, such as Norbert Wiener at the Massachusetts Institute of Technology, who was based in the mathematics department but interacted with the electrical engineering department run by Vannevar Bush (the inventor of the “differential analyzer,” an analogue computer) and through it with Bell Laboratories, and there were also the individual efforts of a number of mathematicians with a European background. One of the most successful of the latter was Harry Bateman, Professor of Aeronautical Research and Mathematical Physics at Caltech in Pasadena, who became a champion of special functions during the 1930s and 1940s, and who had earlier (immediately prior to his emigration from England in 1910) discussed the Laplace transform and applications to differential equations. However, American academia was late in recognizing applied mathematics, as exemplified by the abovementioned report on *Numerical Integration of Differential Equations* (1933), in which the authors write that the report was produced “without special grant for relief from teaching from any of the institutions represented.” Mathematical physicist Warren Weaver (who later, in World War II, would lead the Applied Mathematics Panel within the American war effort) was surprised, as late as 1930, “at the emphasis given, in the discussion [on a planned journal for applied mathematics], to the field between mathematics and engineering.” During the 1920s and 1930s, Rockefeller money had primarily been geared toward supporting pure academic mathematical and physical research, leaving applied research in the hands of industry. It was left to the clever negotiations of Richard Courant (Göttingen’s adherent to applied mathematics) to win Rockefeller fellowships for the applied candidates under his tutelage, such as Wilhelm Cauer and Alwin Walther.

The 1920s and 1930s were also a time in which mathematical modeling came to the fore, although the term

“mathematical modeling” was rarely used before World War II. In a 1993 article on the emergence of biomathematics in *Science in Context*, the author Giorgio Israel emphasizes the increasing role of mathematical modeling in the nonphysical sciences:

Another important characteristic of the new trends of mathematical modeling and applied mathematics is interest in the mathematization of the nonphysical sciences. The 1920s offer in fact an extraordinary concentration of new research in these fields, which is developed from points of view more or less reflecting the modeling approach. So the systematic use of mathematics in economics (both in the context of microeconomics and game theory) is found in the work of K. Menger, J. Von Neumann, O. Morgenstern, and A. Wald, starting from 1928. The basic mathematical model of the spread of an epidemic (following the research of R. Ross on malaria) was published in 1927 [by W. O. Kermack and A. G. McKendrick]; the first papers by S. Wright, R. A. Fisher and J. B. S. Haldane on mathematical theory of population genetics appeared in the early twenties; the first contributions of Volterra and Lotka to population dynamics and the mathematical theory of the struggle for existence were published in 1925 and 1926; and many isolated contributions (such as van der Pol’s model) also appeared in these years.

Moreover, during the twentieth century there was a certain tendency for mathematicians to be less inspired by physics and to resort instead to less rigorous or less complete models from other sciences, including engineering. In 1977 Garrett Birkhoff, George Birkhoff’s son, wrote:

Engineers and physicists create and adopt mathematical models for very different purposes. Physicists are looking for universal laws (of “natural philosophy”), and want their models to be exact, universally valid, and philosophically consistent. Engineers, whose complex artifacts are usually designed for a limited range of operating conditions, are satisfied if their models are reasonably realistic under those conditions. On the other hand, since their artifacts do not operate in sterilized laboratories, they must be “robust” with respect to changes in many variables. This tends to make engineering models somewhat fuzzy yet kaleidoscopic. In fluid mechanics, Prandtl’s “mixing length” theory and von Kármán’s theory of “vortex streets” are good examples; the “jet streams” and “fronts” of meteorologists are others.

The same author, himself a convert from abstract algebra to hydrodynamics, explains resistance to mathematical models in economics, pointing to the fact that they did not fit well into Bourbaki’s “conventional

framework of pure mathematics." The latter has often been described as in some respects being inimical to applications and (since the "New Math" of the 1960s) as being pedagogically disastrous. However, as detailed by Israel in the paper quoted above, the relationship between Bourbaki and the new practices in modeling has not necessarily been negative. Some mathematicians considered Bourbaki's notion of mathematics as an "abstract scheme of possible realities" to be the right way to liberate mathematics from the classical reductionist mechanistic approach that had often relied on linearization methods. There have even been efforts, for instance by logicians, to introduce "planned artificial language" into the sciences, as exemplified in J. H. Woodger's *The Axiomatic Method in Biology* (1937). However, these efforts seem to have had limited success. It took another step in the development of computers in the 1980s before necessarily simplified models of biological processes could be abandoned, and investigations of cellular automata, membrane computing, simulation of ecological systems, and similar tasks from modern mathematical biology could be undertaken.

During the 1920s and 1930s, many further results in different fields of application were obtained. Well-known examples include Alan Turing's work during the 1930s on the theory of algorithms and computability, and the Russian Leonid Kantorovich's work on linear programming within an economic context (1939), which escaped the attention of Western scholars for several decades.

This was also a period in which some of the foundations were laid for what would, from the late 1940s on, be called numerical analysis. In 1928 Courant and his students Kurt Friedrichs and Hans Lewy, all three of whom eventually emigrated to the United States, published "On the partial difference equations of mathematical physics" in *Mathematische Annalen*. The paper was translated in the *IBM Journal of Research and Development* as late as 1967 on the grounds that it was "one of the most prophetically stimulating developments in numerical analysis... before the appearance of electronic digital computers.... The ideas exposed still prevail." In the history of numerical analysis, the paper gained special importance because it contains the germ of the notion of numerical stability and involves the problem of well-posedness of partial differential equations (as proposed by Hadamard in 1902).

5 Applied Mathematics during and after World War II

World War II, like World War I, was not a mathematicians' war. Indeed, in early 1942 the chemist, and Harvard president, James Conant said: "The last was a war of chemistry but this one is a war of physics." This of course partially reflected the increasing role of mathematics in World War II, revealed by the use of ballistics, operations research, statistics, and cryptography throughout the conflict. In fact, the president of the American National Academy of Sciences, the physicist Frank B. Jewett, responded to Conant with the words: "It may be a war of physics but the physicists say it is a war of mathematics." However, at the time, due to lingering tradition, mathematics was not given the same high priority as the other sciences either in the preparation for warfare nor in war-related research. In the early 1940s within the leading research organizations in the United States, in Germany, and in other countries, mathematics was still subordinate to other fields, such as engineering and physics. In addition, the mathematicians themselves were not prepared for a new and broader social role, e.g., as professionals in industry, such as might be demanded by the war. When considering the future of their field during and after the war, many pure mathematicians were worried that mathematics would suffer from a too utilitarian point of view. This is exemplified by the well-known essay *A Mathematician's Apology* written by the leading English mathematician G. H. Hardy in 1940.

But not long after Hardy's essay was written, another Cambridge mathematician, Alan Turing, demonstrated the potential of sophisticated mathematics—a mix of logic, number theory, and Bayesian statistics—for warfare, when he and his collaborators at Bletchley Park broke the code of the German Enigma machine.

In Germany, the Diplommathematiker (mathematics degree with diploma), which was designed for careers in industry and the civil service, was officially introduced in 1942, and teaching as a career for mathematicians began to lose its monopoly.

The entry of the United States into World War II in December 1941 brought with it deep changes in the way mathematicians worked together with industry, the military, and government. In the *American Mathematical Monthly*, rich memoirs on the state of industrial mathematics and (academic) applied mathematics in the United States by Thornton Fry (1941) and Roland

Richardson (1943), respectively, were published. Probably the most spectacular development in communications mathematics took place in the 1940s at Bell Laboratories with the formulation of information theory by Claude Shannon.

Based on their European experiences, immigrants to the United States such as von Kármán, Jerzy Neyman, von Neumann, and Courant contributed substantially to a new kind of collaboration between mathematicians and users of mathematics. In the mathematical war work organized by the Applied Mathematics Panel, where the leading positions were occupied by Americans, with Warren Weaver at the head, the applied mathematicians cooperated with mathematicians of an originally purer persuasion, natives of the United States (Oswald Veblen, Marston Morse) and immigrants (von Neumann) alike.

As well as their political and administrative experience, the immigrants brought to their new environment European research traditions from engineering mathematics, classical analysis, and discrete mathematics. Ideas, such as those of von Neumann in theoretical computing, could gradually mature and materialize within the industrial infrastructure of the United States (Bell Laboratories, etc.), aided during the war by seemingly unlimited public money (Los Alamos, etc.). In March 1945, while the war was still on, von Neumann sent a famous memo on the “Use of variational methods in hydrodynamics” to Veblen. Von Neumann recommended the “great virtue of Ritz’s method” and deplored that before, and even during, the war mathematical work had not been sufficiently centralized for a systematic attack on the nonlinear equations occurring in fluid mechanics and related fields. In the same memo von Neumann pointed to the “increasing availability of high-power computing devices,” a development to which he had of course contributed substantially. As mentioned in the introduction to the SIAM “History of numerical analysis and scientific computing” Web pages:

Modern numerical analysis can be credibly said to begin with the 1947 paper by John von Neumann and Herman Goldstine, “Numerical inverting of matrices of high order” (*Bulletin of the AMS*, Nov. 1947). It is one of the first papers to study rounding error and include discussion of what today is called scientific computing.

Von Neumann and Goldstine’s results were soon followed up and critically discussed by English mathematicians (Leslie Fox and James Wilkinson, as well as

Alan Turing) at the National Physical Laboratory at Teddington.

After the war, the increased level of U.S. federal funding for mathematics was maintained. Although partly fueled by the beginning of the Cold War, it was nevertheless no longer restricted to applications. Much of it was channeled through the department of defense (e.g., by the Office of Naval Research) and the new National Science Foundation (NSF), which was founded in 1950. The NSF was initiated by the electrical engineer Vannevar Bush, who had led the Office for Scientific Research and Development, the American war-research organization. The concerns about exaggerated militarism that were harbored by pure mathematicians before the war therefore turned out to be groundless.

As George Dantzig, the creator of the SIMPLEX METHOD [IV.11 §3.1], observed, the outpouring of papers in linear programming between 1947 and 1950 coincided with the building of the first digital computers, which made applications in the field possible. Mathematical approaches to logistics, warehousing, and facility location were practiced from at least the 1950s, with early results in optimization by Dantzig, William Karush, Harold Kuhn, and Albert Tucker being enthusiastically received by (and utilized in the logistics programs of) the United States Air Force and the Office of Naval Research. These optimization techniques are still highly relevant to industry today.

The papers of the 1950 Symposium on Electromagnetic Waves, sponsored by the United States Air Force and published in the new journal *Communications on Pure and Applied Mathematics*, summarized the war effort in the field. Richard Courant, by then at New York University, pointed to the importance of a new approach to classical electromagnetism, where “a great number of new problems were suggested by engineers.” This strengthened the feeling, already evident before the war, that the predominance of academic mathematical physics as the main source of inspiration for mathematical applications had begun to wane. Ironically, Courant’s paper of 1943 on variational methods for the solution of problems of equilibrium and vibrations, which would later be widely considered to be one of the starting points for the FINITE-ELEMENT METHOD [II.12] (the name being coined by R. W. Clough in 1960), lay in obscurity for many years because Courant, not being an engineer, did not link the idea to networks of discrete elements. Another reason for the later breakthrough was a development of variational methods of

approximation in the theory of partial differential equations, which would ultimately prove to be vital to the development of finite-element methods in the 1960s (see J. T. Oden's chapter in Nash (1990)). A thoughtful historical look at the different ways mathematicians and engineers use finite-element methods is given in Babuška (1994).

New institutions for mathematical research, both pure and applied, were created after the war. Among them the institute under Richard Courant at New York University developed the most strongly. In a 1954 government report it was stated that Courant's institute had an

enrollment of over 400 graduate students in mathematics of which about half have a physics or engineering background.... The next largest figure, reported from Brown University, is a whole order of magnitude smaller! In the way of a rough estimate this means that New York University alone provides about one third of this country's annual output of applied mathematicians with graduate training.

The figures are based on a questionnaire prepared in connection with a conference organized in 1953 at Columbia University in New York by F. Joachim Weyl, the son of Hermann Weyl, as part of a Survey of Training and Research in Applied Mathematics sponsored by the American Mathematical Society and by the National Research Council under contract with the NSF. The conference proceedings and the report both included discussions on not only the training of applied mathematicians (particularly for industry, and including international comparisons) but also the increasing use of electronic computing; a summary was published in the *Bulletin of the American Mathematical Society* in 1954.

Between 1947 and 1954 the Institute for Numerical Analysis at the University of California, Los Angeles, sponsored by the National Bureau of Standards, played a special role in training university staff in numerical analysis and computer operations. The institute was closed in 1954, a victim of McCarthyism.

Brown University's summer school of applied mechanics, which were organized by Richardson from 1941 onward, had relied heavily on the contributions of immigrants. This is also partly true of the first American journal of applied mathematics, the *Quarterly of Applied Mathematics*, which began in 1943, and of *Mathematical Tables and Other Aids to Computation*, another Brown journal, which started the same year under Raymond Archibald.

Figure 6 M. Abramowitz and I. A. Stegun, eds, *Handbook of Mathematical Functions* (1964).

Various projects on mathematical tables and special functions that had their origins early in the twentieth century in various countries (the United Kingdom, Germany, and the United States) received a boost from the war. At Caltech, Arthur Erdélyi, with financial support from the Office of Naval Research, oversaw the Bateman Manuscript Project—the collation and publication of material collected by Harry Bateman, who had died in 1946—which led to the three-volume *Higher Transcendental Functions* (1953–55).

The Mathematical Tables Project, which had been initiated by the Works Progress Administration in New York in 1938, with Gertrude Blanch as its technical director, was disbanded after the war but many of its members moved to Washington in 1947 to become part of the new National Applied Mathematics Laboratories of the National Bureau of Standards. The latter's conference of 1952 resulted in one of the best-selling applied mathematics books of all time, *Handbook of Mathematical Functions with Formulas, Graphs and Mathematical Tables* (1964) by Milton Abramowitz and Irene

Stegun, both of whom had worked under Blanch (figure 6). Meanwhile, Blanch herself, rather than go to Washington, took a position at the Institute for Numerical Analysis at University of California, Los Angeles until its closure in 1954, where she worked with John Todd and Olga Taussky. Taussky, a rare example of a female pure mathematician who made contributions to applied mathematics, had worked during the war in Frazer's group at the National Physical Laboratory on flutter problems in supersonic aircraft and was an important figure in the development of matrix theory. Aware of certain resentments against applied mathematics from some mathematical quarters, in 1988 Taussky said:

When people look down on matrices, remind them of great mathematicians such as Frobenius, Schur, C. L. Siegel, Ostrowski, Motzkin, Kac, etc., who made important contributions to the subject. I am proud to have been a torchbearer for matrix theory, and I am happy to see that there are many others to whom the torch can be passed.

Computer developments rapidly changed the character of the table-making aspect of applied mathematics. As a result, Archibald's journal had a rather short life in its original form, being renamed *Mathematics of Computation* in 1960 in order "to reflect the broadened scope of the journal," which, as the editor Harry Polachek described, had "expanded to meet the need in [the United States] for a publication devoted to numerical analysis and computation." Private and government institutes such as the Research and Development Corporation (RAND), founded within the Douglas Aircraft Company in October 1945, and professional organizations such as the Association for Computing Machinery (1947), the Operations Research Society of America (1952), the Society for Industrial and Applied Mathematics (1952), and the Institute of Management Sciences (1953) all testified to the broadening social base for applied mathematics.

The technological development of computers and software had ramifications for the development of mathematical algorithms, particularly with respect to their speed and reliability. In his treatment of ordinary differential equations around 1910, Carl Runge had no need of systematic error estimation—it was not until after World War II that John Couch Adams's multistep methods for the numerical solution of ordinary differential equations from the mid-nineteenth century were analyzed with respect to error estimation, after

they had been brought into a more practical form by W. E. Milne in the United States ("Milne device") in 1926. However, postwar increases in computing speed led to greater concern about numerical stability and to the abandonment of methods like those of Milne. Europeans were also strongly involved in these theoretical developments. For example, in the 1930s the Englishman Richard Southwell had developed the so-called relaxation method, an iterative method connected to the numerical solution of partial differential equations in elasticity theory. The story goes that Garrett Birkhoff gave his doctoral student David M. Young the task of "automating relaxation," and Young introduced successive overrelaxation in his 1950 thesis (see Young's chapter in Nash (1990)). Young's deep analysis showed how to choose the relaxation parameters automatically in some important cases and thus provided a method suitable for programming on digital computers. This was an important advance on Southwell's method, which had been designed for computation by hand. The Norwegian-German Werner Romberg's elimination approach (1955) for improving the accuracy of the trapezoidal rule relied on Richardson extrapolation, a technique developed by the Englishman Lewis Fry Richardson early in the century. Richardson introduced finite-difference methods for the numerical solution of partial differential equations in 1910, of which extrapolation is just one part. And he was the first to apply mathematics, in particular the method of finite differences, to WEATHER PREDICTION [V.18]. His book *Weather Prediction by Numerical Process* (1922) was republished by Cambridge University Press in 2007 with a new foreword. The Richardson-Romberg procedure became widely known after it had been subjected to a rigorous error analysis by the German Friedrich L. Bauer and the Swiss Eduard L. Stiefel in the 1960s. In 1956 the Swede Germund Dahlquist introduced, within his theory of numerical instability, what Nick Trefethen (in *The Princeton Companion to Mathematics*) called "the fundamental theorem of numerical analysis: consistency + stability = convergence."

A major step in understanding the effects of rounding errors in linear algebra algorithms such as Gaussian elimination was the development, principally by the Englishman James Wilkinson, of BACKWARD ERROR ANALYSIS [I.2 §23], as described in Wilkinson's influential 1963 and 1965 research monographs. The all-important role of computer developments for the practical realization of previously existing theory is also evident in the history of the FAST FOURIER TRANSFORM

[II.10] (FFT), made famous by Cooley and Tukey in 1965: the FFT was originally discovered by Gauss but it could not be effectively applied before the advent of digital computers.

Many of the European mathematicians mentioned above worked in the United States for some of their careers. The “Brain Drain” gradually replaced the flight from Europe for political reasons, as observed in 1953 by the Dutch mathematician A. van Wijngaarden when attending a Columbia University symposium:

The one thing that continues to worry us is that we lose many of our best people to that big sink of European scientific talent, the U.S.A.

However, there were many European mathematicians who did not (or could not) follow the Brain Drain and who worked on an equal level with the Americans, among them many Russians. Nevertheless, there is no doubt about the superior technological and industrial infrastructure, particularly with respect to computing facilities and software development, that existed in the United States. Although this superiority was sometimes met with resentment, including by Alan Turing, it was admitted by Russians such as A. P. Ershov and M. R. Shura-Bura (Metropolis et al. 1980) and by Western European applied mathematicians such as the Frenchmen Louis Couffignal, the cybernetics pioneer, and Jacques-Louis Lions, the numerical analyst. For this reason, the latter cooperated strongly with Russian applied mathematicians, and he sometimes felt that the lack of access to cutting-edge technology increased the theoretical depth of their collaborative work.

From the 1930s Russian mathematicians had begun publishing exclusively in Russian and no longer also published in French and German. This practice, which continued after the war, prompted the American Mathematical Society, with funding from the Office of Naval Research, to begin a Russian translation project in 1947. SIAM followed suit in 1956, with support from the NSF. The “Sputnik crisis” in 1957 caused American mathematicians to look even more closely at the work being done in the Soviet Union. The Russian-born American topologist Solomon Lefschetz, who was prompted out of retirement by the event, persuaded the Martin Aircraft Company to set up a mathematics research center, at which he directed a large group working on nonlinear differential equations.

And yet during the two decades following the war, despite the relatively favorable material conditions of the United States, applied mathematics lost some of

its reputation in comparison with pure mathematics. In retrospect, of course, this period can be seen as one of consolidation of methods and of waiting for more powerful computational technology and for deeper theoretical foundations to arrive.

For example, one could argue that parts of the reform movement in teaching (“New Math”) in the early 1960s, which was meant to correct obvious and perceived shortcomings in American secondary education, counteracted efforts to develop applied mathematics. This movement was strongly influenced by the “purist” ideology of Bourbaki and had worldwide ramifications, threatening to undermine the development of pupils’ attitudes toward applications. In 1961, at a symposium organized by SIAM in Washington, DC, on research and education in applied mathematics, the chairman deemed that

applied mathematics is something of a stepchild; I might even say an out-of-step child, whose creations are looked upon with equal disinterest by mathematicians, physicists and engineers.

SIAM Review (1961)

On January 24 of the same year, the *New York Times* ran a column entitled, “Russia may be losing its traditional leadership in mathematics because of overemphasis on applied research,” which prompted the applied mathematician Harvey Greenspan from MIT to make a critical response in *American Mathematical Monthly* saying that, to the contrary,

the increased Russian emphasis in this area is really cause for some serious concern on our part.... The present system does not produce adequate numbers of applied mathematicians and remedial steps must soon be taken. The great majority of the senior faculty in applied mathematics are products of a European education.

The real breakthrough for applied mathematics in the United States came, however, with the rise of computer technology and computer science in the 1970s and 1980s, when, at the same time, the ideology of Bourbaki was in retreat. The so-called Davis Report of 1984 on “Renewing U.S. Mathematics” was an important event, leading to a near doubling of federal investment in mathematical research and including a special mathematics of computing initiative. In 1989 the Hungarian-born Peter Lax—who emigrated with his parents to the United States in 1941 and studied at New York University, and who in 2005 was a recipient of

the Abel Prize in Mathematics “for his groundbreaking contributions to the theory and application of partial differential equations and to the computation of their solutions”—signaled a new level of acceptance for applied mathematics in his widely distributed paper in *SIAM Review* on “The flowering of applied mathematics in America”:

Whereas in the not so distant past a mathematician asserting “applied mathematics is bad mathematics” or “the best applied mathematics is pure mathematics” could count on a measure of assent and applause, today a person making such statements would be regarded as ignorant.

The publication of articles by working applied mathematicians in Metropolis et al. (1980) and Nash (1990), and the extensive seven-volume historical project undertaken by the *Journal of Computational and Applied Mathematics* (2000), which was republished in Brezinski and Wuytack (2001), seem to testify to a growing self-confidence of applied mathematics within mathematics more widely. Some efforts, such as the publication of the “Top ten algorithms” in *Computing in Science and Engineering* in 2000 (six of which are contained in [I.5, table 2]), provoked controversial discussions. Many practitioners of applied mathematics in these and other publications reveal awareness of problems regarding the rigor and reliability of their methods, showing that the links between pure and applied mathematics exist and continue to stimulate the field. However, the standard philosophical approaches to mathematics—circling repetitively around formalism, logicism, and intuitionism, with no consideration of applications and doing no justice to the ever-increasing range of mathematical practice—are no longer satisfying either to mathematicians or to the public.

The unabated loyalty to pure mathematics as the mother discipline sometimes leads to overcautious reflection on the part of the applied mathematician. A nice example is provided by Trefethen (again in *The Princeton Companion to Mathematics*) in the context of rounding errors and the problem of numerical stability:

These men, including von Neumann, Wilkinson, Forsythe, and Henrici, took great pains to publicize the risks of careless reliance on machine arithmetic. These risks are very real, but the message was communicated all too successfully, leading to the current widespread impression that the main business of numerical analysis is coping with rounding errors. In fact, the main business of numerical analysis is designing algorithms

that converge quickly; rounding-error analysis, while often a part of the discussion, is rarely the central issue. If rounding errors vanished, 90% of numerical analysis would remain.

But it is not only these methodological concerns that hold back applied mathematics. For example, Lax (1989) mentions persisting problems in education and the need to maintain training in classical analysis:

The applied point of view is essential for the much-needed reform of the undergraduate curriculum, especially its sorest spot, calculus. The teaching of calculus has been in the doldrums ever since research mathematicians gave up responsibility for undergraduate courses.

The education and training of applied mathematicians remains a central concern, and it is not even clear whether the situation has changed significantly since the Columbia University Conference of 1953. At that time the applied mathematician and statistician John Wilder Tukey, best known for the development of the FFT algorithm and the box plot, declared with reference to what is now called modeling:

Formulation is the most important part of applied mathematics, yet no one has started to work on the theory of formulation—if we had one, perhaps we could teach applied mathematics.

A 1998 report by the NSF states that:

Careers in mathematics have become less attractive to U.S. students. [Several]... factors contribute to this change: (i) students mistakenly believe that the only jobs available are collegiate teaching jobs, a job market which is saturated (more than 1,100 new Ph.D.s compete for approximately 600 academic tenure-track openings each year); (ii) academic training in the mathematical sciences tends to be narrow and to leave students poorly prepared for careers outside academia; (iii) neither students nor faculty understand the kinds of positions available outside academia to those trained in the mathematical sciences.

The same report underscores the undiminished dependence of American pure and applied mathematics on immigration from Europe and (now) from Asia, South America, and elsewhere:

Although the United States is the strongest national community in the mathematical sciences, this strength is somewhat fragile. If one took into account only

home-grown experts, the United States would be weaker than Western Europe. Interest by native-born Americans in the mathematical sciences has been steadily declining. Many of the strongest U.S. mathematicians were trained outside the United States and even more are not native born. A very large number of them emigrated from the former Soviet Union following its collapse. (Russia's strength in mathematics has been greatly weakened with the disappearance of research funding and the exodus of most of its leading mathematicians.) Western Europe is nearly as strong in mathematics as the United States, and leads in important areas. It has also benefited by the presence of émigré Soviet mathematical scientists.

The Fields Medals for Pierre-Louis Lions (son of Jacques-Louis Lions) (1994), Jean-Christophe Yoccoz (1994), Stanislav Smirnov (2010), and Cédric Villani (2010) testify to the growing strength of European applied mathematics and to the changed status of the field within mathematics. Likewise, the awarding of the Abel Prize of the Norwegian Academy of Science and Letters to Peter Lax (2005), Srinivasa Varadhan (2007), and Endre Szemerédi (2012) for predominantly applied topics is a further indication of this shift. In addition, prestigious prizes devoted specifically to applications, with particular emphasis on connections to technological developments, have been founded in recent decades. The fact that several of these prizes have been named for mathematicians of outstanding theoretical ability—the ACM A. M. Turing Award (starting in 1966), the IMU Rolf Nevanlinna Prize (1981), the DMV and IMU Carl Friedrich Gauss Prize (2006)—underscores the unity of mathematics in its pure and applied aspects.

Meanwhile, problems remain in the academic-industrial relationship and, connected to it, in the professional image of the applied mathematician, as described in the two most recent reports on “Mathematics in Industry” (1996 and 2012) published by SIAM. The report for 2012 summarizes the situation:

Industrial mathematics is a specialty with a curious case of double invisibility. In the academic world, it is invisible because so few academic mathematicians actively engage in work on industrial problems. Research in industrial mathematics may not find its way into standard research journals, often because the companies where it is conducted do not want it to. (Some companies encourage publication and others do not; policies vary widely.) And advisors of graduates who go into industry may not keep track of them as closely as they keep track of their students who stay in academia.

However, most of the problems mentioned in this article with respect to academic applied mathematics (research funding, the lack of applications in mathematics education, the need for migration between national cultures) concern pure and applied mathematics alike. On the purely cognitive and theoretical level, the difference between the two aspects of mathematics—for all its interesting and important historical and sociological dimensions—hardly exists, as the above-quoted NSF report of 1998 underscores:

Nowadays all mathematics is being applied, so the term applied mathematics should be viewed as a different cross cut of the discipline.

Part II

Concepts

II.1 Asymptotics

P. A. Martin

When sketching the graph of a function, $y = f(x)$, we may notice (or look for) lines that the graph approaches, often as $x \rightarrow \pm\infty$. For example, the graph of $y = x^2/(x^2 + 1)$ approaches the straight line $y = 1$ as $x \rightarrow \infty$ (and as $x \rightarrow -\infty$). This line is called an *asymptote*. Asymptotes need not be horizontal or straight, and they may be approached as $x \rightarrow x_0$ for some finite x_0 . For example, $y = x^4/(x^2 + 1)$ approaches the parabola $y = x^2$ as $x \rightarrow \pm\infty$, and $y = \log x$ approaches the vertical line $x = 0$ as $x \rightarrow 0$ through positive values. Another example is that $\sinh x = \frac{1}{2}(e^x + e^{-x})$ approaches $\frac{1}{2}e^x$ as $x \rightarrow \infty$: we say that $\sinh x$ grows exponentially with x .

The qualitative notions exemplified above can be made much more quantitative. One feature that we want to retain when we say something like “ $y = f(x)$ approaches $y = g(x)$ as $x \rightarrow \infty$ ” is that, to be useful, $g(x)$ should be simpler than $f(x)$, where “simpler” will depend on the context. This is a familiar idea; for example, we can approximate a smooth curve near a chosen point on the curve by the tangent line through that point.

When $\lim_{x \rightarrow x_0} [f(x)/g(x)] = 1$, we write $f(x) \sim g(x)$ as $x \rightarrow x_0$, and we say that $g(x)$ is an *asymptotic approximation* to $f(x)$ as $x \rightarrow x_0$. For example, $\sinh x \sim x$ as $x \rightarrow 0$ and $\tanh x \sim 1$ as $x \rightarrow \infty$. A famous asymptotic approximation of this kind is Stirling’s formula from 1730: $n! \sim (2\pi n)^{1/2} (n/e)^n$ as $n \rightarrow \infty$.

According to our definition, we have $e^x \sim 1$, $e^x \sim 1 + x$, and $e^x \sim 1 + 2x$, all as $x \rightarrow 0$. On the other hand, we have the Maclaurin expansion, $e^x = 1 + x + \frac{1}{2}x^2 + \dots$, which converges for all x ; truncating this infinite series gives good approximations to e^x near $x = 0$, and these approximations improve if we take more terms in the series. This suggests that we should select $1+x$ and not

$1 + 2x$, so our definition of “ \sim ” is too crude. We want asymptotic approximations to be approximations, and we want to be able to improve them by taking more terms, if possible. With this in mind, suppose we have a sequence of functions, $\phi_n(x)$, $n = 0, 1, 2, \dots$, with the property that $\phi_{n+1}(x)/\phi_n(x) \rightarrow 0$ as $x \rightarrow x_0$. Standard examples are $\phi_n(x) = x^n$ as $x \rightarrow 0$ and $\phi_n(x) = x^{-n}$ as $x \rightarrow \infty$. Let $R_N(x) = \sum_{n=0}^N a_n \phi_n(x)$ for some coefficients a_n . We write

$$f(x) \sim \sum_{n=0}^{\infty} a_n \phi_n(x) \quad \text{as } x \rightarrow x_0,$$

and say that the series is an *asymptotic expansion* of $f(x)$ as $x \rightarrow x_0$ when, for each $N = 0, 1, 2, \dots$,

$$[f(x) - R_N(x)]/\phi_N(x) \rightarrow 0 \quad \text{as } x \rightarrow x_0. \quad (1)$$

In words, the “error” $f - R_N$ is comparable to the first term omitted, the one with $n = N + 1$. Note that the definition does not require the infinite series to be convergent (so that $R_N(x)$ may not have a limit as $N \rightarrow \infty$ for fixed x). Instead, for each fixed N , we impose a requirement on the error as $x \rightarrow x_0$, namely (1).

Asymptotic approximations may be convergent. For example, we have $e^x \sim 1 + x + \frac{1}{2}x^2 + \dots$ as $x \rightarrow 0$. However, many interesting and useful asymptotic expansions are divergent. As an example, the *complementary error function*

$$\begin{aligned} \operatorname{erfc}(x) &= \frac{2}{\sqrt{\pi}} \int_x^{\infty} e^{-t^2} dt \\ &\sim \frac{e^{-x^2}}{x\sqrt{\pi}} \left[1 + \sum_{n=1}^{\infty} (-1)^n \frac{1 \cdot 3 \cdots (2n-1)}{(2x^2)^n} \right] \end{aligned}$$

as $x \rightarrow \infty$, where the series is obtained by repeated integration by parts of the defining integral. The series is divergent, but taking a few terms gives a good approximation to $\operatorname{erfc} x$, an approximation that improves as x becomes larger.

Many techniques have been devised for obtaining asymptotic expansions. Some are designed for functions defined by integrals (such as $\operatorname{erfc} x$), others for functions that solve differential equations. Asymptotic methods can also be used to estimate the complexity

of an algorithm or to predict properties of large combinatorial structures and complex networks.

In many cases of interest, the function to be estimated depends on parameters. Their presence may be benign, but complications can arise. Suppose we are interested in $f(x, \lambda)$ when both x and the parameter λ are large. Using standard methods, we may be able to show that $f(x, \lambda) \sim g(x, \lambda)$ as $x \rightarrow \infty$ for fixed λ , and that $f(x, \lambda) \sim h(x, \lambda)$ as $\lambda \rightarrow \infty$ for fixed x . Then, the natural question to ask is: if we estimate $g(x, \lambda)$ for large λ and $h(x, \lambda)$ for large x , do we get the same answer? Simpler questions of this kind arise when investigating the commutativity of limits: given that

$$L_1 = \lim_{x \rightarrow \infty} \lim_{y \rightarrow \infty} F(x, y), \quad L_2 = \lim_{y \rightarrow \infty} \lim_{x \rightarrow \infty} F(x, y),$$

when does $L_1 = L_2$? In our context, with, for example, $f(x, \lambda) = (x + \lambda)/(x + 2\lambda)$, $f \sim 1$ as $x \rightarrow \infty$ but $f \sim \frac{1}{2}$ as $\lambda \rightarrow \infty$, so standard asymptotic approximations may fail when there are two or more variables. In these situations, *uniform asymptotic expansions* are needed. Inevitably, these are more complicated, but they are often needed to gain a full understanding of certain physical phenomena. For example, consider the shadow of an illuminated sphere on a flat screen. It is a dark circular disk. However, close inspection shows that the shadow boundary is not sharp: the image changes rapidly but smoothly as we cross the circular boundary. Standard asymptotic techniques explain what is happening in the illuminated and shadow regions (the wavelength of light is much smaller than the radius of the sphere, so their small ratio can be exploited in building asymptotic approximations), but uniform asymptotic approximations are needed to explain the transition between the two.

For more on asymptotic methods, see the articles on PERTURBATION THEORY AND ASYMPTOTICS [IV.5], SPECIAL FUNCTIONS [IV.7], and DIVERGENT SERIES: TAMING THE TAILS [V.8]. Another good source is chapter 2 of *NIST Handbook of Mathematical Functions* (Cambridge University Press, Cambridge, 2010), edited by F. W. J. Olver, D. W. Lozier, R. F. Boisvert, and C. W. Clark. (An electronic version of the book is available at <http://dlmf.nist.gov>.)

II.2 Boundary Layer

The mathematical idea of a boundary layer emerged from an analysis of a physical problem arising in FLUID DYNAMICS [IV.28]; the flow of a viscous fluid past a rigid body. Suppose that the body has diameter L and U is

the speed of the flow far from the body. The *Reynolds number* for the flow is $Re = UL/\nu$, where ν is the dynamic viscosity coefficient. Assume that the fluid is not very viscous (meaning that $Re \gg 1$) so that the flow can be well approximated by solving the governing equations for a nonviscous fluid, the EULER EQUATIONS [III.11]. This approximation is not good near the surface of the body. There, viscous effects are important, so the NAVIER-STOKES EQUATIONS [III.23] must be used. Nevertheless, good approximations can be constructed by exploiting the fact that $Re \gg 1$. This is done within a thin viscous *boundary layer*. The two solutions, one in the boundary layer and one in the outer region, are matched in a region where both are assumed to be valid, and we therefore obtain a good approximation everywhere in the fluid. This whole scheme was first described and implemented by Ludwig Prandtl in 1904.

The idea of joining two solutions together is part of an extensive suite of asymptotic techniques in which large (or small) dimensionless parameters are identified and exploited. There can be more than two regions and more than one large parameter. Sophisticated matching procedures have been developed and applied to many complicated problems, not just those arising in fluid dynamics. See the article on PERTURBATION THEORY AND ASYMPTOTICS [IV.5].

II.3 Chaos and Ergodicity

Paul Glendinning

The term *chaos* is used with greater or lesser degrees of precision to describe deterministic dynamics that is nonperiodic and unpredictable. The word was first used in this context by Li and Yorke in the title of their article “Period three implies chaos” in 1975. Li and Yorke were careful not to define the term too narrowly and described their mathematical results using clearly defined properties of solutions. In one of the early textbooks on the subject (published in 1989), Devaney defined chaos for discrete maps T on a metric space X with $x_{n+1} = T(x_n)$, $x_n \in X$. Devaney’s definition is that $T: X \rightarrow X$ is chaotic on X if

- (i) periodic orbits are dense in X ,
- (ii) the dynamics is transitive (so for any points $x, y \in X$ it is possible to find a point in X that is arbitrarily close to x whose orbit passes arbitrarily close to y), and
- (iii) the system has sensitive dependence on initial conditions (*SDIC*) on X .

SDIC means that there exists a precision $\varepsilon > 0$ such that for every $x \in X$ and $\delta > 0$ there exists a point $y \in X$ within a distance δ of x and a time n such that solutions started at x and y are at least a distance ε apart after time n . SDIC is often described as implying a loss of predictability, or a loss of memory of initial conditions, although it is a little more complicated than this suggests. Devaney's definition was intended to make it possible to ask sensible examination questions about chaos at undergraduate level, and by 1992 two groups had shown that (for appropriate systems) the first two conditions imply the third, suggesting it is not an ideal definition!

Another commonly used definition of chaos uses the idea of Lyapunov exponents. These measure the asymptotic local expansion properties of solutions, so if (x_n) is an orbit of the one-dimensional map $x_{n+1} = T(x_n)$ and T is differentiable, then the Lyapunov exponent of x_0 is

$$\lambda(x_0) = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} \log |T'(x_k)|$$

provided the limit exists. The dynamics is regarded as chaotic if it is not "simple" (a union of periodic points, for example) and typical points have positive Lyapunov exponents.

Issues around definition notwithstanding, the idea of chaos has radically changed the choices that applied mathematicians make when modeling systems with complicated temporal behavior. In particular, chaos theory shows that apparently random behavior may have a deterministic origin (see also DYNAMICAL SYSTEMS [IV.20] and THE LORENZ EQUATIONS [III.20]).

The analogy with probability theory is made mathematically precise using *ergodic theory*, which connects time averages of a quantity along an orbit with an expected value. This expected value is a spatial integral, and hence it is independent of the initial conditions.

The definition of ergodicity uses two ideas: invariant sets and invariant measures. An *invariant set* X of a map T satisfies $X = T^{-1}(X)$, and a map T with an invariant set X has an *invariant probability measure* if there is a measure μ such that $\mu(S) = \mu(T^{-1}(S))$ for all measurable sets S in X and $\mu(X) = 1$.

The map T is *ergodic* with respect to an invariant measure μ if $\mu(S)$ is either zero or one for all invariant sets S . In other words, every invariant set is either very small (measure zero) or it is essentially (up to sets of measure zero) the whole set X . This means that the dynamics is not decomposable into smaller sets,

a role played by the transitive property in Devaney's definition of chaos.

Ergodic maps have nice averaging properties. For all integrable functions f on X the time average of f along typical orbits equals the spatial average obtained by integrating X with respect to the invariant measure:

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} f(T^k(x)) = \int_X f \, d\mu$$

for almost all $x \in X$ (with respect to the invariant measure μ). Thus μ can be interpreted as a probability measure of the dynamics, and if $d\mu = h(x) dx$, then h can be interpreted as a sort of probability density function for the iterates of points under T . The "typical" Lyapunov exponent of a one-dimensional map can then be interpreted as the integral of $f = \log |T'|$ with respect to the invariant measure.

II.4 Complex Systems

Paul Glendinning

Complex systems are dynamical models that involve the interaction of many components. The study of these systems is called complexity theory. Complex systems are characterized by having large dimension and complicated interactions.

There are many examples of complex systems across the sciences. The reactions between chemicals in a living cell can be considered as a complex system, where the variables are the concentrations of chemicals and the dynamics is defined by the chemical reactions that can take place. A chemical can react with only a small set of the chemicals present, so the connectivity is generally low.

Other examples include the Internet, where individual computers are linked together in complex ways, and electronic systems whose components are connected on a circuit board. Agent-based models of human behavior such as opinion formation within groups or the movement of crowds are also complex systems.

It is often hard to do much more than numerical simulations to determine the behavior of systems, leading to a somewhat limited phenomenological description of their behavior. There are two central methods in the study of complex systems that go further than this, though again with limited concrete predictive power. These are graph theory to characterize how components influence each other, and dimension reduction methods to capture (where applicable) any lower-dimensional approximations that determine the evolution of the system.

If the system has real variables x_i , $i = 1, \dots, N$, then each variable can be identified with the node of a graph labeled by i , with an edge from i to j if the dynamics of x_j is directly influenced by x_i (see GRAPH THEORY [II.16]). For example, if the evolution is determined by a differential equation then $\dot{x}_i = f_i(x_1, x_2, \dots, x_N)$, but not every variable need appear explicitly in the argument of f_i , so there is an edge from x_j to x_i only if $\partial f_i / \partial x_j$ is not identically zero. This graph can be represented by an adjacency matrix (a_{ij}) with $a_{ij} = 1$ if there is an edge from i to j and $a_{ij} = 0$ otherwise. The degree of a node is the number of edges at the node (this can be split into the in-degree (respectively, out-degree) if only edges ending (respectively, starting) at the node are counted). The proportion of nodes with degree k is the degree distribution of the network. Properties of the degree distribution are often used to characterize the network. For example, if the degree distribution obeys a power law, the network is said to be scale free (the Internet is supposedly of this type; see NETWORK ANALYSIS [IV.18]).

By analyzing subgraphs of biological models it was found that some subgraphs appear in examples much more often than would be expected on the basis of a statistical analysis. This has led to the conjecture that these *motifs* may have associated functional properties.

In many complex systems the individual components of the system behave according to very simple, though often nonlinear, rules. For example, a bird in a flock may change its direction of flight as a function of the average direction of flight of nearby birds. Although this is a local rule, the effect across the entire flock of birds is to produce coherent movement of the flock as a whole. This effect, whereby simple local rules lead to interesting global results, is called *emergent behavior*. The emergent behavior resulting from given local rules is often unclear until the system is simulated numerically.

In some cases the dimension of the problem can be reduced, so fewer variables need to be considered, mak-

ing the system easier to simulate and more amenable to analysis. The methods of dimension reduction often rely on SINGULAR VALUE DECOMPOSITION [II.32] techniques to identify the more dynamically active directions in phase space, and then an attempt is made to project the system onto these directions and analyze the resulting system.

In some systems the mean-field theory of theoretical physics can be used to understand collective behavior.

Since complexity theory encompasses so many different models, the range of possible dynamic phenomena is vast, even before further complications such as stochastic effects or network evolution are included. Complex systems describing neuron interactions in the brain can model pattern recognition and memory (see MATHEMATICAL NEUROSCIENCE [VII.21]). Numerical models of partial differential equations are complex systems, and the dynamical behavior can include synchronization, in which all components lock on to a similar pattern of behavior, and PATTERN FORMATION [IV.27]. Different parts of the system may behave in dynamically different ways, with regions of frustration (or fronts) separating them. Interactions may have different strengths, leading to different timescales in the problem. This is particularly true of many biological models and adds to the difficulty of modeling phenomena accurately.

II.5 Conformal Mapping

Darren Crowdy

1 What Is a Conformal Mapping?

Conformal mapping is the name given to the idea of interpreting an analytic function of a complex variable in a geometric fashion. Let $z = x + iy$ and suppose that another complex variable w is defined by

$$w = f(z) = \phi(x, y) + i\psi(x, y),$$

where ϕ and ψ are, respectively, the real and imaginary parts of some function $f(z)$, an analytic function

of z . One can think of this relation as assigning a correspondence between points in the complex z -plane and points in the complex w -plane. Under this function a designated region of the z -plane is transplanted, or “mapped,” to some region in the w -plane, as illustrated in figure 1. The shape of the image will depend on f . The fact that f is an *analytic* function implies certain special properties of this mapping of regions. If the mapping is to be one-to-one, then a necessary, but not sufficient, condition is that the derivative $f'(z) = df/dz$ does not vanish in the z -region of interest.

A simple example is the *Cayley mapping*

$$w = f(z) = \frac{1+z}{1-z}.$$

This maps the interior of the unit disk $|z| < 1$ in the z -plane to the right half w -plane $\operatorname{Re} w > 0$. The point $z = 1$ maps to $w = \infty$, and $z = -1$ maps to $w = 0$. The unit circle $|z| = 1$ maps to the imaginary w -axis. Conformal mappings clearly preserve neither area nor perimeters; their principal geometrical feature is that they locally preserve angles. To see this, note that since $f(z)$ is analytic at a point z_0 , it has a local Taylor expansion there:

$$w = f(z_0) + f'(z_0)(z - z_0) + \dots$$

If $\delta z = z - z_0$ is an infinitesimal line element through z_0 in the z -plane, its image δw under the mapping defined as $\delta w = w - w_0$, where $w_0 = f(z_0)$, is, to leading order,

$$\delta w \approx f'(z_0)\delta z.$$

But $f'(z_0)$ is just a nonzero complex number so, under a conformal mapping, all infinitesimal line elements through z_0 are transplanted to line elements through w_0 in the w -plane that are simply rescaled by the modulus of $f'(z_0)$ and rotated by its argument. In particular, the angle between two given line elements through z_0 is preserved by the mapping.

2 The Riemann Mapping Theorem

The Riemann mapping theorem is considered by many to be the pinnacle of achievement of nineteenth-century mathematics. It is an existence theorem: it states that there exists a conformal mapping from the unit z -disk to *any* given simply connected region (no holes) in the w -plane, so long as it is not the entire plane.

3 Conformal Invariance

One reason why conformal mappings are an important tool in applied mathematics is the property of *conformal invariance* of certain boundary-value problems

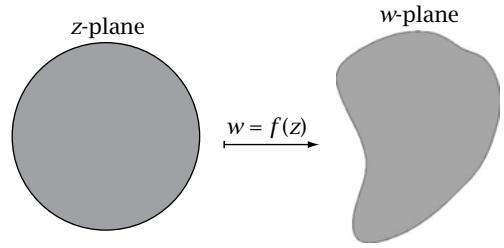

Figure 1 A conformal mapping from a region in a complex z -plane to a region in a complex w -plane.

arising in applications. An example is the boundary-value problem determining Green's function $G(z; z_0)$ for the Laplace equation in a region D in \mathbb{R}^2 with boundary ∂D , which can be written as

$$\nabla^2 G = \delta^{(2)}(z - z_0) \quad \text{in } D \text{ with } G = 0 \text{ on } \partial D,$$

where z_0 is some point inside D and $\delta^{(2)}$ is the two-dimensional DIRAC DELTA FUNCTION [III.7]. The Green function for the unit disk $|z| < 1$ is known to be

$$G(z; z_0) = \operatorname{Im} \left[\frac{i}{2\pi} \log \left(\frac{z - z_0}{|z_0|(z - 1/\bar{z}_0)} \right) \right],$$

where \bar{z}_0 is the complex conjugate of z_0 . Now if D is any other simply connected region of a complex w -plane, the corresponding Green function in D is nothing other than $G(f^{-1}(w); f^{-1}(w_0))$, where $f^{-1}(w)$ is the inverse function of the conformal mapping taking the unit z -disk to D . Geometrically, $f^{-1}(w)$ is just the inverse conformal mapping transplanting D to the unit disk $|z| < 1$. The Green function in any simply connected region D is therefore known immediately provided the conformal mapping between D and the unit disk can be found.

4 Schwarz–Christoffel Mappings

The Riemann mapping theorem is nonconstructive and, while the existence of a conformal mapping between given simply connected regions is guaranteed, the practical matter of actually constructing it is another story. One of the few general constructions often used in applications is the *Schwarz–Christoffel mapping*. This is a conformal mapping from a standard region such as the unit z -disk $|z| < 1$ to the region interior or exterior to an N -sided polygon. At the preimage of any vertex of the polygon (a *prevertex*), the local argument outlined earlier demonstrating the preservation of angles between infinitesimal line elements must fail. Indeed, at any such prevertex it can be argued that the derivative $f'(z)$ of the conformal mapping must have a simple

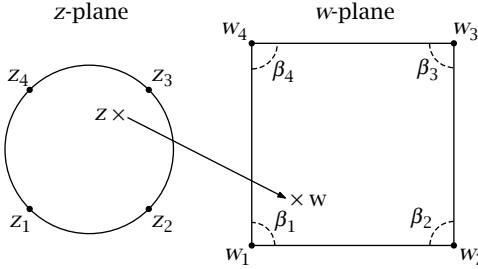

Figure 2 A Schwarz-Christoffel mapping from the unit z -disk to the interior of a square in a w -plane. A function of the form (1) with $N = 4$ identifies a point w with a point z . Here, $\beta_1 = \beta_2 = \beta_3 = \beta_4 = \pi/2$.

zero, a simple pole, or a branch point singularity. The general formula for a mapping from $|z| < 1$ to the interior of a bounded polygon in a w -plane is

$$w = f(z) = A + B \int^z \prod_{k=1}^N \left(1 - \frac{z'}{z_k}\right)^{(\beta_k/\pi-1)} dz', \quad (1)$$

while the formula for a mapping from $|z| < 1$ to the exterior of a bounded polygon in a w -plane, with $z = 0$ mapping to $w = \infty$, is

$$w = f(z) = A + B \int^z \prod_{k=1}^N \left(1 - \frac{z'}{z_k}\right)^{(\beta_k/\pi-1)} \frac{dz'}{z'^2}. \quad (2)$$

The parameters $\{\beta_k \mid k = 1, 2, \dots, N\}$ are the *turning angles* shown in figure 2; the points $\{z_k \mid k = 1, 2, \dots, N\}$ are the prevertices. A and B are complex constants. These so-called *accessory parameters* are usually computed numerically by fixing geometrical features such as ensuring that the sides of the polygon have the required length. A famous mapping of Schwarz-Christoffel type known for its use in aerodynamics is the *Joukowski mapping*,

$$w = f(z) = \frac{1}{2} \left(z + \frac{1}{z} \right),$$

which maps the unit disk $|z| < 1$ to the infinite region exterior to a flat plate, or airfoil, lying on the real w -axis between $w = -1$ and $w = 1$. It is a simple matter to derive it from (2) with the prevertices $z_1 = 1$, $z_2 = -1$ and turning angles $\beta_1 = \beta_2 = 2\pi$. Since it is natural, given any two-dimensional shape, to approximate it by taking a set of points on the boundary and joining them with straight line segments to form a polygon, the Schwarz-Christoffel formula has found many uses in applied mathematics. Versatile numerical software to compute the accessory parameters has also been developed.

II.6 Conservation Laws

Barbara Lee Keyfitz

1 Quasilinear Hyperbolic Partial Differential Equations

A system of first-order partial differential equations (PDEs) in the form

$$\mathbf{u}_t + \sum_{i=1}^d A_i(x, t, \mathbf{u}) \mathbf{u}_{x_i} + \mathbf{b}(x, t, \mathbf{u}) = 0, \quad (1)$$

where $\mathbf{u} \in \mathbb{R}^n$, $\mathbf{b} \in \mathbb{R}^n$, the A_i are $n \times n$ matrices, and $\mathbf{u}_t \equiv \partial \mathbf{u} / \partial t$ and $\mathbf{u}_{x_i} \equiv \partial \mathbf{u} / \partial x_i$, is said to be *quasilinear*; the system is nonlinear as defined in the article PARTIAL DIFFERENTIAL EQUATIONS [IV.3], but the terms containing derivatives of \mathbf{u} appear only in linear combination. Identifying t as a time variable and $x = (x_1, \dots, x_d)$ as a space variable, the *Cauchy problem* asks for a solution to (1) for $t > 0$ with the initial condition

$$\mathbf{u}(x, 0) = \mathbf{u}_0(x). \quad (2)$$

By analogy with the theory of linear PDEs, one expects this problem to be well-posed only if the system is *hyperbolic*, which means that all the roots $\tau(\xi)$ (known as *characteristics*) of the polynomial equation

$$\det \left(\tau I + \sum_{i=1}^d A_i \xi_i \right) = 0 \quad (3)$$

are real for all $\xi \in \mathbb{R}^d$ and, as eigenvalues of the matrix $\sum_{i=1}^d A_i \xi_i$, each has equal ALGEBRAIC AND GEOMETRIC MULTIPLICITIES [II.22].

In 1974 Fritz John showed that if $d = 1$, and the system is *genuinely nonlinear* (meaning that $\nabla_\xi \tau_i \cdot \mathbf{r}_i \neq 0$ for each root τ_i of (3) and corresponding eigenvector \mathbf{r}_i), then for smooth Cauchy data at least one component of $\nabla \mathbf{u}$ tends to infinity in finite time, exactly as in the BURGERS EQUATION [III.4] (see also PARTIAL DIFFERENTIAL EQUATIONS [IV.3 §3.6]).

Characteristics in hyperbolic systems define the speed of propagation of signals in specific directions (normal to ξ), so genuine nonlinearity says that this speed is a nontrivial function of the state \mathbf{u} . This has physical significance as a description of the phenomena

modeled by conservation laws, and it has mathematical implications for the existence of smooth solutions. Specifically, the behavior seen in solutions of the Burgers equation typifies solutions of genuinely nonlinear hyperbolic systems.

Furthermore, despite the fact that DISTRIBUTION SOLUTIONS [IV.3 §5.2] are well defined for linear hyperbolic equations, the concept fails for quasilinear systems since, in the first place, A_i and $A_i \mathbf{u}_{x_i}$ are not defined if \mathbf{u} lacks sufficient smoothness, and, in the second, the standard procedure of creating the weak form of an equation (multiply by a smooth test function and integrate by parts) does not usually succeed in eliminating $\nabla \mathbf{u}$ from the system when $A = A(\mathbf{u})$ depends in a nontrivial way on \mathbf{u} . The exception is when each $A_i \mathbf{u}_{x_i}$ is itself a derivative: $A_i \mathbf{u}_{x_i} = \partial_{x_i} f_i(\mathbf{u})$. This happens if each row of each A_i is a gradient, and that happens only if the requisite mixed partial derivatives are equal.

In this case, we have a *system of balance laws*:

$$\mathbf{u}_t + \sum_{i=1}^d (f_i(x, t, \mathbf{u}))_{x_i} + \mathbf{b}(x, t, \mathbf{u}) = 0. \quad (4)$$

In the important case in which $\mathbf{b} \equiv 0$, we have a system of *conservation laws*. The weak form of (4) is

$$\iint \left[\mathbf{u} \varphi_t + \sum_{i=1}^d (f_i(x, t, \mathbf{u})) \varphi_{x_i} - \mathbf{b}(x, t, \mathbf{u}) \varphi \right] dx dt = 0. \quad (5)$$

Since this is the only case in which solutions to (1) can be unambiguously defined, the subject of quasilinear hyperbolic systems is often referred to as “conservation laws.”

A mathematical challenge in conservation laws is to find spaces of functions that are inclusive enough to admit weak solutions for general classes of conservation laws but regular enough that solutions and their approximations can be analyzed. At this time, there is a satisfactory well-posedness theory only in a single space dimension.

2 How Conservation Laws Arise

Problems of importance in physics, engineering, and technology lead to systems of conservation laws; a sample selection of these problems follows.

2.1 Compressible Flow

The basic equations of compressible fluid flow, derived from the principles of conservation of mass, momentum, and energy, along with constitutive equations

relating thermodynamic quantities, take the form

$$\left. \begin{aligned} \rho_t + \operatorname{div}(\rho \mathbf{u}) &= 0, \\ (\rho \mathbf{u})_t + \operatorname{div}(\rho \mathbf{u} \otimes \mathbf{u}) + \nabla p &= 0, \\ (\rho E)_t + \operatorname{div}(\rho \mathbf{u} H) &= 0, \end{aligned} \right\} \quad (6)$$

where ρ represents density, \mathbf{u} velocity, p pressure, E energy, and H enthalpy, with

$$E = \frac{1}{2} |\mathbf{u}|^2 + \frac{1}{\gamma - 1} \frac{p}{\rho}, \quad H = \gamma E,$$

and γ a constant that depends on the fluid ($\gamma = 1.4$ for air). To obtain the first equation in (6), one notes that the total amount of mass in an arbitrary control volume D is the integral over D of the density, and this changes in time if there is flux through the boundary Γ of D . Furthermore, the flux is precisely the product of the density and the velocity normal to that boundary, from which we obtain

$$\frac{d}{dt} \iint_D \rho dV = - \int_{\Gamma} \rho \mathbf{u} \cdot \mathbf{n} dA. \quad (7)$$

(The negative sign will remind the reader of the convention that \mathbf{n} is the outward normal, and flow out of D will decrease the mass contained in D .) Interchanging differentiation and integration on the left in (7), along with an application of the DIVERGENCE THEOREM [I.2 §24] on the right, immediately yields

$$\iint_D (\rho_t + \operatorname{div}(\rho \mathbf{u})) dV = 0. \quad (8)$$

Finally, the observation that D is an arbitrary domain in the region allows one to pass to the infinitesimal version in (6). The integral version (8) also justifies the weak form (5), since if (8) holds on arbitrary domains then it is possible to form weighted averages with arbitrary differentiable functions φ and to integrate by parts, which produces (5).

In compressible flow, the speed of sound is finite; in (6) it is one of the characteristics. Steady flow at speeds that exceed the speed of sound also gives a hyperbolic system of conservation laws (6) with the time derivatives absent. In this case, the hyperbolic direction (the time-like variable) is given by the flow direction.

Conservation principles also lead to equations for ELASTICITY [IV.26 §3.3] and MAGNETOHYDRODYNAMICS [IV.29]. Industrial applications include continuum models for multiphase flow (e.g., water mixed with steam in nuclear reactor cooling systems, or multicomponent flows in oil reservoirs).

The necessity of solving, or at least approximating, conservation laws for many of these applications has

resulted in extensive techniques for numerical simulation of solutions, even when existence of solutions remains an open question.

2.2 Chromatography

Chromatography is a widely used industrial process for separating chemical components of a mixture by differential adsorption on a substrate. Modeling a chromatographic column leads to a system of conservation laws in a single space variable that takes the form

$$c_x + (\mathbf{f}(\mathbf{c}))_t = 0,$$

where $\mathbf{c} = (c_1, \dots, c_n)$ is a vector of component concentrations and \mathbf{f} is the equilibrium column isotherm. A common model for \mathbf{f} uses the Langmuir isotherm and gives, with positive parameters α_i measuring the relative adsorption rates,

$$f_i = c_i + \frac{\alpha_i c_i}{1 + \sum c_j}, \quad 1 \leq i \leq n.$$

2.3 Other Models

Many other physical phenomena lead naturally to conservation laws. For example, a continuum model for vehicular traffic on a one-way road is the scalar equation

$$u_t + q(u)_x = 0,$$

where u represents the linear density of traffic and $q(u) = uv(u)$ the flux, where v is velocity. As in (7), this equation is a conservation law, the “law of conservation of cars.” This model assumes that the velocity at which traffic moves depends only on the traffic density. Although this model is too simple to be of much practical use, it is appealing as a pedagogical tool. Adaptations of it are of interest in current research.

II.7 Control

A *system* is a collection of objects that interact and produce various outputs in response to different inputs. Systems arise in a wide variety of situations and include chemical plants, cars, the human body, and a country’s economy. Control problems associated with these systems include the production of a chemical, control of self-driving cars, the regulation of bodily functions such as temperature and heartbeat, and the control of debt. In each case one wants to have a way of controlling these processes automatically without direct human intervention.

A general control system is depicted in figure 1. The state of the system is described by n *state variables* x_i , and these span the *state space*. In general, the x_i cannot be observed or measured directly, but p *output variables* y_i , which depend on the x_i , are known. The system is controlled by manipulating m *control variables* u_i .

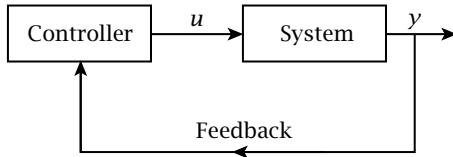

The system might be expressed as a system of difference equations (discrete time) or differential equations (continuous time). In the latter case a linear, time-invariant control problem takes the form

$$\begin{aligned} \frac{dx}{dt} &= Ax(t) + Bu(t), \\ y(t) &= Cx(t) + Du(t), \end{aligned}$$

where A , B , C , and D are $n \times n$, $n \times m$, $p \times n$, and $p \times m$ matrices, respectively. This is known as a *state-space system*. In some cases an additional $n \times n$ matrix E , which is usually singular, premultiplies the dx/dt term; these so-called *descriptor systems* or *generalized state-space systems* lead to DIFFERENTIAL-ALGEBRAIC EQUATIONS [I.2 §12].

A natural question is whether, given a starting value $x(0)$, the input u can be chosen so that x takes a given value at time t . Questions of this form are fundamental in classical control theory.

If feedback occurs from the outputs or state variables to the controller, then the system is called a *closed-loop system*. In *output feedback*, illustrated in figure 1, u depends on y , while in *state feedback* u depends on x .

**Figure 1** Control system.

For example, in state feedback we may have $u = Fx$, for some $m \times n$ matrix F . Then $dx/dt = (A + BF)x$, which leads to questions about what properties the matrix $A + BF$ can be given by suitable choice of F .

For more details, see CONTROL THEORY [IV.34].

II.8 Convexity

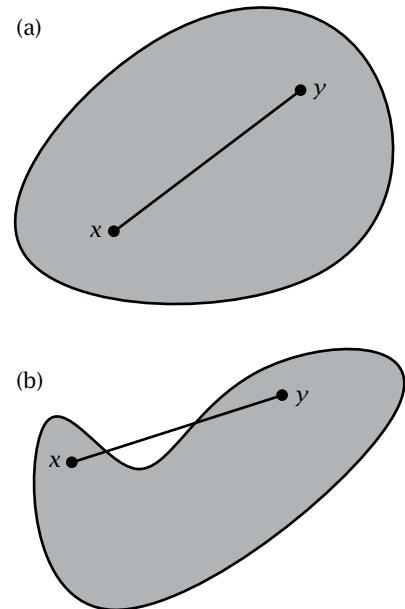

Didier Henrion

The notion of convexity is central in applied mathematics. It is also used in everyday life in connection with the curvature properties of a surface. For example, an optical lens is said to be convex if it is bulging outward.

Convexity appears in ancient Greek geometry, e.g., in the description of the five regular convex space polyhedra (the platonic solids). Archimedes (ca. 250 B.C.E.) seems to have been the first to give a rigorous definition of convexity, similar to the geometric definition we use today: a set is convex if it contains all line segments between each of its points.

In his study of singularities of real algebraic curves, Newton (ca. 1720) introduced a convex polygon in the plane built from the exponents of the monomials of the polynomial defining the curve; this is known as the Newton polygon. Cauchy (ca. 1840) studied convex curves and remarked, for example, that, if a closed convex curve is contained in a circle, then its perimeter is smaller than that of the circle. Convex polyhedra were studied by Fourier (ca. 1825) in connection with the problem of the solvability of linear inequalities.

A central figure in the modern development of convexity is Minkowski, who was motivated by problems from number theory. In 1891 Minkowski proved that, in Euclidean space \mathbb{R}^n , every compact convex set with center at the origin and volume greater than 2^n contains at least one point with integer coordinates different from the origin. From Minkowski's work follows the classical isoperimetric inequality, which states that among all convex sets with given volume, the ball is the one with minimal surface area. In 1896 Minkowski considered systems of the form $Ax \geqslant 0$, where A is a real $m \times n$ matrix and $x \in \mathbb{R}^n$. Together with

**Figure 1** (a) A convex set. (b) A nonconvex set.

the above-mentioned contribution by Fourier, this laid the groundwork for LINEAR PROGRAMMING [IV.11 §3], which emerged in the late 1940s, with key contributions by Kantorovich (1912–86) and Dantzig (1914–2005). In the second half of the twentieth century, convexity was developed further by Fenchel (1905–88), Moreau (1923–), and Rockafellar (1935–), among many others. Convexity is now a key notion in many branches of applied mathematics: it is essential in mathematical programming (to ensure convergence of optimization algorithms), functional analysis (to ensure existence and uniqueness of solutions of problems of calculus of variations and optimal control), geometry (to classify sets and their invariants, or to relate geometrical quantities), and probability and statistics (to derive inequalities).

Convex objects can be thought of as the opposite, geometrically speaking, to fractal objects. Indeed, fractal objects arise in maximization problems (sponges, lungs, batteries) and they have a rough boundary. In contrast, convex objects arise in minimization problems (isoperimetric problems, smallest energy) and they have a smoother boundary.

Mathematically, a set X is *convex* if, for all $x, y \in X$ and for all $\lambda \in [0, 1]$, $\lambda x + (1 - \lambda)y \in X$ (see figure 1). Geometrically, this means that the line segment between any two points of the set belongs to

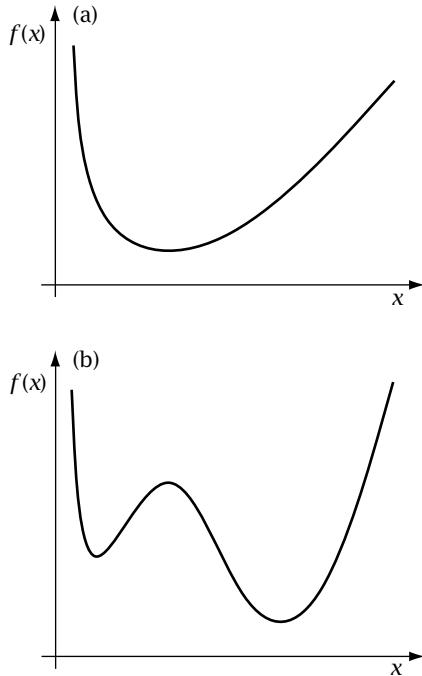

Figure 2 (a) A convex function. (b) A nonconvex function.

the set. A real-valued function $f: X \rightarrow \mathbb{R}$ is *convex* if, for all $x, y \in X$ and for all $\lambda \in [0, 1]$, it holds that $f(\lambda x + (1 - \lambda)y) \leq \lambda f(x) + (1 - \lambda)f(y)$. Geometrically, this means that the line segment between any two points on the graph of the function lies above the graph (see figure 2). This is the same as saying that the *epigraph* $\{(x, y) : x \in X, y \geq f(x)\}$ is a convex set. If a function is twice continuously differentiable, convexity of the function is equivalent to nonnegativity of the quadratic form of the matrix of second-order partial derivatives (the Hessian).

If the function f is convex, then $f(\lambda_1 x_1 + \dots + \lambda_m x_m) \leq \lambda_1 f(x_1) + \dots + \lambda_m f(x_m)$ for all $x_1, \dots, x_m \in X$ and λ in the m -dimensional unit simplex $\{\lambda \in \mathbb{R}^m : \lambda_1 + \dots + \lambda_m = 1, \lambda_1 \geq 0, \dots, \lambda_m \geq 0\}$. This is called Jensen's inequality, and more generally it can be expressed as $f(\int x \mu(dx)) \leq \int f(x) \mu(dx)$ for every probability measure μ supported on X , or equivalently as $f(E[x]) \leq E[f(x)]$, where E denotes the expectation of a random variable.

A function f is *concave* whenever the function $-f$ is convex. If a function f is both convex and concave, it is affine. For this reason, convexity can sometimes be interpreted as a one-sided linearity, and in some instances (e.g., in problems of calculus of variations

and partial differential equations), nonlinear convex functions behave similarly to linear functions.

A set X is a *cone* if $x \in X$ implies $\lambda x \in X$ for all $\lambda \geq 0$. A convex cone is therefore a set that is closed under addition and under multiplication by positive scalars. Convex cones are central in optimization, and conic programming is the minimization of a linear function over an affine section of a convex cone. Important examples of convex cones include the linear cone (also called the positive orthant), the quadratic cone (also called the Lorentz cone), and the semidefinite cone (which is the set of nonnegative quadratic forms, or, equivalently, the set of positive-semidefinite matrices).

The *convex hull* of a set X is the smallest closed convex set containing X , which is sometimes denoted by $\text{conv } X$. If X is the union of a finite number of points, then $\text{conv } X$ is the polytope with vertices among these points. A theorem by Carathéodory states that given a set $X \subset \mathbb{R}^{n-1}$, every point of $\text{conv } X$ can be expressed as $\lambda_1 x_1 + \dots + \lambda_n x_n$ for some choice of x_1, \dots, x_n in X and λ in the n -dimensional unit simplex.

A theorem of Minkowski (generalized to infinite-dimensional spaces in 1940 by Krein and Milman) states that every compact convex set is the closure of the convex hull of its extreme points (a point $x \in X$ is *extreme* if $x = (x_1 + x_2)/2$ for some $x_1, x_2 \in X$ implies $x_1 = x_2$). Finally, we mention the Brunn–Minkowski theorem, which relates the volume of the sum of two compact convex sets (all points that can be obtained by adding a point of the first set to a point of the second set) to the respective volumes of the sets.

II.9 Dimensional Analysis and Scaling

Daniela Calvetti and Erkki Somersalo

Dimensional analysis makes it possible to analyze in a systematic way dimensional relationships between

physical quantities defining a model. In order to explain how this works, we need to introduce some definitions and establish the notation that will be used below. Consider a system that contains n physical quantities, q_1, q_2, \dots, q_n , that we believe to be relevant for describing the system's behavior, the quantities being expressed using r fundamental units, or dimensions, denoted by d_1, d_2, \dots, d_r . The generally accepted SI unit system consists of $r = 7$ basic dimensions and numerous derived dimensions. More precisely, d_1 is the meter (m), d_2 the second (s), d_3 the kilogram (kg), d_4 the ampere (A), d_5 the mole (mol), d_6 the kelvin (K), and d_7 the candela (cd). The number r can be smaller, since not all units are always needed. The physical dimension of a quantity q is denoted by $[q]$.

A meaningful mathematical relation between the quantities q_j should obey the *principle of dimensional homogeneity*, which can be summarized as follows: *summing up quantities is meaningful only if all the terms have the same dimension*. Furthermore, any functional relation of the type

$$f(q_1, q_2, \dots, q_n) = 0 \quad (1)$$

should remain valid if expressed in different units. In other words, since *dimensional scaling must not change the equation*, it is natural to seek to express the relations in terms of dimensionless quantities. It is therefore not a surprise that dimensionless quantities, known as *Π -numbers*, have a central role in dimensional analysis. A canonical example of a Π -number is π , the invariant ratio of the circumference and the diameter of circles of all sizes.

Given a system described by the physical quantities q_1, q_2, \dots, q_n , we will define a Π -number, or a *dimensionless group*, to be any combination of those quantities of the form

$$R = q_1^{\mu_1} q_2^{\mu_2} \cdots q_n^{\mu_n}, \quad (2)$$

where the μ_j are *rational numbers*, not all equal to zero, and R is dimensionless. If, in such a system, we are able to identify k Π -numbers, R_1, \dots, R_k , that characterize it, we can describe it with a dimensionless version of (1) of the form

$$\varphi(R_1, R_2, \dots, R_k) = 0.$$

The advantage of the latter formulation is that it automatically satisfies the dimensional homogeneity; moreover, it does not change with any scaling of the model that leaves the values of the Π -numbers invariant. These points are best clarified by a classical example of dimensional analysis.

Consider steady fluid flow in a pipe of constant diameter D . The fluid is assumed to be incompressible, having density ρ and viscosity μ . By denoting the pressure drop across a distance L by Δp and the (average) velocity by v , we may assume that there is an algebraic relation between the quantities:

$$f(L, D, \rho, \mu, v, \Delta p) = 0. \quad (3)$$

In SI units, the dimensions of the variables involved are

$$\left. \begin{aligned} [L] &= [D] = \text{m}, & [\rho] &= \frac{\text{kg}}{\text{m}^3}, & [\mu] &= \frac{\text{kg}}{\text{m} \cdot \text{s}}, \\ [v] &= \frac{\text{m}}{\text{s}}, & [\Delta p] &= \frac{\text{kg}}{\text{m} \cdot \text{s}^2}. \end{aligned} \right\} \quad (4)$$

In his classic paper of 1883, Osborne Reynolds suggested a scaling law of the form

$$\Delta p = \rho v^2 \frac{L}{D} F\left(\frac{\rho v D}{\mu}\right), \quad (5)$$

where F is some function; Reynolds himself considered the power law $F(R) = cR^{-n}$ with different values of n and experimentally validated it. Equation (5) can be seen as a dimensionless version of (3),

$$\varphi(R_1, R_2, R_3) = 0,$$

where

$$R_1 = \frac{\rho v D}{\mu}, \quad R_2 = \frac{\Delta p}{\rho v^2}, \quad R_3 = \frac{L}{D}.$$

The quantities R_1 and R_2 are known as the *Reynolds number* and the *Euler number*, respectively, and it is a straightforward matter to check that R_1 , R_2 , and R_3 are dimensionless. The scaling law (5) has been experimentally validated in a range of geometric settings. An example of its use is the design of miniature models. If the dimensions are scaled by a factor α , $L \rightarrow \alpha L$, $D \rightarrow \alpha D$, we may assume that the flow in the miniature model gives a good prediction for the actual system if we scale the velocity and pressure as $v \rightarrow v/\alpha$ and $\Delta p \rightarrow \Delta p/\alpha^2$, leaving the dimensionless quantities intact.

In view of the above example it is natural to ask how many Π -numbers characterize a given system and if there is a systematic way of finding them. To address these questions it is important to identify possible redundancy among the physical quantities, on the one hand, and the dimensions, on the other. With this in mind we introduce the concepts of *independency* and *relevance* of the dimensions.

The dimensions d_1, \dots, d_r are *independent* if none can be expressed as a rational product of the others, that is,

$$d_1^{\alpha_1} d_2^{\alpha_2} \cdots d_r^{\alpha_r} = 1 \quad (6)$$

if and only if $\alpha_1 = \alpha_2 = \dots = \alpha_r = 0$. The dimensions d_j may be the fundamental dimensions of the SI unit system or derived dimensions, such as the newton ($N = \text{kg}/\text{m} \cdot \text{s}^2$).

It is not a coincidence that this definition strongly resembles that of linear independency in linear algebra, as will become evident later.

Let a system be described by n quantities, q_1, \dots, q_n , and r dimensions, d_1, \dots, d_r , with the dimensional dependency

$$[q_j] = d_1^{\mu_{j1}} d_2^{\mu_{j2}} \cdots d_r^{\mu_{jr}}, \quad 1 \leq j \leq n. \quad (7)$$

We say that the dimensions d_k , $1 \leq k \leq r$, are *relevant* if for each d_k there are rational coefficients α_{kj} such that

$$d_k = [q_1]^{\alpha_{k1}} [q_2]^{\alpha_{k2}} \cdots [q_n]^{\alpha_{kn}}. \quad (8)$$

In other words, the dimensions d_k are relevant if they can be expressed in terms of the dimensions of the variables q_k . It follows immediately that, if the quantities q_j can be measured, then there must exist an operational description of all units in terms of the measurements. Identifying relevant quantities may be more subtle than it seems.

For the sake of definiteness, assume that we adhere to the SI system, and denote the seven basic SI units by e_1, e_2, \dots, e_7 , the ordering being unimportant. We now proceed to define an associated dimension space: to each e_i we associate a vector $\mathbf{e}_i \in \mathbb{R}^7$, where \mathbf{e}_i is the i th unit coordinate vector. Further, we define a group homomorphism between the \mathbb{Q} -moduli of dimensions and vectors; since any dimension d can be represented in the SI system in terms of the seven basic units e_i as

$$d = e_1^{v_1} \cdots e_7^{v_7},$$

we associate d with a vector \mathbf{d} , where

$$\mathbf{d} = v_1 \mathbf{e}_1 + \cdots + v_7 \mathbf{e}_7.$$

Along these lines, we associate with a quantity q with dimensions

$$[q] = d_1^{\mu_1} \cdots d_r^{\mu_r}$$

the vector

$$\mathbf{q} = \mu_1 \mathbf{d}_1 + \cdots + \mu_r \mathbf{d}_r.$$

It is straightforward to verify that the representation of \mathbf{q} in terms of the basis vectors \mathbf{e}_j is unambiguous.

We are now ready to revisit independency of units in the light of the associated vectors. In linear algebraic terms, condition (6) is equivalent to saying that

$$\alpha_1 \mathbf{d}_1 + \cdots + \alpha_r \mathbf{d}_r = \mathbf{0},$$

and therefore *the independency of dimensions is equivalent to the linear independency of the corresponding dimension vectors*.

Next we look for a connection with linear algebra to help us reinterpret the concept of relevance. In the dimension space, condition (7) can be expressed as

$$\mathbf{q}_j = \mu_{j1} \mathbf{d}_1 + \cdots + \mu_{jr} \mathbf{d}_r = \sum_{k=1}^r \mu_{jk} \mathbf{d}_k,$$

which implies that every \mathbf{q}_j is in the subspace spanned by the vectors \mathbf{d}_k , while the linear algebraic formulation of condition (8),

$$\mathbf{d}_k = \alpha_{k1} \mathbf{q}_1 + \cdots + \alpha_{kn} \mathbf{q}_n = \sum_{\ell=1}^n \alpha_{k\ell} \mathbf{q}_{\ell},$$

states that the vectors \mathbf{d}_k are in the subspace spanned by the vectors \mathbf{q}_{ℓ} . We therefore conclude that the relevance of dimensions is equivalent to the condition that

$$\text{span}\{\mathbf{q}_1, \dots, \mathbf{q}_n\} = \text{span}\{\mathbf{d}_1, \dots, \mathbf{d}_r\}.$$

It is obvious that when $n > r$, there must be redundancy among the quantities because the subspace can be spanned by fewer than n vectors. This redundancy is indeed the key to the theory of Π -numbers.

Let us take a second look at the definition of Π -number, (2). In order for a quantity to be dimensionless, the coefficients of the dimension vectors must all vanish, which, in the new formalism, is equivalent to the corresponding dimension vector being the zero vector. In other words, equation (2) is equivalent to

$$\mu_1 \mathbf{q}_1 + \mu_2 \mathbf{q}_2 + \cdots + \mu_n \mathbf{q}_n = \mathbf{0}.$$

If we now define the *dimension matrix* of the quantities q_1, \dots, q_n to be

$$Q = (\mathbf{q}_1 \quad \mathbf{q}_2 \quad \cdots \quad \mathbf{q}_n) \in \mathbb{R}^{r \times n},$$

we can immediately verify that the vector $\mu \in \mathbb{R}^n$ with entries μ_j must satisfy $Q\mu = \mathbf{0}$, so μ must be in the null space of Q , $\mathcal{N}(Q)$.

We can now restate the definition of Π -number in the language of linear algebra: $R = q_1^{\mu_1} \cdots q_n^{\mu_n}$ is a Π -number if and only if $\mu \in \mathcal{N}(Q)$.

It is a central question in dimensional analysis how many essentially different Π -numbers can be found that correspond to a given system. If R_1 and R_2 are two Π -numbers, their product and ratio are also Π -numbers, yet they are not independent. To find out how to determine which Π -numbers are independent, assume that R_1 and R_2 correspond to vectors μ and ν in the null space of Q . From the observation that

$$R_1 \times R_2 = q_1^{\mu_1} \cdots q_n^{\mu_n} \times q_1^{\nu_1} \cdots q_n^{\nu_n} = q_1^{\mu_1 + \nu_1} \cdots q_n^{\mu_n + \nu_n},$$

it follows that multiplication of two Π -numbers corresponds to addition of the corresponding vectors in the null space of the dimension vector. This naturally leads to the definition that the Π -numbers $\{R_1, \dots, R_k\}$ are *essentially different* if the corresponding coefficient vectors in $\mathcal{N}(Q)$ are linearly independent. In particular, the number of essentially different Π -numbers is equal to the dimension of $\mathcal{N}(Q)$, and a maximal set of essentially different Π -numbers corresponds to a basis for $\mathcal{N}(Q)$.

It is now easy to state the following central theorem of dimensional analysis, which is a corollary of the theorem about the dimensions of the FOUR FUNDAMENTAL SUBSPACES [I.2 §21] of a dimension matrix.

Buckingham's Π theorem. *If a physical problem is described by n variables, with every variable expressed in terms of r independent and relevant dimensions, the number of essentially different Π -numbers (dimensionless groups whose numerical values depend on the properties of the system) is at most $n - r$.*

It is important to stress that the number of essentially different Π -numbers is “at most” $n - r$ because the system may actually admit fewer. It is a nice corollary that the Π -numbers of a system can be found by computing a basis for the null space of the dimension matrix by Gaussian elimination, which results in rational coefficients.

Returning to our example from fluid dynamics, let a system be described by the five quantities length (L), a characteristic scalar velocity (v_0), density (ρ), viscosity (μ), and pressure (p), the dimensions of which were given in (4). We characterize the system with three SI units, m, s, and kg. The dimension matrix in this case is

$$Q = \begin{pmatrix} 1 & 1 & -3 & -1 & -1 \\ 0 & -1 & 0 & -1 & -2 \\ 0 & 0 & 1 & 1 & 1 \end{pmatrix}.$$

To find a basis of the null space we reduce the matrix to its row echelon form by Gauss–Jordan elimination, which shows that its rank is three. This implies that the null space is two dimensional, with a basis consisting of the two vectors

$$\mathbf{u}_1 = \begin{pmatrix} 1 \\ 1 \\ 1 \\ -1 \\ 0 \end{pmatrix}, \quad \mathbf{u}_2 = \begin{pmatrix} 0 \\ -2 \\ -1 \\ 0 \\ 1 \end{pmatrix},$$

corresponding to the Reynolds number and the Euler number, respectively:

$$R_1 = L^1 v_0^1 \rho^1 \mu^{-1} p^0, \quad R_2 = L^0 v_0^2 \rho^{-1} \mu^0 p^1.$$

To appreciate the usefulness of finding these Π -numbers, consider the nondimensionalization of the NAVIER–STOKES EQUATION [III.23],

$$\rho \left(\frac{\partial \mathbf{v}}{\partial t} + \mathbf{v} \cdot \nabla \mathbf{v} \right) = -\nabla p + \mu \Delta \mathbf{v},$$

where $\Delta = \nabla \cdot \nabla$. Assuming that a characteristic speed v_0 (e.g., an asymptotic value) and a characteristic length scale L are given, first we nondimensionalize the velocity and the spatial variable, writing

$$\mathbf{v} = v_0 \boldsymbol{\vartheta}, \quad \mathbf{x} = L \boldsymbol{\xi},$$

and then we define a dimensionless pressure field based on the nondimensionality of the Euler number R_2 ,

$$\pi(\boldsymbol{\xi}) = \frac{1}{\rho v_0^2} p(L \boldsymbol{\xi}),$$

arriving at the scaled version of the equation:

$$\frac{\rho v_0^2}{L} \left(\frac{L}{v_0} \frac{\partial \boldsymbol{\vartheta}}{\partial t} + \boldsymbol{\vartheta} \cdot \nabla' \boldsymbol{\vartheta} \right) = -\frac{\rho v_0^2}{L} \nabla' \pi + \frac{\mu v_0}{L^2} \Delta' \boldsymbol{\vartheta},$$

where $\nabla' = \nabla \boldsymbol{\xi}$ and $\Delta' = \nabla' \cdot \nabla'$. By going further and defining the time in terms of the characteristic timescale L/v_0 ,

$$t = \frac{L}{v_0} \tau,$$

the nondimensional version of the Navier–Stokes equation ensues:

$$\frac{\partial \boldsymbol{\vartheta}}{\partial \tau} + \boldsymbol{\vartheta} \cdot \nabla' \boldsymbol{\vartheta} = -\nabla' \pi + \frac{1}{R_1} \Delta' \boldsymbol{\vartheta}.$$

This form provides a natural justification for the different approximations corresponding to, for example, nonviscous fluid flow (R_1 large) or nonturbulent flow (R_1 small).

II.10 The Fast Fourier Transform

Daniel N. Rockmore

In 1965 James Cooley and John Tukey wrote a brief article (a note, really) that laid out an efficient method for computing the various trigonometric sums necessary for computing or approximating the Fourier transform of a function on the real line. While theirs was not the first such article (it was later discovered that the algorithm's fundamental step was first sketched in papers of Gauss), what was very different was the context. Newly invented analog-to-digital converters had now enabled the accumulation of (for the time) extraordinarily large data sets of sampled time series, whose analysis required the computation of the underlying signal's Fourier transform. In this new world of 1960s "big data," a clever reduction in computational complexity (a term not yet widely in use) could make a tremendous difference.¹

While the Cooley-Tukey approach is what is usually associated with the phrase "fast Fourier transform" (or "FFT"), this term more correctly refers to a family of algorithms designed to accomplish the efficient calculation of the FOURIER TRANSFORM [II.19] (or an approximation thereof) of a real-valued function f sampled at points x_j (on either the real line, the unit interval, or the unit circle): samples go in and Fourier coefficients are returned. The discrete sums of interest

$$\hat{f}(k) = \sum_{j=0}^{n-1} f(j) \omega_n^{jk} \quad (1)$$

computed for each $k = 0, \dots, n - 1$, where $\omega_n = e^{2\pi i/n}$ is a primitive n th root of unity and $f(j) = f(x_j)$, make up what is usually called the "discrete Fourier transform" (DFT). This can be written succinctly as the outcome of the matrix-vector multiplication

$$\hat{f} = \Omega f, \quad (2)$$

where the (j, k) element of Ω is ω_n^{jk} .

1 The Cooley-Tukey FFT

If computed directly, the DFT requires n^2 multiplications and $n(n-1)$ additions, or $2n^2 - n$ arithmetic operations (assuming the $f(j)$ values and the powers of the

1. Many years later Cooley told me that he believed that the fast Fourier transform could be thought of as one of the inspirations for asymptotic algorithmic analysis and the study of computational complexity, as previous to the publication of his paper with Tukey very few people had considered data sets large enough to suggest the utility of an asymptotic analysis.

root of unity have been precomputed and stored). Note that this is approximately $2n^2$ (and, asymptotically, $O(n^2)$) operations. The "classical" FFT (i.e., the Cooley-Tukey FFT) can be employed in the case in which n can be factored, $n = pq$, whereupon we can take advantage of a concomitant factorization of the calculation (which, in turn, is a factorization of the matrix Ω) that can be cast as a DIVIDE AND CONQUER ALGORITHM [I.4 §3], writing the DFT of order n as p DFTs of order q (or q DFTs of order p). More explicitly, in this case we can write

$$j = j(a, b) = aq + b, \quad 0 \leq a < p, \quad 0 \leq b < q,$$

$$k = k(c, d) = cp + d, \quad 0 \leq c < q, \quad 0 \leq d < p,$$

so that (1) can be rewritten as

$$\hat{f}(c, d) = \sum_{b=0}^{q-1} \omega_n^{b(cp+d)} \sum_{a=0}^{p-1} f(a, b) \omega_p^{ad} \quad (3)$$

using the fact that $\omega_n^{adq} = \omega_p^{ad}$.

Computation of \hat{f} is now performed in two steps.

First, compute for each b the inner sums (for all d)

$$\tilde{f}(b, d) = \sum_{a=0}^{p-1} f(a, b) \omega_p^{ad}, \quad (4)$$

which have the form of DFTs of length p equispaced among multiples of q . In engineering language, (4) would be called "a subsampled DFT of length p ."

Direct calculation of all the $\tilde{f}(b, d)$ requires $pq[p + (p - 1)]$ arithmetic operations. Step two is to then compute an additional pq transforms of length q ,

$$\hat{f}(c, d) = \sum_{b=0}^{q-1} \omega_n^{b(cp+d)} \tilde{f}(b, d),$$

requiring at most an additional $pq[q + (q - 1)]$ operations to complete the calculation. Thus, instead of the approximately $2n^2 = 2(pq)^2$ operations required by direct computation, the above algorithm uses approximately $2(pq)(p + q)$ operations. If n can be factored further, this approach works even better. When n is a power of two, the successive splittings of the calculation give the well-known $O(n \log_2 n)$ complexity result (in comparison to $O(n^2)$).

Since $\Omega^* \Omega = nI$, from (2) we have $f = n^{-1} \Omega^* \hat{f}$, so the discretized function $f = (f(0), \dots, f(n - 1))$ (sample values) can be recovered from its Fourier coefficients via

$$f(m) = \frac{1}{n} \sum_k \hat{f}(k) \omega_n^{-mk},$$

a so-called inverse transform. The inverse transform expresses f as a superposition of (sampled) exponentials or, equivalently, sines and cosines of frequencies that are multiples of $2\pi/n$, so that if we think of f as a function of time, the DFT is a change of basis from the “time domain” to the “frequency domain.”

In the case in which $n = 2N - 1$ and the $f(x_j)$ represent equispaced samples of a bandlimited function on the circle (or, equivalently, on the unit interval), so that $x_j = j/n$, and of bandlimit N (i.e., $\hat{f}(k) = 0$ for all $k > N$), then (up to a normalization) the sums exactly compute the Fourier coefficients of the function f (suitably indexed). The form of the inverse transform can itself be restated as a DFT, so that an FFT enables the efficient change of basis between the time and frequency domains.

The utility of an efficient algorithm for computing these sums cannot be overstated—occupying as it does a central position in the world of SIGNAL PROCESSING [IV.35], IMAGE PROCESSING [VII.8], and INFORMATION PROCESSING [IV.36]—not only for the intrinsic interest in the Fourier coefficients (say, in various forms of spectral analysis, especially for time series) but also for their use in effecting an efficient convolution of data sequences via the relation (for two functions on n points)

$$\widehat{(f \star g)}(k) = \hat{f}(k)\hat{g}(k),$$

where

$$(f \star g)(k) = \sum_{m=0}^{n-1} f(k-m)g(m). \quad (5)$$

If computed directly for all k , (5) requires $n[n + (n - 1)] = O(n^2)$ operations. An efficient FFT-based convolution is effected by first computing \hat{f} and \hat{g} , then using n operations for pointwise multiplication of the transformed sequences, and then using another FFT for the efficient inverse transform back to the time domain.

This relationship is the key to FFTs that work for data streams of prime length p . The best-known ideas make use of rewriting the DFT at nonzero frequencies in terms of a convolution of length $p - 1$ and then computing the DFT at the zero frequency directly. One well-known example is Rader’s prime FFT, which uses the fact that we can find a generator g of $\mathbb{Z}/p\mathbb{Z}^\times$, a cyclic group (under multiplication) of order $p - 1$, to write $\hat{f}(g^{-b})$ as

$$\hat{f}(g^{-b}) = f(0) + \sum_{a=0}^{p-2} f(g^a)e^{2\pi i g^{a-b}/p}. \quad (6)$$

The summation in (6) has the form of a convolution of length $p - 1$ of the sequence $f'(a) = f(g^a)$ with the function $z(a) = e^{2\pi i g^a/p}$.

Through the use of these kinds of reductions—contributions by various members of the “FFT family”—we achieve a general $O(n \log_2 n)$ algorithm.

II.11 Finite Differences

In the definition of the derivative of a real function f of a real variable, $f'(x) = \lim_{\varepsilon \rightarrow 0} (f(x + \varepsilon) - f(x))/\varepsilon$, we can take a small positive $\varepsilon = h > 0$ and form the approximation

$$f'(x) \approx \frac{f(x + h) - f(x)}{h}.$$

This process is called *discretization* and the approximation is called a *forward difference* because we evaluate f at a point to the right of x . We could instead take a small negative ε , so that with $h = -\varepsilon$ we have

$$f'(x) = \frac{f(x - h) - f(x)}{-h} = \frac{f(x) - f(x - h)}{h}.$$

The latter approximation is a *backward difference*. Higher derivatives can be approximated in a similar fashion. An example is the *centered second difference* approximation

$$f''(x) \approx \frac{f(x + h) - 2f(x) + f(x - h)}{h^2}.$$

The term *finite differences* is used to describe such approximations to derivatives by linear combinations of function values. One way to derive finite-difference approximations, and also to analyze their accuracy, is by manipulating TAYLOR SERIES [I.2 §9] expansions. A more systematic approach is through the *calculus of finite differences*, which is based on operators such as the *forward difference operator* $\Delta f(x) = f(x + h) - f(x)$ and its powers: $\Delta^2 f(x) = \Delta(\Delta f(x)) = f(x + 2h) - 2f(x + h) + f(x)$.

$2h) - 2f(x + h) + f(x)$ and so on. The term “calculus” is used because there are many analogies between these operators and the differentiation operator. Finite-difference calculus is thoroughly developed in classical numerical analysis texts of the last century, but it is less commonly encountered nowadays.

Finite differences can be used to approximate partial derivatives in an analogous way. For example, if $f(x, y)$ is a function of two variables, then

$$\frac{\partial f}{\partial x}(x, y) \approx \frac{f(x + \varepsilon, y) - f(x, y)}{\varepsilon}.$$

Finite differences are widely used in numerical methods for solving ORDINARY DIFFERENTIAL EQUATIONS [IV.12] and PARTIAL DIFFERENTIAL EQUATIONS [IV.13].

II.12 The Finite-Element Method

The finite-element method is a method for approximating the solution of a partial differential equation (PDE) with boundary conditions over a given domain using piecewise polynomial approximations to the unknown function. The domain is partitioned into elements, typically triangles for a two-dimensional region or tetrahedrons in three dimensions, and on each element the solution is approximated by a low-degree polynomial. The approximations are obtained by solving a variational form of the PDE within the corresponding finite-dimensional subspace, which reduces to solving a sparse linear system of equations for the coefficients.

For more on the finite-element method, see NUMERICAL SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS [IV.13 §4] and MECHANICS OF SOLIDS [IV.32 §4.2].

II.13 Floating-Point Arithmetic

Nicholas J. Higham

The real line, \mathbb{R} , contains infinitely many numbers, but in many practical situations we must work with a finite subset of the real line. For example, computers have a finite number of storage locations in their random access memory, so they can represent only a finite set of numbers, whereas in a bank savings account amounts of money are recorded to two decimal places (dollars and cents, for example) and may be limited to some maximum value. In the latter situation, assuming a representation with n base-10 digits, all possible numbers can be expressed as $\pm d_1 d_2 \dots d_{n-2}.d_{n-1} d_n$, where the d_i are integers between 0 and 9. This is called a *fixed-point number system* because the decimal point

Figure 1 The ticks denote the nonnegative numbers in the simple floating-point number system (1).

is in a fixed position, here just before the $(n - 1)$ st digit. A *floating-point number system* differs in that an extra multiplicative term that is a variable power of the base allows the decimal point (or its analogue for other bases) to move around.

A simple example of a floating-point number system is the set of numbers, with base 2,

$$x = \pm 2^e \left(\frac{d_1}{2} + \frac{d_2}{4} + \frac{d_3}{8} \right) = \pm 2^e f, \quad (1)$$

where the exponent $e \in \{-1, 0, 1, 2, 3\}$, and each binary digit d_i is either 0 or 1. The number $f = (0.d_1 d_2 d_3)_2$ is called the *significand* (or mantissa). If we assume that $d_1 \neq 0$ (hence $d_1 = 1$) then each x in the system has a unique representation (1) and the system is called *normalized*. The nonnegative numbers in this system are

$$0, 0.25, 0.3125, 0.3750, 0.4375, 0.5, 0.625, 0.750, 0.875, 1.0, 1.25, 1.50, 1.75, 2.0, 2.5, 3.0, 3.5, 4.0, 5.0, 6.0, 7.0,$$

and they are represented pictorially in figure 1.

Notice that the spacing of the numbers in this example increases by a factor 2 at every power of 2. It is a very important feature of all floating-point number systems that the spacing of the numbers is not constant (whereas for fixed-point systems the spacing is constant).

Other floating-point number systems are obtained by varying the range of values that the exponent e can take, by varying the number of digits d_i in the significand, and by varying the base. Historically, computers have mainly used base 16 or base 2. Pocket calculators instead use base 10, in order to avoid users being confused by the effects of the errors in converting from one base to another.

To use a floating-point number system, F , for practical computations, we need to put our data into it. Some real numbers can be exactly represented in F , while others can only be approximated. How should the conversion from \mathbb{R} to F be done, and how large an error is committed? The mapping from \mathbb{R} to F is called *rounding* and is denoted by “fl.” The usual definition of $\text{fl}(x)$, for $x \in \mathbb{R}$, is that it is the nearest number in F to x . A rule is needed to break ties when x lies midway between two members of F ; the most common rule is to take

whichever number has an even last digit in the significand. Following this rule in our toy system (1), we have $\text{fl}(1.1) = 1.0$ and $\text{fl}(5.5) = 6.0 = 2^3(0.110)_2$. If x has magnitude greater than the magnitude of every number in F then we say $\text{fl}(x)$ overflows, while if $x \neq 0$ rounds to zero we say that $\text{fl}(x)$ underflows.

Let F be a floating-point system with base β and t digits d_i . It is possible to prove that, if $|x|$ lies between the smallest nonzero number in F and the largest number in F , then $\text{fl}(x) = x(1 + \delta)$ with $|\delta| \leq u$, where $u = \frac{1}{2}\beta^{1-t}$ is called the *unit roundoff*. This means that the relative error in representing x in F is at most u . For example, in our toy system we can represent π with relative error at most $\frac{1}{2}2^{1-3} = \frac{1}{8}$.

When we multiply two t -digit numbers $x_1, x_2 \in F$ the product has $2t - 1$ or $2t$ significant digits, and thus in general is not itself in F . The best we can do is to round the result and take that as our approximation to the product: $y = \text{fl}(x_1 x_2)$. Similarly, addition, subtraction, and division of numbers in F also generally incur errors. If again we take the rounded version of the exact result then we can say that

$$\text{fl}(x \text{ op } y) = (x \text{ op } y)(1 + \delta), \quad |\delta| \leq u, \quad (2)$$

for $\text{op} = +, -, *, /$.

Virtually all today's computers implement floating-point arithmetic in conformance with a 1985 IEEE standard. This standard defines two forms of base-2 floating-point arithmetic: one called single precision, with $t = 24$, and one called double precision, with $t = 53$. In IEEE arithmetic the elementary operations $+$, $-$, $*$, and $/$ are defined to be the rounded exact operations, and so (2) is satisfied. This makes (2) a very useful tool for analyzing the effects of rounding errors on numerical algorithms.

Historically, (2) has been just a model for floating-point arithmetic—an assumption on which analysis was based. Prior to the widespread adoption of the IEEE standard, different computer manufacturers used different forms of arithmetic, some of which did not satisfy (2) or lacked certain other desirable properties. This led to bizarre situations such as the expression $x/\sqrt{x^2 + y^2}$ occasionally evaluating to a floating-point number greater than 1. Fortunately, the IEEE standard ensures that elementary floating-point computations retain many of the properties of arithmetic. However, special-purpose processors, such as graphics processing units (GPUs), do not necessarily (fully) comply with the IEEE standard.

It is often thought that subtraction of nearly equal floating-point numbers is dangerous because of cancellation. In fact, the subtraction is done exactly. Indeed, if x and y are floating-point numbers with $y/2 \leq x \leq 2y$ then $\text{fl}(x - y) = x - y$ (as long as $x - y$ does not underflow). The danger of cancellation is that it causes a loss of significant digits and can thereby bring into prominence errors committed in earlier computations. A classic example is the usual formula for solving a quadratic equation such as $x^2 - 56x + 1 = 0$, which gives $x_1 = 28 + \sqrt{783}$ and $x_2 = 28 - \sqrt{783}$. Working to four significant decimal digits, $\sqrt{783} = 27.98$, and therefore the computed results are $\hat{x}_1 = 55.98 = 5.598 \times 10^1$ and $\hat{x}_2 = 0.02 = 2.000 \times 10^{-2}$. However, the correct results to four significant digits are $x_1 = 5.598 \times 10^1$ and $x_2 = 1.786 \times 10^{-2}$. So while the larger computed root has all four digits correct, the smaller one is very inaccurate due to cancellation. Fortunately, since $x^2 - 56x + 1 = (x - x_1)(x - x_2)$, the product of the roots is 1, and so we can obtain an accurate value for the smaller root x_2 from $x_2 = 1/x_1$.

II.14 Functions of Matrices

Nicholas J. Higham

Given the scalar function $f(x) = (x-1)/(1+x^2)$ we can define $f(A)$ for an $n \times n$ matrix A by $f(A) = (A-I)(I+A^2)^{-1}$, as long as A does not have $\pm i$ as an eigenvalue, so that $I + A^2$ is nonsingular. This notion of “replacing x by A ” is very natural and produces useful results. For example, we can define the exponential of A by

$$e^A = I + A + \frac{A^2}{2!} + \frac{A^3}{3!} + \dots$$

The resulting function satisfies analogues of the properties of the scalar exponential, such as $e^A e^{-A} = I$, $e^A = \lim_{s \rightarrow \infty} (I + A/s)^s$, and $(d/dt)e^{At} = Ae^{At} = e^{At}A$. Thanks to the latter relation, the matrix exponential plays a fundamental role in linear differential equations. In particular, the general solution to $dy/dt = Ay$ is $y(t) = e^{At}c$, for a constant vector c . However, not every scalar relation generalizes. In particular, $e^{A+B} =$

$e^A e^B$ holds if A and B commute, but it does not hold in general.

More generally, for any function with a Taylor series expansion the scalar argument can be replaced by a square matrix as long as the eigenvalues of the matrix are within the radius of convergence of the Taylor series. Thus we have

$$\begin{aligned}\cos(A) &= I - \frac{A^2}{2!} + \frac{A^4}{4!} - \frac{A^6}{6!} + \dots, \\ \sin(A) &= A - \frac{A^3}{3!} + \frac{A^5}{5!} - \frac{A^7}{7!} + \dots, \\ \log(I + A) &= A - \frac{A^2}{2} + \frac{A^3}{3} - \frac{A^4}{4} + \dots, \quad \rho(A) < 1,\end{aligned}$$

where ρ denotes the SPECTRAL RADIUS [I.2 §20]. The series for \log raises two questions: does $X = \log(I + A)$ satisfy $e^X = I + A$ and, if so, which of the many matrix logarithms is produced (note that if $e^X = I + A$ then $e^{X+2k\pi i} = e^X e^{2k\pi i} = I + A$ for any integer k)? The answer to the first question is yes. The answer to the second question is that the logarithm produced is the *principal logarithm*, which for a matrix with no eigenvalues lying on the nonpositive real axis is the unique logarithm all of whose eigenvalues have imaginary parts lying in the interval $(-\pi, \pi)$.

Defining $f(A)$ via a power series may specify the function only for a certain range of A , as for the logarithm, and moreover, some functions do not have a (convenient) power series. For more general functions a different approach is needed.

If f is analytic on and inside a closed contour Γ that encloses the spectrum of A , then we can define

$$f(A) := \frac{1}{2\pi i} \int_{\Gamma} f(z)(zI - A)^{-1} dz,$$

which is a generalization to matrices of the CAUCHY INTEGRAL FORMULA [IV.1 §7]. Another definition can be given in terms of the JORDAN CANONICAL FORM [II.22] $Z^{-1}AZ = J = \text{diag}(J_1, J_2, \dots, J_p)$, where J_k is an $m_k \times m_k$ Jordan block with eigenvalue λ_k . The definition is

$$f(A) := Zf(J)Z^{-1} = Z \text{diag}(f(J_k))Z^{-1},$$

where

$$f(J_k) := \begin{bmatrix} f(\lambda_k) & f'(\lambda_k) & \cdots & \frac{f^{(m_k-1)}(\lambda_k)}{(m_k-1)!} \\ & f(\lambda_k) & \ddots & \vdots \\ & & \ddots & f'(\lambda_k) \\ & & & f(\lambda_k) \end{bmatrix}.$$

This definition does not require f to be analytic but merely requires the existence of the derivatives $f^{(j)}(\lambda_k)$ for j up to one less than the size of the largest

block in which λ_k appears. Note that when A is diagonalizable, that is, $A = ZDZ^{-1}$ for $D = \text{diag}(\lambda_i)$, the definition is simply $f(A) = Zf(D)Z^{-1}$, where $f(D) = \text{diag}(f(\lambda_i))$.

The Cauchy integral and Jordan canonical form definitions are equivalent when f is analytic.

Some key properties that follow from the definitions are that $f(A)$ commutes with A , $f(X^{-1}AX) = X^{-1}f(A)X$ for any nonsingular X , and $f(A)$ is upper (lower) triangular if A is. It can also be shown that certain forms of identity carry over from the scalar case to the matrix case, under assumptions that ensure that all the relevant matrices are defined. Examples are $\exp(iA) = \cos(A) + i\sin(A)$ and $\cos^2(A) + \sin^2(A) = I$. However, care is needed when dealing with multi-valued functions; for example, for the principal logarithm, $\log(e^A)$ cannot be guaranteed to equal A without restrictions on the spectrum of A .

Another important class of functions is the p th roots: the solutions of $X^p = A$, where p is a positive integer. For nonsingular A there are many p th roots. The one usually required in practice is the *principal p th root*, defined for A with no eigenvalues lying on the nonpositive real axis as the unique p th root whose eigenvalues lie strictly within the wedge making an angle π/p with the positive real axis, and denoted by $A^{1/p}$. Thus $A^{1/2}$ is the square root whose eigenvalues all lie in the open right half-plane.

The function $\text{sign}(A) = A(A^2)^{-1/2}$, defined for any A having no pure imaginary eigenvalues, is the *matrix sign function*. It has applications in control theory, in particular for solving ALGEBRAIC RICCATI EQUATIONS [III.25], and corresponds to the scalar function mapping complex numbers in the open left and right half-planes to -1 and 1 , respectively.

Matrix functions provide one-line solutions to many problems. For example, the second-order ordinary differential equation initial-value problem

$$\frac{d^2y}{dt^2} + Ay = 0, \quad y(0) = y_0, \quad y'(0) = y'_0,$$

with y an n -vector and A an $n \times n$ matrix, has solution

$$y(t) = \cos(\sqrt{A}t)y_0 + (\sqrt{A})^{-1} \sin(\sqrt{A}t)y'_0,$$

where \sqrt{A} denotes *any* square root of A . Alternatively, by writing $z = \begin{bmatrix} y' \\ y \end{bmatrix}$ we can convert the problem into two first-order differential equations:

$$z' = \begin{bmatrix} y'' \\ y' \end{bmatrix} = \begin{bmatrix} 0 & -A \\ I & 0 \end{bmatrix} \begin{bmatrix} y' \\ y \end{bmatrix} = \begin{bmatrix} 0 & -A \\ I & 0 \end{bmatrix} z,$$

from which follows the formula

$$\begin{bmatrix} y'(t) \\ y(t) \end{bmatrix} = \exp \left(\begin{bmatrix} 0 & -tA \\ tI & 0 \end{bmatrix} \right) \begin{bmatrix} y'_0 \\ y_0 \end{bmatrix}.$$

There is an explicit formula for a function of a 2×2 triangular matrix:

$$f \left(\begin{bmatrix} \lambda_1 & \alpha \\ 0 & \lambda_2 \end{bmatrix} \right) = \begin{bmatrix} f(\lambda_1) & \alpha f[\lambda_1, \lambda_2] \\ 0 & f(\lambda_2) \end{bmatrix},$$

where

$$f[\lambda_1, \lambda_2] = \begin{cases} \frac{f(\lambda_2) - f(\lambda_1)}{\lambda_2 - \lambda_1}, & \lambda_1 \neq \lambda_2, \\ f'(\lambda_2), & \lambda_1 = \lambda_2, \end{cases}$$

is a first-order divided difference. This formula extends to $n \times n$ triangular matrices T , although the formula for the (i, j) element contains up to 2^n terms and so is not computationally useful unless n is very small. It is nevertheless possible to compute $F = f(T)$ for an $n \times n$ triangular matrix in $n^3/3$ operations using the *Parlett recurrence*, which is obtained by equating elements in the equation $TF = FT$.

II.15 Function Spaces

Hans G. Feichtinger

While in the early days of mathematics each function was treated individually, it became appreciated that it was more appropriate to make collective statements for all continuous functions, all integrable functions, or all continuously differentiable ones. Fortunately, most of these collections of functions (f_k) are closed under addition and allow the formation of linear combinations $\sum_{k=1}^K c_k f_k$ for real or complex coefficients c_k , $1 \leq k \leq K$. They are, therefore, vector spaces. In addition, most of these spaces are endowed with a suitable NORM [I.2 §19.3] $f \mapsto \|f\|$, allowing one to measure the size of their members and hence to introduce concepts of closeness by looking at the distance $d(f_1, f_2) := \|f_1 - f_2\|$. One can therefore say that a *function space* is a normed space consisting of (generalized) functions on some domain.

For the vector space $C_b(D)$ of bounded and continuous functions on some domain $D \subset \mathbb{R}^d$, the sup-norm

$\|f\|_\infty := \sup_{z \in D} |f(z)|$ is the appropriate norm. With this norm, $C_b(D)$ is a Banach space (that is, a complete normed space), i.e., every CAUCHY SEQUENCE [I.2 §19.4] with respect to this norm is convergent to a unique limit element in the space. Hence, such Banach spaces of functions share many properties with the Euclidean spaces of vectors in \mathbb{R}^d , with the important distinction that they are not finite dimensional.

1 Lebesgue Spaces $L^p(\mathbb{R}^d)$

The completeness of the *Lebesgue space* $L^1(\mathbb{R}^d)$, consisting of all (measurable) functions with $\|f\|_1 := \int_{\mathbb{R}^d} |f(z)| dz < \infty$, is the reason why the Lebesgue integral is preferred over the Riemann integral. Note that in order to ensure the property that $\|f\|_1 = 0$ implies $f = 0$ (the null function), one has to regard two functions f_1 and f_2 as equal if they are equal up to a set of measure zero, i.e., if the set $\{z \mid f_1(z) \neq f_2(z)\}$ has Lebesgue measure zero.

Another norm that is important for many applications is the L^2 -norm, $\|f\|_2 := (\int_{\mathbb{R}^d} |f(z)|^2)^{1/2}$. It is related to an inner product defined as $\langle f, g \rangle := \int_{\mathbb{R}^d} f(z)g(z) dz$ via the formula $\|f\|_2 := \langle f, f \rangle^{1/2}$. $(L^2(\mathbb{R}^d), \|\cdot\|_2)$ is a Hilbert space, and one can talk about orthogonality and unitary linear mappings, comparable with the situation of the Euclidean space \mathbb{R}^d with its standard inner product.

Having these three norms, namely $\|\cdot\|_1$, $\|\cdot\|_2$, and $\|\cdot\|_\infty$, it is natural to look for norms “in between.” This leads to the L^p -spaces, defined by the finiteness of $\|f\|_p^p := \int_{\mathbb{R}^d} |f(z)|^p dz$ for $1 \leq p < \infty$. The limiting case for $p \rightarrow \infty$ is the space $L^\infty(\mathbb{R}^d)$ of essentially bounded functions.

Since these spaces are not finite dimensional, it is necessary to work with the set of all bounded linear functionals, the so-called dual space, which is often, but not always, a function space. For $1 \leq p < \infty$ the dual space to L^p is L^q , with $1/p + 1/q = 1$, meaning that any continuous linear functional on $L^p(\mathbb{R}^d)$ has the form $f \mapsto \int_{\mathbb{R}^d} f(z)g(z) dz$ for a unique function $g \in L^q(\mathbb{R}^d)$.

$L^1(\mathbb{R}^d)$ also appears as the natural domain for the Fourier transform, given for $s \in \mathbb{R}^d$ by

$$\mathcal{F}: f \mapsto \hat{f}(s) = \int_{\mathbb{R}^d} f(t) \exp \left\{ -2\pi i \sum_{j=1}^d s_j t_j \right\} dt,$$

while $(L^2(\mathbb{R}^d), \|\cdot\|_2)$ allows us to describe \mathcal{F} as a *unitary* (and hence isometric) automorphism.

2 Related Function Spaces

The Lebesgue spaces are prototypical for a much larger class of *Banach function spaces* or *Banach lattices*, a class that also includes *Lorentz spaces* $L(p, q)$ or *Orlicz spaces* L^Φ , which are all *rearrangement invariant*. This means that for any transformation $\alpha: \mathbb{R}^d \rightarrow \mathbb{R}^d$ that has the property that it preserves the (Lebesgue) measure $|M|$ of a set, i.e., with $|\alpha(M)| = |M|$, one has $\|f\| = \|\alpha^*(f)\|$, where $\alpha^*(f)(z) := f(\alpha(z))$.

In contrast, *weighted spaces* such as $L_w^p(\mathbb{R}^d)$, characterized by $\|f\|_{p,w} = \|fw\|_p < \infty$, allow us to capture the decay of f at infinity using some strictly positive *weight function* w . For applications in the theory of partial differential equations (PDEs), polynomial weights such as $w_s(x) = (1 + |x|^2)^{s/2}$ are important. For $s \geq 0$, *Sobolev spaces* $\mathcal{H}_s(\mathbb{R}^d)$ can be defined as inverse images of $L_{w_s}^2(\mathbb{R}^d)$ under the Fourier transform. For $s \in \mathbb{N}$ they consist of those functions that have (in a distributional sense) s derivatives in $L^2(\mathbb{R}^d)$. *Mixed norm* L^p spaces (using different p -norms in different directions) are also not invariant in this sense, but they are still very useful.

A large variety of function spaces arose out of the attempt to characterize smoothness, including fractional differentiability. Examples are *Besov spaces* $B_{p,q}^s(\mathbb{R}^d)$ and *Triebel-Lizorkin spaces* $F_{p,q}^s(\mathbb{R}^d)$; the classical Sobolev spaces are the only function spaces that belong to both families. The origin of this theory is in the theory of Lipschitz spaces $\text{Lip}(\alpha)$, where the range $\alpha \in (0, 1)$ allows us to express the degree of smoothness (differentiability corresponds intuitively to the case $\alpha = 1$).

3 Wavelets and Modulation Spaces

Many of the spaces mentioned above are highly relevant for PDEs, e.g., the description of elliptic PDEs. Their characterization using Paley-Littlewood (dyadic Fourier) decompositions has ignited wavelet theory. For $1 < p < \infty$ they can be characterized via (weighted) summability conditions of their wavelet coefficients with respect to (sufficiently “good”) mother wavelets. In the limiting case, one obtains the *real Hardy space* $H^1(\mathbb{R}^d)$ and its dual, the BMO-space, which consists of functions of *bounded mean oscillation*. Both spaces are important for the study of Calderon-Zygmund operators or the Hardy-Littlewood maximal operator. Wavelets provide unconditional bases for these spaces, including *Besov* and *potential* spaces.

For the affine “ $ax + b$ ”-group acting on the space $L^2(\mathbb{R}^d)$, function spaces are defined using the continuous wavelet transform, and atomic characterizations (involving *Banach frames*) of the above smoothness spaces are obtained. Alternatively, the Schrödinger representation of the Heisenberg group, again on $L^2(\mathbb{R}^d)$ via time-frequency shifts, gives rise to the family of *modulation spaces* $M_{p,q}^s$. They were introduced as *Wiener amalgam spaces* on the Fourier transform side, using uniform partitions of unity (instead of dyadic ones).

Using engineering terminology, the now-classical spaces $M_{p,q}^s(\mathbb{R}^d)$ are characterized by the behavior of the *short-time Fourier transform* of their members (replacing the continuous wavelet transform). They play an important role in time-frequency analysis, and their atomic characterizations use *Gabor expansions*.

A variety of Banach spaces of analytic or polyanalytic functions play an important role in complex analysis. Again, integrability conditions over their domain are typically used to define these spaces. The corresponding L^2 -spaces are typically reproducing kernel Hilbert spaces, with good localization of these kernels allowing one to view them as continuous mappings on (weighted, mixed-norm) L^p -spaces as well. We mention some of the spaces that are important in the context of complex analysis or Toeplitz operators: Fock spaces, Bergman spaces, and Segal-Bargmann spaces.

4 Variations of the Theme

One of the first important examples of a Banach space of functions was the space *BV* of functions of *bounded variation*. One simple characterization of functions of this type (the so-called Jordan decomposition) is that they are the difference of two bounded and nondecreasing functions (the ascending part of the function minus the descending part of it). Via Fourier-Stieltjes integrals, F. Riesz showed that there is a one-to-one correspondence between the dual space of $(C[0, 1], \|\cdot\|_\infty)$ and $BV[0, 1]$ endowed with the variation norm. More recently, total variation in a two-dimensional setting has been fundamental to IMAGE RESTORATION ALGORITHMS [VII.8]. Another family of function spaces that captures variation at different scales are the Morrey-Campanato spaces.

In addition to Banach spaces of functions there are also topological vector spaces and Fréchet spaces of functions, among them the *spaces of test functions* that are used in distribution theory. *Generalized functions*

consist of the continuous linear functionals on such spaces. The “theory of function spaces” as developed by Hans Triebel includes a large variety of Banach spaces of such generalized functions (or distributions).

II.16 Graph Theory

Timothy A. Davis and Yifan Hu

At the back of most airline magazines you will find a map of airports and the airline routes that connect them. This is just one example of a *graph*, a widely used mathematical entity that represents relationships between discrete objects. More precisely, a graph $G = (V, E)$ consists of a set of *nodes* V and a set of *edges* $E \subseteq \{(i, j) \mid i, j \in V\}$ that connect them. A graph is not a diagram but it can be drawn, as illustrated in figure 1.

Graphs arise in a vast array of applications, including social networks (a node is a person and an edge is a relationship between two people), computational fluid dynamics (a node is an unknown such as the pressure at a certain point and an edge is the physical connection between two unknowns), finding things on the web (a node is a web page and an edge is a link), circuit simulation (the wires are the edges), economics (a node is a financial entity and the edges represent trade between two entities), and many others.

In some problems, an edge connects in both directions, and in this case the graph is *undirected*. For example, friendship is mutual, so if Alice and Bob are friends, the edges (Alice, Bob) and (Bob, Alice) are the same. In other cases, the direction of the edge is important. If Alice follows Bob on Twitter, this does not mean that Bob follows Alice. In this *directed* graph, the edge (Alice, Bob) is not the same as the edge (Bob, Alice).

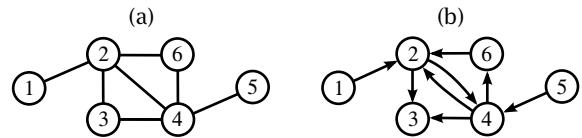

Figure 1 Two example graphs:
(a) undirected and (b) directed.

In a *simple* graph, an edge (i, j) can appear just once, but in a *multigraph* it can appear multiple times (E becomes a multiset). Simple graphs do not have *self-edges* (i, i) , but a *pseudograph* can have multiple edges and self-edges. The airline route map in the back of the magazine is an example of a simple undirected graph. Representing each flight for a whole airline would require a directed multigraph: the flight from Philadelphia to New York is not the same as the flight in the opposite direction, and there are many flights each day between the two airports. If sightseeing tours are added (self-edges), then a pseudograph would be needed.

The *adjacency set* of a node i , also called its *neighbors*, is the set of nodes j where edge (i, j) is in the graph. For a directed graph, this is the out-adjacency; the in-adjacency of node i is the set $\{j \mid (j, i) \in E\}$. A graph can be represented as a binary *adjacency matrix*, with entries $a_{ij} = 1$ if $(i, j) \in E$, and $a_{ij} = 0$ otherwise. The *degree* of a node is the size of its adjacency set.

Graphs can contain infinite sets of nodes and edges. Consider the directed graph on the natural numbers \mathbb{N} with the edges (i, j) , where j is an integer multiple of i . A prime number $j > 1$ in this graph has in-adjacency $\{1, j\}$ and an in-degree of 2 (including the self-edge (j, j)); a composite number $j > 1$ has a larger in-degree.

Nodes i and j are *incident* on the edge (i, j) and, likewise, the edge (i, j) is incident on its two nodes. A *subgraph* of G consists of a subset of its nodes and edges, $\tilde{G} = (\tilde{V}, \tilde{E})$, where $\tilde{V} \subseteq V$ and $\tilde{E} \subseteq E$. If an edge (i, j) appears in \tilde{E} , then its two incident nodes must also appear in \tilde{V} , but the opposite need not hold. Two special kinds of subgraphs are *node-induced* and *edge-induced* subgraphs. A node-induced subgraph starts with a subset of nodes \tilde{V} ; the edges \tilde{E} are all those edges whose two incident nodes are both in \tilde{V} . An *edge-induced* subgraph starts with a subset of edges \tilde{E} and then \tilde{V} consists of all nodes incident on those edges. A graph is *completely connected* if it has an edge between every pair of nodes. A *clique* is a completely connected subgraph.

A *path* from i to j is a list of nodes (i, \dots, j) with edges between adjacent pairs of nodes. The path cannot traverse a directed edge backward. The *length* of the path is the number of nodes in the list minus one. In a *simple* path, a node can appear only once. If there is a path from i to j , then node j is *reachable* from node i . The set of all nodes reachable from i is the *reach* of i . Among all paths from i to j , one with the shortest length is a *shortest path*, its length the (*geodesic*) *distance* from i to j . The *diameter* of a graph is the length of the longest possible shortest path. In a *small-world graph*, each node is a small distance (logarithmic in the number of nodes) away from any other node.

An undirected graph is *connected* if there is a path between each pair of nodes, but there are two kinds of connectivity in a directed graph. If a path exists between every pair of nodes, then a directed graph is *strongly connected*. A directed graph is *weakly connected* if its *underlying undirected graph* is connected; to obtain such a graph, all edge directions are dropped.

A *cycle* is a path that starts and ends at the same node i ; the cycle is *simple* if no node is repeated (except for node i itself). There are no cycles in an *acyclic* graph. The acronym DAG is often used for a directed acyclic graph.

The undirected graph in figure 1(a) is connected. Nodes $\{2, 3, 4\}$ form a clique, as do $\{2, 4, 6\}$. The path $(1, 2, 4, 3, 2, 6)$ has length 5 and is not simple. A simple path from 1 to 6 is $(1, 2, 4, 6)$ of length 3, but the shortest path is $(1, 2, 6)$ of length 2, which traverses the edges $(1, 2)$ and $(2, 6)$. The path $(2, 3, 4, 2)$ is a cycle of length 3. Node 2 has degree 4, with neighbors $\{1, 3, 4, 6\}$. The diameter of the graph is 3. Since the graph is connected, the reach of node 2 is the whole graph. This graph is the underlying undirected graph of the directed graph in part (b) of the figure.

The largest clique in this directed graph has only two nodes: $\{2, 4\}$. The out-adjacency of node 2 is the set $\{3, 4\}$ and its in-adjacency is $\{1, 4, 6\}$. The reach of node 2 is $\{2, 3, 4, 6\}$. The graph is not strongly connected since there is no path from 1 to 5, but it is weakly connected since its underlying undirected graph is connected.

Figure 2 illustrates a *bipartite* graph. The nodes of a bipartite graph are partitioned into two sets, and no edge in the graph is incident on a pair of nodes in the same partition. Bipartite graphs arise naturally when modeling a relationship between two very different sets. For example, in term/document analysis, a bipartite graph of m terms and n documents has an

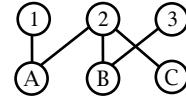

Figure 2 An undirected bipartite graph.

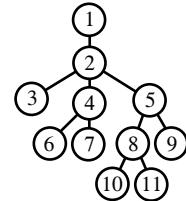

Figure 3 A tree of height 4, with node 1 as the root.

edge (i, j) if term i appears in document j . No edge connects two terms, nor two documents. An undirected bipartite graph is often represented as a rectangular $m \times n$ adjacency matrix, where $a_{ij} = 1$ if the edge (i, j) appears in the graph and $a_{ij} = 0$ otherwise.

An undirected acyclic graph is a *forest*. An important special case is a *tree*, which is a connected forest. In a tree, there is a unique simple path between each pair of nodes. In a *rooted tree*, one node is designated as the *root*. The *ancestors* of node i are all the nodes on the path from i to the root (excluding i itself). The first node after i in this path is the *parent* of i , and node i is its *child*. The length of this path is the *level* of the node (the root has level zero). The *height* of a tree is the maximum level of its nodes.

In a tree, all nodes except the root have a single parent. Nodes can have any number of children, and a node with no children is a *leaf*. *Internal* nodes have at least one child. In a *binary* tree, nodes have at most two children, and in a *full binary* tree, all internal nodes have exactly two children. Node i is a *descendant* of all nodes in the path from i to the root (excluding i itself). The *subtree* rooted at node i is the subgraph induced by node i and its descendants.

In the example in figure 3, the parent of node 5 is 2, its descendants are $\{8, 9, 10, 11\}$, its ancestors are $\{1, 2\}$, and its children are $\{8, 9\}$. Since node 2 has three children, the tree is not binary.

Sometimes a graph with its nodes and edges is not enough to fully represent a problem. Edges in a graph do not have a length, but this is useful for the airline route map, and thus nodes and edges are often augmented with additional data. Attaching a single numerical value to each node and/or edge is common; this

results in a *weighted* graph. In this graph, the length of a path is the sum of the weights of its edges.

Drawing a graph requires node positions, so they must be computed for graphs without natural node positions. In the *force-directed* method that created the graphs in plates 1–4, nodes are given an electrical charge and edges become springs. A low-energy state is found, which often leads to a visually pleasing layout that reveals the graph's large-scale structure.

Be aware that there are many minor variations in the terminology of graph theory. For example, nodes can be called *vertices*, edges are also called *arcs*, and self-edges are sometimes called *loops*. Directed graphs are also called *digraphs*. Sometimes the term *arc* is restricted to directed edges. In a common alternative terminology, a path becomes a *walk*, a simple path becomes a path (conflicting with the definition here), a *trail* is a walk with no repeated edges, and a cycle becomes a *closed walk*.

II.17 Homogenization

Homogenization is a method for obtaining an equation whose solution approximates the solution of a partial differential equation (PDE) with rapidly varying coefficients. In many cases the approximate equation is a PDE, but in some it may be an integro-differential equation. PDEs with rapidly varying coefficients arise in the study of the response of composite materials. The method is best illustrated by an example in heat conduction. Let $u(x_1, x_2)$ represent temperature in a composite medium occupying a domain Ω . The composite is modeled by a conductivity $a > 0$ that is rapidly oscillating in both x_1 and x_2 . To represent this mathematically, the conductivity is written as

$$a(x_1/\varepsilon, x_2/\varepsilon),$$

where the function $a(y_1, y_2)$ is unit periodic, i.e., $a(y_1 + 1, y_2) = a(y_1, y_2)$ and $a(y_1, y_2 + 1) = a(y_1, y_2)$. Therefore, one can see that ε represents the periodicity of the medium and is small when the

medium is rapidly oscillating. The governing equation is

$$\nabla \cdot a \nabla u = f,$$

where f represents the heat source.

Homogenization, which is based on multiscale asymptotics, allows one to obtain an approximate equation for the heat conduction problem when $\varepsilon \ll 1$. The resulting equation,

$$\nabla \cdot A \nabla u = f,$$

is referred to as the homogenized equation and has a constant, albeit anisotropic (A may be a matrix), conductivity. The conductivity in the homogenized equation in this particular case is easily identified as A and is referred to as the effective property of the medium.

Periodicity is essential in deriving the homogenized equation. When the medium is not periodic, e.g., when it is random, the method of homogenization may still be applied, although its interpretation is different and more difficult. In this case there is no simple way to obtain the effective property of the random medium, but a connection to EFFECTIVE MEDIUM THEORIES [IV.31] can be made.

For periodic media, homogenization can be applied to PDEs that model other phenomena such as fluid flow in porous media, elasticity, wave propagation, vibration, electrostatics, and electromagnetics. Recent research in homogenization has explored its use in situations where the medium is almost periodic, that is, in PDEs where the coefficients are oscillatory with almost constant period or where the coefficients are periodic with the exception of a few “defect” regions.

II.18 Hybrid Systems

Paul Glendinning

A hybrid system is a system that combines both continuous and discrete variables. A simple motivating example is the thermostat. A thermostat switches a heater to one of two discrete states, *on* or *off*, depending on the ambient temperature (a continuous variable), which evolves differently if the heater is in the *on* or *off* states. The specification of the thermostat includes transition rules. If the thermostat is in the *off* state and the temperature falls below a critical value, then the thermostat is switched to *on*, possibly with some (deterministic or random) delay in time. If the thermostat is in the *on* state and the temperature rises above

a critical value, then the thermostat is switched to off, possibly with some (deterministic or random) delay in time.

This type of system—for which the value of a discrete variable determines the rules of evolution of continuous variables, and with jumps in the discrete variables according to another rule—provides a formal description of many systems in computer science, control theory, and dynamics. The bouncing ball is another simple example and the reader may like to think about how this fits into the formalism described below.

There are many different ways a hybrid system could be defined, and the choice of definition will depend on the application area or the level of generality that is required. However, the basic structure is as follows. A hybrid system's state is determined by two variables, a continuous variable x on some manifold M (often \mathbb{R}^n) and a discrete variable $d \in \{1, 2, \dots, D\}$. For each d there is a domain M_d in M and an evolution equation that determines the time evolution of x . This may be a differential equation or a stochastic differential equation, for example. Therefore, given d there is a well-defined rule for the evolution of x in a subset of M .

The next part of the specification determines how the discrete variable can change. For each pair $e = (d_0, d_1)$ there is a set $G_e \subseteq M_{d_0}$, possibly empty, such that if $x \in G_e$ then there is a finite probability that the dynamics will be instantaneously reset so that the discrete variable becomes d_1 and the continuous variable becomes $R(x, e)$ for some reset map $R: M \times D \times D \rightarrow M$. After this, the dynamics continues in the new domain M_{d_1} according to the evolution rule for d_1 until the next transition is made.

Of course, for this specification to make sense a number of consistency conditions must be satisfied, e.g., $R(x, e) \in M_{d_1}$, and it is possible that the continuous variable may leave the region M_d on which its dynamics is defined before a transition is made, in which case the dynamics becomes undefined. There are therefore many checks that need to be made to ensure that, given an initial condition in some set $\text{Init} \subseteq M \times D$, the solution is well defined. In the deterministic case uniqueness may also be an issue.

A solution with an infinite sequence of transitions in finite time is called a *Zeno solution*. In computer science, where the transitions are executions in some program, this is not useful. In other contexts, however, the infinite sequence may have physical significance. Chattering in mechanical impacts can be modeled as a Zeno phenomenon.

Hybrid systems are used to examine reachability and verification problems in computer science. The reachability problem is that of determining all the possible states that can be reached from a given set of initial conditions. This is also relevant to CONTROL THEORY [IV.34], where it might be important to know that a given control system keeps a car on the road or avoids collisions. The existence of transitions or jumps makes hybrid systems useful in models of mechanical impacts as well (see SLIPPING, SLIDING, RATTLING, AND IMPACT [VI.15]). Control systems with thresholds can also be modeled as hybrid systems.

The existence of transitions means that many classic results for smooth dynamical systems, such as stability theorems, are made considerably harder to prove, but it could be argued that the piecewise-smooth nature of these models is a much more generally applicable feature for modern applications in electronics and biology than the smooth dynamical systems approach that has dominated so much of dynamical systems theory.

II.19 Integral Transforms and Convolution

An *integral transform* is an operator J mapping a function f of a real variable to another function Jf according to

$$(Jf)(s) = \int_a^b K(s, t)f(t) dt,$$

where K is called the *kernel* of the transformation. There are many different integral transforms, depending on the choice of a , b , and K . They are used to transform one problem into another, the intent being that the new problem is simpler than the original one. Having solved the new problem, the solution f is obtained by applying the appropriate inverse operator, J^{-1} ; this is often another integral transform.

Important special cases include the *Fourier transform*

$$(\mathcal{F}f)(s) = \int_{-\infty}^{\infty} f(t)e^{ist} dt$$

and the *Laplace transform*

$$(\mathcal{L}f)(s) = \int_0^\infty f(t)e^{-st} dt.$$

This definition of \mathcal{L} is standard, but the definition of \mathcal{F} is one of many; for example, some authors insert an extra factor $(2\pi)^{-1/2}$, and some use e^{-ist} . Always check the author's definition when reading a book or article in which Fourier transforms are used!

Many integral transforms have an associated *convolution*; given two functions of a real variable, f and g , their convolution is another function of a real variable, denoted by $f * g$. It is defined so that $J(f * g) = (Jf)(Jg)$; the transform of the convolution is the product of the transforms. For the Fourier transform

$$(f * g)(t) = \int_{-\infty}^{\infty} f(t-s)g(s) ds,$$

while for the Laplace transform

$$(f * g)(t) = \int_0^t f(t-s)g(s) ds.$$

It is easy to see that, in both cases, $f * g = g * f$. Convolution is an important operation in SIGNAL PROCESSING [IV.35] and in many applications involving Fourier analysis and INTEGRAL EQUATIONS [IV.4].

There are also discrete versions of integral transforms in which the integral is replaced by a finite sum of terms. The *discrete Fourier transform* is especially important because it can be computed rapidly using the FAST FOURIER TRANSFORM [II.10] (FFT).

II.20 Interval Analysis

Warwick Tucker

Interval analysis is a calculus based on set-valued mathematics. In its simplest (and by far most popular) form, it builds upon interval arithmetic, which is a natural extension of real-valued arithmetic. Despite its simplicity, this kind of set-valued mathematics has a very wide range of applications in computer-aided proofs for continuous problems. In a nutshell, interval arithmetic enables us to bound the range of a continuous function, i.e., it produces a set *enclosing* the range of a given function over a given domain. This, in turn, enables us to prove mathematical statements that use open conditions, such as strict inequalities, fixed-point theorems, etc.

1 Interval Arithmetic

In this section we will briefly describe the fundamentals of interval arithmetic. Let \mathbb{IR} denote the set of closed

intervals of the real line. For any element $\mathbf{a} \in \mathbb{IR}$, we use the notation $\mathbf{a} = [\underline{a}, \bar{a}]$. If \star is one of the operators $+, -, \times, /$, we define arithmetic on elements of $\mathbf{a}, \mathbf{b} \in \mathbb{IR}$ by

$$\mathbf{a} \star \mathbf{b} = \{a \star b : a \in \mathbf{a}, b \in \mathbf{b}\}, \quad (1)$$

except that \mathbf{a}/\mathbf{b} is undefined if $0 \in \mathbf{b}$. Working exclusively with closed intervals, the resulting interval can be expressed in terms of the endpoints of the arguments. This makes the arithmetic very easy to implement in software.

Note that a generic element in \mathbb{IR} has no additive or multiplicative inverse. For example, we have $[1, 2] - [1, 2] = [-1, 1] \neq [0, 0]$, and $[1, 2]/[1, 2] = [\frac{1}{2}, 2] \neq [1, 1]$. This is known as the *dependency problem*, and it can cause large overestimations. In practice, however, the use of high-order (e.g., Taylor series) representations greatly mitigates this problem.

A key feature of interval arithmetic is that it is *inclusion monotonic*; i.e., if $\mathbf{a} \subseteq \mathbf{a}'$ and $\mathbf{b} \subseteq \mathbf{b}'$, then by (1) we have

$$\mathbf{a} \star \mathbf{b} \subseteq \mathbf{a}' \star \mathbf{b}'.$$

This is of fundamental importance: it says that, if we can enclose the arguments, we can enclose the result.

More generally, when we extend a real-valued function f to an interval-valued one F , we demand that it satisfies the *inclusion principle*

$$\text{range}(f; \mathbf{x}) = \{f(x) : x \in \mathbf{x}\} \subseteq F(\mathbf{x}). \quad (2)$$

If this can be arranged for a finite set of *standard* functions, then the inclusion principle will also hold for any *elementary* function constructed by arithmetic and composition applied to the set of standard functions.

Multivariate functions can be handled by working componentwise on interval vectors (boxes) $\mathbf{x} = (\mathbf{x}_1, \dots, \mathbf{x}_n)$.

When implementing interval arithmetic on a computer, the endpoints must be FLOATING-POINT NUMBERS [II.13]. This introduces rounding errors, which must be properly dealt with. As an example, interval addition becomes

$$\mathbf{a} + \mathbf{b} = [\nabla(\underline{a} + \underline{b}), \Delta(\bar{a} + \bar{b})].$$

Here, $\nabla(x)$ is the largest floating-point number no greater than x , and $\Delta(x) = -\nabla(-x)$. The IEEE standard for floating-point computations guarantees that this type of *outward rounding* preserves the inclusion principle for $+, -, \times$, and $/$. For other operations (such as trigonometric functions) there are no such assurances; interval extensions of these functions must be built from scratch.

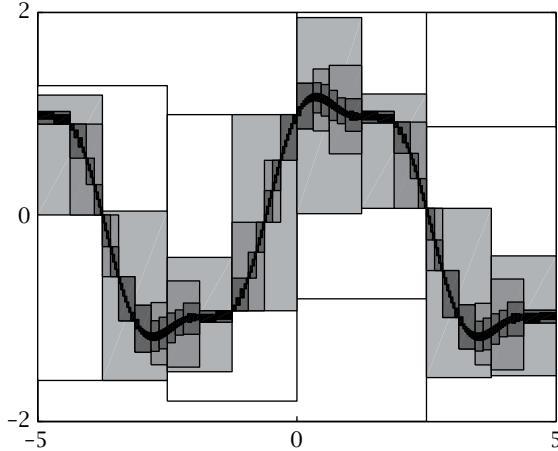

Figure 1 Successively tighter enclosures of a graph.

2 Interval Analysis

The inclusion principle (2) enables us to capture continuous properties of a function, using only a finite number of operations. Its most important use is to explicitly bound discretization errors that naturally arise in numerical algorithms.

As an example, consider the function $f(x) = \cos^3 x + \sin x$ on the domain $x = [-5, 5]$. For any decomposition of the domain \mathbf{x} into a finite set of subintervals $\mathbf{x} = \bigcup_{i=1}^n \mathbf{x}_i$, we can form the set-valued graph consisting of the pairs $(\mathbf{x}_1, F(\mathbf{x}_1)), \dots, (\mathbf{x}_n, F(\mathbf{x}_n))$. As the partition is made finer (that is, as $\max_i \text{diam}(\mathbf{x}_i)$ is made smaller), the set-valued graph tends to the graph of f (see figure 1). And, most importantly, every such set-valued graph contains the graph of f .

This way of incorporating the discretization errors is extremely useful for quadrature, optimization, and equation solving. As one example, suppose we wish to compute the definite integral $I = \int_0^8 \sin(x + e^x) dx$.

A MATLAB function `simpson` that implements a simple textbook adaptive Simpson quadrature algorithm produces the following result.

```
% Compute integral I with tolerance 1e-6.
>> I = simpson(@(x) sin(x + exp(x)), 0, 8)
I =
    0.251102722027180
```

A (*very naive*) set-valued approach to quadrature is to enclose the integral I via

$$I \in \sum_{i=1}^n F(\mathbf{x}_i) \text{diam}(\mathbf{x}_i),$$

which, for a sufficiently fine partition, produces the integral enclosure

$$I \in 0.3474001726^{66}_{49}.$$

Thus, it turns out that the result from `simpson` was completely wrong! This is one example of the importance of rigorous computations.

3 Recent Developments

There is currently an ongoing effort within the IEEE community to standardize the implementation of interval arithmetic. The hope is that we will enable computer manufacturers to incorporate these types of computations at the hardware level. This would remove the large computational penalty incurred by repeatedly having to switch rounding modes—a task that central processing units were not designed to perform efficiently.

II.21 Invariants and Conservation Laws

Mark R. Dennis

As important as the study of *change* in the mathematical representation of physical phenomena is the study of *invariants*. Physical laws often depend only on the *relative* positions and times between phenomena, so certain physical quantities do not change; i.e., they are *invariant*, under continuous translation or rotation of the spatial axes. Furthermore, as the spatial configuration of a system evolves with time, quantities such as total energy may remain unchanged; that is, they are

conserved. The study of invariants has been a remarkably successful approach to the mathematical formulation of physical laws, and the study of continuous symmetries and conservation laws—which are related by the result known as *Noether's theorem*—has become a systematic part of our description of physics over the last century, from the atomic scale to the cosmic scale.

As an example of so-called *Galilean invariance*, Newton's force law keeps the same form when the velocity of the frame of reference (i.e., the coordinate system specified by x -, y -, and z -axes) is changed by adding a constant; this is equivalent to adding the same constant velocity to all the particles in a mechanical system. Other quantities *do* change under such a velocity transformation, such as the kinetic energy $\frac{1}{2}m|\mathbf{v}|^2$ (for a particle of mass m and velocity \mathbf{v}); however, for an evolving, nondissipative system such as a bouncing, perfectly elastic rubber ball, the total energy is constant in time—that is, energy is conserved.

The development of our understanding of fundamental laws of dynamics can be interpreted by progressively more sophisticated and general representations of space and time themselves: ancient Greek physical science assumed absolute space with a privileged spatial point (the center of the Earth), through static Euclidean space where all spatial points are equivalent, through CLASSICAL MECHANICS [IV.19] where all inertial frames, moving at uniform velocity with respect to each other, are equivalent according to Newton's first law, to the modern theories of special and general relativity. The theory of relativity (both general and special) is motivated by Einstein's principle of covariance, which is described below. In this theory, space and time in different frames of reference are treated as coordinate systems on a four-dimensional pseudo-Riemannian manifold (whose mathematical background is described in TENSORS AND MANIFOLDS [II.33]), which manifestly combines conservation laws and continuous geometric symmetries of space and time. In special relativity (described in some detail in this article), this manifold is flat *Minkowski space-time*, generalizing Euclidean space to include time in a physically natural way. In general relativity, described in detail in GENERAL RELATIVITY AND COSMOLOGY [IV.40], this manifold may be curved, depending in part on the distribution of matter and energy according to EINSTEIN'S FIELD EQUATIONS [III.10].

In quantum physics, the description of a system in terms of a complex vector in Hilbert space gives rise to new symmetries. An important example is the fact

that physical phenomena do not depend on the overall phase (argument) of this vector. Extension of Noether's theorem here leads to the conservation of electric charge, and extension to Yang–Mills theories provides other conserved quantities associated with the nuclear forces studied in contemporary fundamental particle physics. Other phenomena, such as the Higgs mechanism (leading to the Higgs boson recently discovered in high-energy experiments), are a consequence of the breaking of certain quantum symmetries in certain low-energy regimes. Symmetry and symmetry breaking in quantum theory are discussed briefly at the end of this article.

Spatial vectors, such as $\mathbf{r} = (x, y, z)$, represent the spatial distance between a chosen point and the origin, and of course the vector between two such points $\mathbf{r}_2 - \mathbf{r}_1$ is independent of translations of this origin. Similarly, the scalar product $\mathbf{r}_2 \cdot \mathbf{r}_1$ is unchanged under rotation of the coordinate system by an orthogonal matrix \mathbf{R} , under which $\mathbf{r} \rightarrow \mathbf{R}\mathbf{r}$.

Continuous groups of transformations such as translation and rotation, and their matrix representations, are an important tool used in calculations of invariants. For example, the set of two-dimensional matrices $\begin{pmatrix} \cos \theta & -\sin \theta \\ \sin \theta & \cos \theta \end{pmatrix}$, representing rotations through angles θ , may be considered as a continuous one-parameter Abelian group of matrices generated by the MATRIX EXPONENTIAL [II.14] $e^{\theta A}$, where A is the generator $\begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}$. The generator itself is found as the derivative of the original matrix with respect to θ , evaluated at $\theta = 0$. Translations are less obviously represented by matrices; one approach is to append an extra dimension to the position vector with unit entry, such as $(1, x)$ specifying one-dimensional position x ; a translation by X is thus represented by

$$\begin{pmatrix} 1 & 0 \\ X & 1 \end{pmatrix} = \exp \left(X \begin{pmatrix} 0 & 0 \\ 1 & 0 \end{pmatrix} \right). \quad (1)$$

When a physical system is invariant under a one-parameter group of transformations, the corresponding generator plays a role in determining the associated conservation law.

1 Mechanics in Euclidean Space

It is conventional in classical mechanics to define the positions of a set of interacting particles in a vector space. However, we do not observe any unique origin to the three-dimensional space we inhabit, which we therefore take to be the *Euclidean space* \mathbb{E}^3 ; only relative positions between different interacting subsystems

(i.e., positions relative to the common center of mass) enter the equations of motion. The entire system may be translated in space without any effect on the phenomena.

Of course, *external forces* acting on the system may prevent this, such as a rubber ball in a linear gravity field. (In such situations the source of the force, such as the Earth as the source of gravity, is not considered part of the system.) The gravitational force may be represented by a potential $V = gz$ for height z and gravitational acceleration g ; the ball's mass m times the negative gradient, $-m\nabla V$, gives the downward force acting on the ball. The contours of V , given by $z = \text{const.}$, nevertheless have a symmetry: they are invariant to translations of the horizontal coordinates x and y . Since the gradient of the potential is proportional to the gravitational force—which, by virtue of Newton's law equals the rate of change of the particle's linear momentum—the horizontal component of momentum does not change and is therefore conserved even when the particle bounces due to an impulsive, upward force from the floor. The continuous, horizontal translational symmetry of the system therefore leads to conservation of linear momentum in the horizontal plane. In a similar argument employing Newton's laws in cylindrical polar coordinates, the invariance of the potential to rotations about the z -axis leads to the conservation of the vertical component a body's angular momentum, as observed for tops spinning frictionlessly.

2 Noether's Theorem

The Lagrangian framework for mechanics (CLASSICAL MECHANICS [IV.19 §2]), which describes systems acting under forces defined by gradients of potentials (as in the previous section), is a natural mathematical setting in which to explore the connection between a system's symmetries and its conservation laws. Here, a mechanical system evolving in time t is described by n generalized coordinates $q_j(t)$ and their time derivatives \dot{q}_j , for $j = 1, \dots, n$, where the initial values $q_j(t_0)$ at time t_0 and final values $q_j(t_1)$ at t_1 are fixed. The *action* of the system is the functional

$$S[\{q_j\}] = \int_{t_0}^{t_1} L(\{q_j\}, \{\dot{q}_j\}, t) dt,$$

where $L(\{q_j\}, \{\dot{q}_j\}, t)$ is the *Lagrangian*; this is a function of the coordinates, their corresponding velocities, and maybe time, specified here by the total kinetic energy minus the total potential energy of the system

(thereby capturing the forces as gradients of the potential energy). Using the CALCULUS OF VARIATIONS [IV.6], the functions $q_j(t)$ that satisfy the laws of mechanics are those that make the action stationary, and these satisfy Lagrange's equations of motion

$$\frac{\partial L}{\partial q_j} - \frac{d}{dt} \frac{\partial L}{\partial \dot{q}_j} = 0, \quad j = 1, \dots, n. \quad (2)$$

The argument of the time derivative in this expression, $\partial L / \partial \dot{q}_j$, is called the *canonical momentum* p_j for each j . The set of equations (2) involves the combination of partial derivatives of the Lagrangian with respect to the coordinates and velocities, together with the total derivative with respect to time. By the chain rule, this total derivative affects explicit time dependence in L and the implicit time dependence in each q_j and \dot{q}_j . Many of the conservation laws involving Lagrangians involve such an interplay of explicit and implicit time dependence.

Any transformation of the coordinates q_j that does not change the Lagrangian is a symmetry of the system. If L does not have explicit dependence on a coordinate q_j , then the first term in (2) vanishes: $d p_j / d t = 0$, i.e., the corresponding canonical momentum is conserved in time. In the example from the last section of a particle in a linear gravitational field, the coordinates can be chosen to be Cartesian x, y, z , or cylindrical polars r, ϕ, z ; L is independent of x and y , leading to conservation of horizontal momentum, and also ϕ , leading to conservation of angular momentum about the z -axis. The theorem is proved for symmetries of this type in CLASSICAL MECHANICS [IV.19 §2.3]: if a system is homogeneous in space (translation invariant), then linear momentum is conserved, and if it is isotropic (independent of rotations, such as the Newtonian gravitational potential around a massive point particle exerting a central force), then angular momentum is conserved (equivalent to Kepler's second law of planetary motion for gravity).

Since it is the equations (2) that represent the physical laws rather than the form of L or S , the system may admit a more general kind of symmetry whose transformation adds a time-dependent function to the Lagrangian L . If, under the transformation, the Lagrangian transforms $L \rightarrow L + d\Lambda / dt$ involving the total time derivative of some function Λ , the action transforms $S \rightarrow S + \Lambda(t_1) - \Lambda(t_0)$. Thus the transformed action is still made stationary by functions satisfying (2), so transformations of this kind are symmetries of the system, which are also continuous if Λ also depends on a continuous parameter s so that its time derivative is

zero when $s = 0$. It is not then difficult to see that the quantity

$$\sum_{j=1}^n p_j \frac{\partial q_j}{\partial s} \Big|_{s=0} - \frac{\partial \Lambda}{\partial s} \Big|_{s=0}, \quad (3)$$

defined in terms of the generators of the transformation on each coordinate and the Lagrangian, is constant in time. This is Noether's theorem for classical mechanics.

An important example is when the Lagrangian has no explicit dependence on time, $\partial L/\partial t = 0$. In this case, under an infinitesimal time translation $t \rightarrow t + \delta t$, $L \rightarrow L + \delta t dL/dt$, so here Λ is $L\delta t$, with L evaluated at t , and δt plays the role of s . Under the same infinitesimal transformation, $q_j \rightarrow q_j + \delta t \dot{q}_j$, so the relevant conserved quantity (3) is $\sum_j p_j \dot{q}_j - L$, which is the Hamiltonian of the system, which is equal to the total energy in many systems of interest. It is apparently a fundamental law of physics that the total energy in physical processes is conserved in time; energy can be in other forms such as electromagnetic, gravitational, or heat, as well as mechanical. Noether's theorem states that the law of conservation of energy is equivalent to the fact that the physical laws of the system, characterized by their Lagrangian, do not change with time.

The vanishing of the action functional's integrand (i.e., the Lagrangian L) is equivalent to the existence of a first integral for the system of Lagrange equations, which is interpreted in the mechanical setting as a constant of the motion of the system. In this sense, Noether's theorem may be applied more generally in other physical situations described by functionals whose physical laws are given by the corresponding Euler-Lagrange equations. In the case of the Lagrangian approach applied to fields (i.e., functions of space and time), Noether's theorem generalizes to give a continuous density ρ (such as mass or charge density) and a flux vector \mathbf{J} satisfying the continuity equation $\dot{\rho} + \nabla \cdot \mathbf{J} = 0$ at every point in space and time.

3 Galilean Relativity

Newton's first law of motion can be paraphrased as “all inertial frames, traveling at uniform linear velocity with respect to each other, are equivalent for the formulation of mechanics”—that is, without action of external forces, a system will behave in the same way regardless of the motion of its center of mass. The behavior of a mechanical system is therefore independent of its overall velocity; this is a consequence of Newton's second

law, that force is proportional to acceleration. According to pre-Newtonian physics, forces were thought to be proportional to *velocity* (as the effect of friction was not fully appreciated), and it was not until Galileo's thought experiments in friction-free environments that the proportionality of force to *acceleration* was appreciated. In spite of Galilean invariance, problems involving circular motion do in fact seem to require a privileged frame of reference, called *absolute space*. One example due to Newton himself is the problem of explaining, without absolute space, the meniscus formed by the surface of water in a spinning bucket; such problems are properly overcome only in general relativity.

With Galilean relativity, absolute position is no longer defined: events occurring at the same position but at different times in one frame (such as a moving train carriage) occur at different positions in other frames (such as the frame of the train track). However, changes to the state of motion, i.e., accelerations, have physical consequences and are related to forces. This is an example of a *covariance principle*, whose importance for physical theories was emphasized by Einstein. According to this principle, from the statement of physical laws in one frame of reference (such as the laws of motion), one can derive their statement in a different frame of reference from the application of the appropriate transformation rule between reference frames. The statement in the new frame should have the same *mathematical form* as in the previous frame, although quantities may not take the same values in different frames.

Transformations between different inertial frames are represented mathematically in a similar way to the translations of (1); events are labeled by their positions in space and time, such as (t, \mathbf{x}) in one frame and (t, \mathbf{x}') in another moving at velocity v with respect to the first. Since $\mathbf{x}' = \mathbf{x} - vt$, the transformation from (t, \mathbf{x}) to (t, \mathbf{x}') is represented by the matrix $\begin{pmatrix} 1 & 0 \\ -v & 1 \end{pmatrix}$. This Galilean transformation (or *Galilean boost*) differs from (1) in that time t is here appended to the position vector, since the translation from the boost is time-dependent. Galilean boosts in three spatial dimensions, together with regular translations and rotations, define the *Galilean group*. It can be shown that the Lagrangian of a free particle follows directly from the covariance of the corresponding action under the Galilean group.

Infinitesimal velocity boosts generate a Noetherian symmetry on systems of particles interacting via forces that depend only on the positions of the others. Consider N point particles of mass m_k and position \mathbf{r}_k such that V depends only on $\mathbf{r}_k - \mathbf{r}_\ell$ for $k, \ell = 1, \dots, N$. Under

an infinitesimal boost by $\delta\mathbf{v}$ for each k , $\mathbf{r}_k \rightarrow \mathbf{r}_k + t\delta\mathbf{v}$, $\dot{\mathbf{r}}_k \rightarrow \dot{\mathbf{r}}_k + \delta\mathbf{v}$, and

$$L \rightarrow L + \frac{1}{2}|\delta\mathbf{v}|^2 \sum_k m_k + \delta\mathbf{v} \cdot \sum_k m_k \dot{\mathbf{r}}_k.$$

The resulting Noetherian conserved quantity (3) is

$$\mathcal{C} = t \sum_k m_k \dot{\mathbf{r}}_k - \sum_k m_k \mathbf{r}_k. \quad (4)$$

This quantity is constant in time; its value is minus the product of the system's total mass with the position of its center of mass when $t = 0$. Thus, $\dot{\mathcal{C}} = t \sum_k m_k \dot{\mathbf{r}}_k$, that is, t times the sum of the forces on each of the N particles, which is zero by assumption.

4 Special Relativity

Historically, the physics of fields, such as electromagnetic radiation described by MAXWELL'S EQUATIONS [III.22], was developed much later than the mechanics of Galileo and Newton. The simplest wave equations, in fact, suggest a different invariant space-time from the Galilean framework above, which was first investigated by Hendrik Lorentz and Albert Einstein at the turn of the twentieth century.

Consider the time-dependent wave equation $\nabla^2\varphi - c^{-2}\ddot{\varphi} = 0$ for some scalar function $\varphi(t, \mathbf{r})$ and ∇^2 the LAPLACE OPERATOR [III.18]. If all observers agree on the same value of the wave speed c (as proposed by Einstein for c the speed of light, and verified by experiments), this suggests that the transformation between moving inertial frames should be in terms of *Lorentz transformations* (or *Lorentz boosts*) in the x -direction,

$$\begin{pmatrix} ct' \\ x' \end{pmatrix} = \gamma(v) \begin{pmatrix} 1 & -v/c \\ -v/c & 1 \end{pmatrix} \begin{pmatrix} ct \\ x \end{pmatrix}, \quad (5)$$

where (ct', x') denotes position in space and time (multiplied by the invariant speed c) in a frame moving along the x -axis at velocity v with respect to the frame with space-time coordinates (ct, x) , and

$$\gamma(v) = (1 - v^2/c^2)^{-1/2}.$$

Requiring $\gamma(v)$ to be finite, positive, and real-valued implies $|v| < c$. According to the Lorentz transformation with $x = 0$, $t' = \gamma(v)t$, suggesting that $\gamma(v)$ may be interpreted as the rate of flow of time in the transformed frame moving at speed v with respect to time in the reference frame.

According to Einstein's theory of *special relativity*, all physical laws should be invariant to translations, rotations, and Lorentz boosts, and Galilean transformations and Newton's laws arise in the low-velocity limit.

Rotations and Lorentz boosts, together with time reflection and spatial inversion, define the *Lorentz group*; the *Poincaré group* is the semidirect product group of the Lorentz group with space-time translations. Special relativity is therefore also based on the principle of covariance, but with a different set of transformations between frames of reference. All of the familiar results of CLASSICAL MECHANICS [IV.19] are recovered when the boost transformations are restricted to $v \ll c$.

In special relativity different observers measure different time intervals between events, as well as different spatial separations. For a relativistic particle, different observers will disagree on the particle's relativistic energy E and momentum \mathbf{p} . Nevertheless, according to the principle of special relativity, all observers agree on the quantity

$$E^2 - |\mathbf{p}|^2 c^2 = m^2 c^4,$$

so m is an invariant on which all observers agree, called the *rest mass* of the particle. In the frame in which the particle is at rest, $E = mc^2$ arises as a special case. Otherwise, $E = my(v)c^2$, so in special relativity the moving particle's energy is explicitly related to the flow of time in the particle's rest frame with respect to that in the reference frame.

The Lagrangian formalism can be generalized to special relativity, with all observers agreeing on the form of the Euler-Lagrange equations; instead of being equal to its kinetic energy, the Lagrangian of a free particle is $-mc^2/\gamma(v)$.

The set of space-time events (ct, \mathbf{r}) described by special relativity is known as *Minkowski space* or Minkowski space-time (discussed in TENSORS AND MANIFOLDS [II.33]). It is a flat four-dimensional manifold with one time coordinate and three space coordinates (i.e., a manifold with a $3+1$ pseudo-Euclidean metric), and the inertial frames with perpendicular spatial axes are analogous to Cartesian coordinates in Euclidean space. Time intervals and (simultaneous) spatial distances between events are no longer separately invariant; only the *space-time interval*

$$s^2 = |\Delta\mathbf{r}|^2 - c^2 \Delta t^2$$

between two events with spatial separation $\Delta\mathbf{r}$ and time separation Δt is invariant to Lorentz transformations and hence takes the same value in all inertial frames. s^2 may be positive, zero, or negative: if positive, there is a frame in which the pair of events are simultaneous; if zero, the events lie on the trajectory of a light ray; if negative, there is a frame in which the events occur at the same position. Since nothing can travel faster than

c , only events with $s^2 \leq 0$ can be causally connected; the events that may be affected by a given space-time point are those within its *future light cone*.

Being a manifold, the symmetries of Minkowski space are easily characterized, and its continuous symmetries are generated by vector fields, called *Killing vector fields*: dynamics in the space-time manifold is not changed under infinitesimal pointwise translation along these fields. The symmetries are translations in four linearly independent space-time directions, rotation about three linearly independent spatial axes, and Lorentz boosts in three linearly independent spatial directions (which are equivalent to rotations in space-time that mix the t -direction with a spatial direction). There are therefore ten independent symmetry transformations in Minkowski space-time (generating the Poincaré group), such that, for special relativistic systems not experiencing external forces, relativistic energy, momentum, angular momentum, and the analogue of \mathbf{C} in (4) are conserved.

Both electromagnetic fields described by MAXWELL'S EQUATIONS [III.22] and relativistic quantum matter waves (strictly for a single particle) described by the DIRAC EQUATION [III.9] can be expressed as Lagrangian field theories; the combination of these is called *classical field theory*. As described above, Noether's theorem relates continuous symmetries of these theories to continuity equations of relativistic 4-currents. For instance, space-time translation symmetry ensures that the relativistic rank-2 *stress-energy-momentum* tensor, which describes the space-time flux of energy (including matter), is divergence free.

5 Other Theories

Einstein's theory of *general relativity* is a yet more general approach, which admits transformations between any coordinate systems on space-time (not simply inertial frames). This general formulation now applies to an arbitrary coordinate system, such as rotating coordinates (resolving the paradoxes implicit in Newton's bucket problem). This is formulated on a possibly curved, pseudo-Riemannian manifold where local neighborhoods of space-time events are equivalent to Minkowski space and free particles follow geodesics on the manifold. The geometry of the manifold—expressed by the Einstein curvature tensor—is proportional, by EINSTEIN'S FIELD EQUATIONS [III.10], to the stress-energy-momentum tensor, and gravitational forces are fictitious forces as freely falling particles

follow curved space-time geodesics. The symmetries of general relativistic space-time manifolds are much more complicated than those for Minkowski space but are still formulated in terms of Killing vector fields that generate transformations that keep equations invariant.

In quantum physics (in a Galilean or special relativistic setting), the ideas described in this article are very important in *quantum field theory*, required to describe the quantum nature of electromagnetic and other fields, and systems involving many quantum particles. In quantum field theory, all energies in the system are quantized, often around a minimum-energy configuration. However, many field theories involve potentials whose minimum energy is not the most symmetric choice of origin; for instance, a "Mexican hat potential" of the form $|\mathbf{v}|^4 - 2a|\mathbf{v}|^2$ for some field vector \mathbf{v} and constant $a > 0$ is rotationally symmetric around $\mathbf{v} = 0$ but has a minimum for any \mathbf{v} with $|\mathbf{v}| = \sqrt{a}$. A minimum-energy excitation of the system *breaks* this symmetry by choosing an appropriate minimum energy \mathbf{v} . Many phenomena in the quantum theory of condensed matter (such as the Meissner effect in superconductors) and fundamental particles (such as the Higgs boson) arise from this type of symmetry breaking.

In classical mechanics, the time direction is privileged (it is common to all observers), so its space-time structure cannot be phrased simply in terms of manifolds. Nevertheless, the Galilean group of transformations naturally has a fiber bundle structure, with the base space given by the one-dimensional Euclidean line \mathbb{E}^1 describing time and the fiber being the spatial coordinates given by \mathbb{E}^3 .

Galilean transformations can naturally be built into this fiber bundle structure, known as *Newton–Cartan space-time*, by defining the paths of free inertial particles (i.e., straight lines) in the connections of the bundle. This provides a useful mathematical framework to compare the physical laws and symmetries of Newtonian and relativity theories, and interesting connections exist between general relativity and Newtonian gravity in the Newton–Cartan formalism.

II.22 The Jordan Canonical Form

Nicholas J. Higham

A canonical form for a class of matrices is a form of matrix—usually chosen to be as simple as possible—to which all members of the class can be reduced by transformations of a specified kind. The Jordan canonical form (JCF) is associated with similarity transformations on $n \times n$ matrices. A similarity transformation of a matrix A is a transformation from A to $X^{-1}AX$, where X is nonsingular. The JCF is the simplest form that can be achieved by similarity transformations, in the sense that it is the closest to a diagonal matrix.

The JCF of a complex $n \times n$ matrix A can be written $A = ZJZ^{-1}$, where Z is nonsingular and the Jordan matrix J is a block-diagonal matrix

$$\begin{bmatrix} J_1 & & & \\ & J_2 & & \\ & & \ddots & \\ & & & J_p \end{bmatrix}$$

with diagonal blocks of the form

$$J_k = J_k(\lambda_k) = \begin{bmatrix} \lambda_k & 1 & & \\ & \lambda_k & \ddots & \\ & & \ddots & 1 \\ & & & \lambda_k \end{bmatrix}.$$

Here, blanks denote zero blocks or zero entries. The matrix J is unique up to permutation of the diagonal blocks, but Z is not. Each λ_k is an eigenvalue of A and may appear in more than one Jordan block. All the EIGENVALUES [I.2 §20] of the Jordan block J_k are equal to λ_k . By definition, an eigenvector of J_k is a nonzero vector x satisfying $J_kx = \lambda_kx$, and all such x are nonzero multiples of the vector $x = [1 \ 0 \ \cdots \ 0]^T$. Therefore J_k has only one linearly independent eigenvector. Expand x to a vector \tilde{x} with n components by padding it with zeros in positions corresponding to each of the other Jordan blocks J_i , $i \neq k$. The vector \tilde{x} has a single 1, in the r th component, say. A corresponding eigenvector of A is $Z\tilde{x}$, since $A(Z\tilde{x}) = ZJZ^{-1}(Z\tilde{x}) = ZJ\tilde{x} = \lambda_k Z\tilde{x}$; this eigenvector is the r th column of Z .

If every block J_k is 1×1 then J is diagonal and A is similar to a diagonal matrix; such matrices A are called *diagonalizable*. For example, real symmetric matrices are diagonalizable—and moreover the eigenvalues are real and the matrix Z in the JCF can be taken to be orthogonal. A matrix that is not diagonalizable is *defective*; such matrices do not have a complete set of linearly independent eigenvectors or, equivalently, their Jordan form has at least one block of dimension 2 or greater.

To give a specific example, the matrix

$$A = \frac{1}{2} \begin{bmatrix} 3 & 1 & 1 \\ -1 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (1)$$

has a JCF with

$$Z = \begin{bmatrix} 0 & \frac{1}{2} & 1 \\ -1 & -\frac{1}{2} & 0 \\ 1 & 0 & 0 \end{bmatrix}, \quad J = \left[\begin{array}{c|cc} \frac{1}{2} & 0 & 0 \\ \hline 0 & 1 & 1 \\ 0 & 0 & 1 \end{array} \right].$$

As the partitioning of J indicates, there are two Jordan blocks: a 1×1 block with eigenvalue $\frac{1}{2}$ and a 2×2 block with eigenvalue 1. The eigenvalue $\frac{1}{2}$ of A has an associated eigenvector equal to the first column of Z . For the double eigenvalue 1 there is only one linearly independent eigenvector, namely the second column, z_2 , of Z . The third column, z_3 , of Z is a generalized eigenvector: it satisfies $Az_3 = z_2 + z_3$.

The JCF provides complete information about the eigensystem. The *geometric multiplicity* of an eigenvalue, defined as the number of associated linearly independent eigenvectors, is the number of Jordan blocks in which that eigenvalue appears. The *algebraic multiplicity* of an eigenvalue, defined as its multiplicity as a zero of the characteristic polynomial $q(t) = \det(tI - A)$, is the number of copies of the eigenvalue among all the Jordan blocks. For the matrix (1) above, the geometric multiplicity of the eigenvalue 1 is 1 and the algebraic multiplicity is 2, while the eigenvalue $\frac{1}{2}$ has geometric and algebraic multiplicities both equal to 1.

The *minimal polynomial* of a matrix is the unique monic polynomial ψ of lowest degree such that $\psi(A) = 0$. The degree of ψ is certainly no larger than n because the CAYLEY-HAMILTON THEOREM [IV.10 §5.3] states that $q(A) = 0$. The minimal polynomial of an $m \times m$ Jordan block $J_k(\lambda_k)$ is $(t - \lambda_k)^m$. The minimal polynomial of A is therefore given by

$$\psi(t) = \prod_{i=1}^s (t - \lambda_i)^{m_i},$$

where $\lambda_1, \dots, \lambda_s$ are the distinct eigenvalues of A and m_i is the dimension of the largest Jordan block in which λ_i appears. An $n \times n$ matrix is *derogatory* if the minimal polynomial has degree less than n . This is equivalent to some eigenvalue appearing in more than one Jordan block. The matrix A in (1) is defective but not derogatory. The $n \times n$ identity matrix is derogatory for $n > 1$: it has characteristic polynomial $(t - 1)^n$ and minimal polynomial $t - 1$.

Two questions that arise in many situations are, “Do the powers of the matrix A converge to zero?” and “Are the powers of A bounded?” The answers to both questions are easily obtained using the JCF. If $A = ZJZ^{-1}$ then $A^2 = ZJZ^{-1} \cdot ZJZ^{-1} = ZJ^2Z^{-1}$ and, in general, $A^k = ZJ^kZ^{-1}$. Therefore the powers of A converge to zero precisely when the powers of J converge to zero, and this in turn holds when the powers of each individual Jordan block converge to zero. The powers of a 1×1 Jordan block $J_i = (\lambda_i)$ obviously converge to zero when $|\lambda_i| < 1$. In general, since $J_i(\lambda_i)^k$ has diagonal elements λ_i^k , for the powers of $J_k(\lambda_k)$ to converge to zero it is necessary that $|\lambda_k| < 1$, and this condition turns out to be sufficient. Therefore $A^k \rightarrow 0$ as $k \rightarrow \infty$ precisely when $\rho(A) < 1$, where ρ is the *spectral radius*, defined as the largest absolute value of any eigenvalue of A .

Turning to the question of whether the powers of A are bounded, by the argument in the previous paragraph it suffices to consider an individual Jordan block. The powers of $J_k(\lambda_k)$ are clearly bounded when $|\lambda_k| < 1$, as we have just seen, and unbounded when $|\lambda_k| > 1$. When $|\lambda_k| = 1$ the powers are bounded if the block is 1×1 , but they are unbounded for larger blocks. For example, $\begin{bmatrix} 1 & 1 \\ 0 & 1 \end{bmatrix}^k = \begin{bmatrix} 1 & k \\ 0 & 1 \end{bmatrix}$, which is unbounded as $k \rightarrow \infty$. The conclusion is that the powers of A are bounded as long as $\rho(A) \leq 1$ and any eigenvalues of modulus 1 are in Jordan blocks of size 1. Thus the powers of A in (1) are not bounded.

In one sense, defective matrices—those with nontrivial Jordan structure—are very rare because the diagonalizable matrices are dense in the set of all matrices. Therefore if you generate matrices randomly you will be very unlikely to generate one that is not diagonalizable (this is true even if you generate matrices with random integer entries). But in another sense, defective matrices are quite common. Certain types of BIFURCATIONS [IV.21] in dynamical systems are characterized by the presence of nontrivial Jordan blocks in the Jacobian matrix, while in problems where some function of

the eigenvalues of a matrix is optimized the optimum often occurs at a defective matrix.

While the JCF provides understanding of a variety of matrix problems, it is not suitable as a computational tool. The JCF is not a continuous function of the entries of the matrix and can be very sensitive to perturbations. For example, for $\varepsilon \neq 0$, $\begin{bmatrix} 1 & \varepsilon \\ 0 & 1 \end{bmatrix}$ (one Jordan block) and $\begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix}$ (two Jordan blocks) have different Jordan structures, even though the matrices can be made arbitrarily close by taking ε sufficiently small. In practice, it is very difficult to compute the JCF in floating-point arithmetic due to the unavoidable perturbations caused by rounding errors. As a general principle, the SCHUR DECOMPOSITION [IV.10 §5.5] is preferred for practical computations.

II.23 Krylov Subspaces

Valeria Simoncini

1 Definition and Properties

The m th Krylov subspace of the matrix $A \in \mathbb{C}^{n \times n}$ and the vector $v \in \mathbb{C}^n$ is

$$\mathcal{K}_m(A, v) = \text{span}\{v, Av, \dots, A^{m-1}v\}.$$

The dimension of $\mathcal{K}_m(A, v)$ is at most m , and it is less if an invariant subspace of A with respect to v is obtained for some $m_* < m$. In general, $\mathcal{K}_m(A, v) \subseteq \mathcal{K}_{m+1}(A, v)$ (the spaces are nested); if $m_* = n$, then $\mathcal{K}_n(A, v)$ spans the whole of \mathbb{C}^n .

Let $v_1 = v/\|v\|_2$, with $\|v\|_2 = (v^*v)^{1/2}$ the 2-norm, and let $\{v_1, v_2, \dots, v_m\}$ be an orthonormal basis of $\mathcal{K}_m(A, v)$. Setting $\mathcal{V}_m = [v_1, v_2, \dots, v_m]$, from the nesting property it follows that the next basis vector v_{m+1} can be computed by the following Arnoldi relation:

$$A\mathcal{V}_m = [\mathcal{V}_m, v_{m+1}]H_{m+1,m},$$

where $H_{m+1,m} \in \mathbb{C}^{(m+1) \times m}$ is an *upper Hessenberg* matrix (upper triangular plus nonzero entries immediately below the diagonal) whose columns contain the coefficients that make v_{m+1} orthogonal to the already available basis vectors v_1, \dots, v_m .

Suppose we wish to approximate a vector y by a vector $x \in \mathcal{K}_m(A, v)$, measuring error in the 2-norm. Any such x can be written as a polynomial in A of degree at most $m - 1$ times v : $x = \sum_{i=0}^{m-1} \alpha_i A^i v$. If A is Hermitian, then by using a spectral decomposition we can reduce A to diagonal form by unitary transformations, which do not change the 2-norm, and it is then clear that the eigenvalues of A and the decomposition of v

in terms of the eigenvectors of A drive the approximation properties of the space. For non-Hermitian A the approximation error is harder to analyze, especially for highly nonnormal or nondiagonalizable matrices.

By replacing v by an $n \times s$ matrix V , with $s \geq 1$, spaces of dimension at most ms can be obtained. An immediate matrix counterpart is

$$\mathbb{K}_m(A, V) = \left\{ \sum_{i=0}^{m-1} \gamma_i A^i V : \gamma_i \in \mathbb{C} \text{ for all } i \right\}.$$

A richer version is obtained by working with linear combinations of all the available vectors:

$$\mathbb{K}_m^\square(A, V) = \text{range}([V, AV, \dots, A^{m-1}V]).$$

Methods based on this latter space are called “block” methods, since all matrix structure properties are generalized to blocks (e.g., $H_{m+1,m}$ will be block upper Hessenberg, with $s \times s$ blocks). Block spaces are appropriate, for instance, in the presence of multiple eigenvalues or if the original application requires using the same A and different vectors v .

2 Applications and Generalizations

Krylov subspaces are used in projection methods for solving large algebraic linear systems, eigenvalue problems, and matrix equations; for approximating a wide range of matrix functions (analytic functions, trace, determinant, transfer functions, etc.); and in model order reduction.

The general idea is to project the original problem of size n onto the Krylov subspace of dimension $m \ll n$ and then solve the smaller $m \times m$ reduced problem with a more direct method (one that would be too computationally expensive if applied to the original $n \times n$ problem). If the Krylov subspace is good enough, then the projected problem retains sufficient information from the original problem that the sought after quantities are well approximated.

When equations are involved, Krylov subspaces usually play a role as approximation spaces, as well as test spaces. The actual test space used determines the resulting method and influences the convergence properties.

Generalized spaces have emerged as second-generation Krylov subspaces. In the eigenvalue context, the “shift-and-invert” Krylov subspace $\mathcal{K}_m((A - \sigma I)^{-1}, v)$ is able to efficiently approximate eigenvalues in a neighborhood of a fixed scalar $\sigma \in \mathbb{C}$; here I is the identity matrix of size n . In matrix function evaluations and matrix equations, the extended space $\mathcal{K}_m(A, v) +$

$\mathcal{K}_m(A^{-1}, A^{-1}v)$ has shown some advantages over the classical space, while for $\sigma_1, \dots, \sigma_m \in \mathbb{C}$, the use of the more general *rational* space

$$\text{span}\{(A - \sigma_1 I)^{-1}v, \dots, (A - \sigma_m I)^{-1}v\}$$

has recently received a lot of attention for its potential in a variety of advanced applications beyond eigenvalue problems, where it was first introduced in the 1980s. All these generalized spaces require solving systems with some shifted forms of A , so that they are in general more expensive to build than the classical one, depending on the computational cost involved in solving these systems. However, the computed space is usually richer in spectral information, so that a much smaller space dimension is required to satisfactorily approximate the requested quantities. The choice among these variants thus depends on the spectral and sparsity properties of the matrix A .

II.24 The Level Set Method

Fadil Santosa

1 The Basic Idea

The level set method is a numerical method for representing a closed curve or surface. It uses an implicit representation of the geometrical object in question. It has found widespread use in problems where the closed curve evolves or needs to be recomputed often. A main advantage of the method is that such a representation is very flexible and calculation can be done on a regular grid. In computations where surfaces evolve, changes in the topology of the surface are easily handled.

Consider an example in two dimensions in the (x, y) -plane. Suppose one is interested in the motion of a curve under external forcing terms. Let $C(t)$ denote the curve as a function of time t . One method for solving this problem is to track the curve, which can be done by choosing marker points, $(x_i(t), y_i(t)) \in C(t)$,

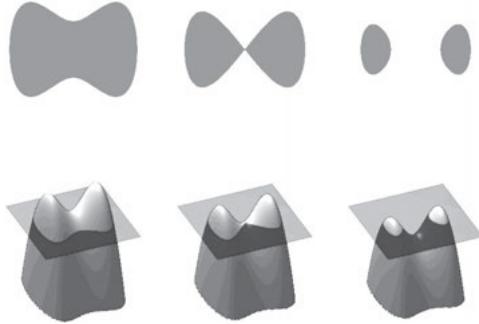

Figure 1 The graphs of a level set function $z = \varphi(x, y, t)$ for three values of t are shown at the bottom of the figure. The plane $z = 0$ intersects these functions. The domains $D(t) = \{(x, y): \varphi(x, y, t) > 0\}$ are shown above. Note that, in this example, $D(t)$ has gone through a topological change as t varies.

$i = 1, \dots, n$, whose motions are determined by the forcing. The curve itself may be recovered at any time t by a prescribed spline interpolation.

The level set method takes a different approach; it represents the curve as the zero level set of a function $\varphi(x, y, t)$. That is, the curve is given by

$$C(t) = \{(x, y): \varphi(x, y, t) = 0\}.$$

One can set up the function so that the interior of the curve $C(t)$ is the set

$$D(t) = \{(x, y): \varphi(x, y, t) > 0\}.$$

In figure 1 the level set function $z = \varphi(x, y, t)$ can be seen to intersect the plane $z = 0$ at various times t . The sets of $D(t)$ (not up to the same scale) are shown above each three-dimensional figure.

An advantage of the level set method is demonstrated in the figure. One can see that a topological change in $D(t)$ has occurred as t is varied. The level set method allows for such a change without the need to redefine the representation, as would be the case for the front-tracking method described previously.

2 Discretization

One of the attractive features of the level set method is that calculations are done on a regular Cartesian grid. Suppose we have discretized the computational domain and the nodes are at coordinates (x_i, y_j) for $i = 1, \dots, m$ and $j = 1, \dots, n$. The values of the level set function $\varphi(x, y, t)$ are then stored at coordinate points $x = x_i$ and $y = y_j$. At any time, if one is interested in the curve $C(t)$, the zero level set, the set

$$C(t) = \{(x, y): \varphi(x, y, t) = 0\}$$

needs to be approximated from the data $\varphi(x_i, y_j, t)$. One is typically interested in such quantities as the normal to the curve and the curvature at a point on the curve. These quantities are easily calculated by evaluating finite-difference approximations of

$$\nu = \frac{\nabla \varphi}{|\nabla \varphi|}$$

and

$$\kappa = \nabla \cdot \nu,$$

where the gradient operator $\nabla = [\partial/\partial x \ \partial/\partial y]^T$.

In practice, it is not necessary to keep all values of the level set function on the nodes. Since one is often interested only in the motion of the curve $C(t)$, the zero level set, one needs only the values of the level set function in the neighborhood of the curve. Such approaches have been dubbed “narrow-band methods” and can potentially reduce the amount of computation in a problem involving complex evolution of surfaces.

It must be noted that, in the two-dimensional example here, $C(t)$ is a one-dimensional object, whereas the level set function $\varphi(x, y, t)$ is a two-dimensional function. Thus, one might say that the ability to track topological changes is made at the cost of increased computational complexity.

3 Applications

A simple problem one may pose is that of tracking the motion of a curve for which every point on the curve is moving in the direction normal to the curve with a given velocity. If the velocity is v , then the equation for the level sets is given by

$$\frac{\partial \varphi}{\partial t} = v |\nabla \varphi|.$$

If one is interested in tracking the motion of the zero level set $C(t)$, then one must specify an initial condition

$$\varphi(x, y, 0) = \varphi_0(x, y),$$

where the initial zero level set is given by

$$C(0) = \{(x, y): \varphi_0(x, y) = 0\}.$$

This evolution of such a curve may be very complicated and go through topological changes. The power of the level set method is demonstrated here because all one needs to do is solve the initial-value problem for $\varphi(x, y, t)$.

Another simple problem is the classical motion by mean curvature. In this “flow,” one is interested in tracking the motion of a curve for which every point on the curve is moving normal to the curve at a velocity

proportional to the curvature. The evolution equation is given by

$$\frac{\partial \varphi}{\partial t} = \nabla \cdot \frac{\nabla \varphi}{|\nabla \varphi|}.$$

A numerical solution of this evolution equation can be used to demonstrate the classical Grayson theorem, which asserts that, if the closed curve starts out without self-intersections, then it will never form self-intersections and it will become convex in finite time.

Significant problems arising from applications from diverse fields have benefited from the level set treatment. The following is an incomplete list meant to give a sense of the range of applications.

Image processing. The level set method can be used for segmentation of objects in a two-dimensional scene. It has also been demonstrated to be effective in modeling surfaces from point clouds.

Fluid dynamics. Two-phase flows, which involve interfaces separating the two phases, can be approached by the level set method. It is particularly effective for problems in which one of the phases is dispersed in bubbles.

Inverse problems. Inverse problems exist in which the unknown that one wishes to reconstruct from data is the boundary of an object. Examples include inverse scattering.

Optimal shape design. When the object is to design a shape that maximizes certain attributes (design objectives), it is often very convenient to represent the shape by a level set function.

Computer animation. The need for physically based simulations in the animation industry has been partially met by solving equations of physics using the level set method to represent surfaces that are involved in the simulation.

Current research areas include improved accuracy in the numerical schemes employed and in applying the method to ever more complex physics.

II.25 Markov Chains

Beatrice Meini

A Markov chain is a type of random process whose behavior in the future is influenced only by its current state and not by what happened in the past. A simple example is a random walk on \mathbb{Z} , where a particle moves among the integers of the real line and is allowed to move one step forward with probability $0 < p < 1$ and one step backward with probability $q = 1 - p$ (see figure 1). The position of the particle at time $n + 1$ (in the future) depends on the position of the particle at time n (at the present time), and what happened before time n (in the past) is irrelevant.

To give a precise definition of a Markov chain we will need some notation. Let E be a countable set representing the states, and let Ω be a set that represents the sample space. Let $X, Y: \Omega \rightarrow E$ be two random variables. We denote by $\mathbb{P}[X = j]$ the probability that X takes the value j , and we denote by $\mathbb{P}[X = j | Y = i]$ the probability that X takes the value j given that the random variable Y takes the value i . A discrete stochastic process is a family $(X_n)_{n \in \mathbb{N}}$ of random variables $X_n: \Omega \rightarrow E$.

A stochastic process $(X_n)_{n \in \mathbb{N}}$ is called a *Markov chain* if

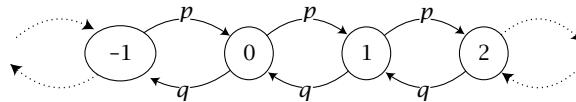

$$\begin{aligned} \mathbb{P}[X_{n+1} = i_{n+1} | X_0 = i_0, \dots, X_n = i_n] \\ = \mathbb{P}[X_{n+1} = i_{n+1} | X_n = i_n] \end{aligned}$$

at any time $n \geq 0$ and for any states $i_0, \dots, i_{n+1} \in E$. This means that the state X_n at time n is sufficient to determine which state X_{n+1} might be occupied at time $n + 1$, and we may forget the past history X_0, \dots, X_{n-1} .

It is often required that the laws that govern the evolution of the system be time invariant. The Markov chain is said to be *homogeneous* if the transitions from one state to another state are independent of the time n , i.e., if

$$\mathbb{P}[X_{n+1} = j | X_n = i] = p_{ij}$$

at any time $n \geq 0$ and for any states $i, j \in E$. The number p_{ij} represents the probability of passing from state i to state j in one time step. The matrix $P = (p_{ij})_{i,j \in E}$ is called the *transition matrix* of the Markov chain. The matrix P is a *stochastic matrix*: that is, it has nonnegative entries and unit row sums ($\sum_{j \in E} p_{ij} = 1$ for all $i \in E$). The dynamic behavior of the Markov chain is governed by the transition matrix P . In particular, the problem of computing the probability that, after n

Figure 1 A random walk on \mathbb{Z} .

steps, the Markov chain is in a given state reduces to calculating the entries of the n th power of P , since

$$\mathbb{P}[X_n = j \mid X_0 = i] = (P^n)_{ij},$$

where $(P^n)_{ij}$ denotes the (i, j) entry of P^n .

In the random walk on \mathbb{Z} , the set of states is $E = \mathbb{Z}$, and the random variable X_n is the position of the particle at time n . The stochastic process $(X_n)_{n \in \mathbb{N}}$ is a homogeneous Markov chain. The transition matrix P is tridiagonal, with $p_{i,i+1} = p$, $p_{i,i-1} = q$, and $p_{ij} = 0$ for $j \neq i - 1, i + 1$.

In many applications, the interest is in the asymptotic behavior of the Markov chain. In particular, the question is to understand if $\lim_{n \rightarrow \infty} \mathbb{P}[X_n = j \mid X_0 = i]$ exists and if that limit is independent of the initial state i . If such a limit exists and is equal to $\pi_j > 0$ for any initial state i , then the vector $\pi = (\pi_j)_{j \in E}$ is such that $\sum_{j \in E} \pi_j = 1$ and $\pi^T P = \pi^T$. This vector π is called the *steady state vector*, or the *probability invariant vector*. If E is a finite set, then the steady state vector is a left eigenvector of P corresponding to the eigenvalue 1; moreover, if in addition the matrix P is irreducible, then there exists a unique steady state vector.

The matrix

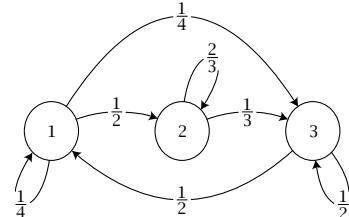

$$P = \begin{bmatrix} \frac{1}{4} & \frac{1}{2} & \frac{1}{4} \\ 0 & \frac{2}{3} & \frac{1}{3} \\ \frac{1}{2} & 0 & \frac{1}{2} \end{bmatrix} \quad (1)$$

is the transition matrix of a Markov chain with space state $E = \{1, 2, 3\}$. The transitions among the states can be represented by the graph of figure 2. The powers of P converge:

$$\lim_{n \rightarrow \infty} P^n = \begin{bmatrix} \frac{1}{4} & \frac{3}{8} & \frac{3}{8} \\ \frac{1}{4} & \frac{3}{8} & \frac{3}{8} \\ \frac{1}{4} & \frac{3}{8} & \frac{3}{8} \end{bmatrix}.$$

Hence the steady state vector is $\pi^T = [\frac{1}{4} \frac{3}{8} \frac{3}{8}]$. A simple computation shows that $\pi^T = \pi^T P$.

Markov chains have applications across a wide range of topics in different areas, including mathematical biology, chemistry, queueing theory, information sciences, economics and finance, Internet applications, and more. According to the model, the transition matrix P can be finite or infinite dimensional and can have

Figure 2 Transitions of the Markov chain having the matrix P of equation (1) as transition matrix.

specific structures, like sparsity or pattern structure. In most of the applications of Markov chains, the interest is in the computation of the steady state vector, assuming that it exists. In this regard, specific algorithms can be designed according to the properties of the matrix P .

II.26 Model Reduction

Peter Benner

“Model reduction” is an ambiguous term; in this article it is understood to mean the reduction of the complexity of a mathematical model by (semi-) automatic mathematical algorithms. Often such techniques are also called “dimension reduction,” “order reduction,” or, inspired by system-theoretic terminology, “model order reduction.” The concept is used in various application areas and in different contexts. Model order reduction has emerged in many disciplines, primarily in structural dynamics, systems and control theory, computational fluid mechanics, chemical process engineering, and, more recently, circuit simulation, microelectromechanical systems, and computational electromagnetics. It now also finds its way into numerous other

application areas such as image processing, computational neuroscience, and computational/computer-aided engineering in general.

Here, we will focus on the reduction of the dimension of the state space of a dynamical system, for which we use the following model equation:

$$E(t, p)\dot{x}(t) = f(t, x(t), u(t), p), \quad (1a)$$

$$x(t_0) = x_0, \quad (1b)$$

$$y(t) = g(t, x(t), u(t), p). \quad (1c)$$

In this set of equations, $x(t) \in \mathbb{R}^n$ is the state of the system at time $t \in [t_0, T]$ ($t_0 < T \leq \infty$), $u(t) \in \mathbb{R}^m$ denotes inputs (control, time-varying parameters), $p \in \Omega \subset \mathbb{R}^d$ is a vector of stationary (material, geometry, design, etc.) parameters, Ω is usually a bounded domain, and $x_0 \in \mathbb{R}^n$ is the initial state of the system. The matrix $E(t, p) \in \mathbb{R}^{n \times n}$ determines the nature of the system. When it is uniformly nonsingular, (1a) represents a system of ordinary differential equations; otherwise (1) is a *descriptor system*. If $d > 0$, i.e., when parameters are present, one may also consider the case $E(t, p) \equiv 0$. Then (1a) becomes a system of (nonlinear) algebraic equations. Model reduction preserving the parameters as symbolic quantities will then accelerate the approximate solution of (1a) in the case of varying parameters (the “many-query context”). The equation (1c) describes an output vector $y(t) \in \mathbb{R}^q$. It may correspond to a practical setting where only a few measurements of the system or observables are available. This equation may also be used to identify quantities of interest when full state information is not required in the application. If full state information is needed, one simply sets $y(t) = x(t)$. The functions f and g are assumed to have sufficient smoothness properties, where for f , Lipschitz continuity is usually a minimum requirement for ensuring existence and uniqueness of local solutions of (1a).

The goal of model reduction is to replace (1) by a system of reduced state-space dimension $r \ll n$ of the same form,

$$\hat{E}(t, p)\dot{\hat{x}}(t) = \hat{f}(t, \hat{x}(t), u(t), p), \quad (2a)$$

$$\hat{x}(t_0) = \hat{x}_0, \quad (2b)$$

$$\hat{y}(t) = g(t, \hat{x}(t), u(t), p), \quad (2c)$$

with the inputs $u(t)$ and the parameter vector p unchanged from (1), such that \hat{y} matches y as closely as possible for all admissible control inputs and parameters. Additionally, one may require the preservation

of structural properties like stability, passivity, dissipativity, etc. It should be clear that it is difficult to fulfill all these demands at once, and various model order reduction methods for specific applications have therefore been developed. A common principle can be found in many of these, and the mathematical core of the methods is often very similar.

1 The Basic Concept

The basic principle behind most model order reduction methods is the projection of the state equation (1a) onto a low-dimensional subset $\mathcal{V} \subset \mathbb{R}^n$, possibly along a complementary subspace \mathcal{W} of the same dimension. The projection onto nonlinear subsets like central or (approximate) inertial manifolds is the topic of the theory of dynamical systems and has been applied so far mainly in reaction kinetics, process engineering, and systems biology. Most other successful families of methods—such as *modal truncation*, *balanced truncation*, *Padé approximation/Krylov subspace methods/moment matching* (which are all instances of rational interpolation), and *proper orthogonal decomposition* and *reduced basis methods*—use linear projection subspaces, and they can mostly be categorized as (Petrov–) Galerkin projection methods. Suppose we are given an orthogonal basis of \mathcal{V} , represented by the column space of $V \in \mathbb{R}^{n \times r}$, and a basis of \mathcal{W} forming the column space of $W \in \mathbb{R}^{n \times r}$ (where $\mathcal{W} = \mathcal{V}$ and $W = V$ in the Galerkin case) such that $W^T V = I_r$ (the $r \times r$ identity matrix). The reduced-order model is then obtained by setting $\hat{x} = W^T x$, $\hat{x}_0 = W^T x_0$, and making the residual of (1a) for \hat{x} orthogonal to \mathcal{W} :

$$\begin{aligned} W \perp E(t, p)\dot{x} - f(t, x, u, p) & \quad \forall \text{ admissible } t, u, p \\ \Leftrightarrow 0 &= W^T(E(t, p)\dot{x} - f(t, x, u, p)). \end{aligned}$$

The different methods now mainly differ in the way V (and W) are computed. The full state x of (1) is approximated by $\hat{x} = V\hat{x}(t) = VW^T x(t)$.

As an example, consider a linear time-invariant system without parameters:

$$E(t, p) \equiv E, \quad (3a)$$

$$f(t, x, u, p) = Ax + Bu, \quad (3b)$$

$$g(t, x, u, p) = Cx, \quad (3c)$$

with $A, E \in \mathbb{R}^{n \times n}$, $B \in \mathbb{R}^{n \times m}$, $C \in \mathbb{R}^{q \times n}$. For instance, interpolation methods (and also balanced truncation) utilize the transfer function

$$G(s) = C(sE - A)^{-1}B, \quad s \in \mathbb{C},$$

of (1), which in the linear time-invariant case is obtained by taking Laplace transforms and inserting the transformed equation (1a) into the transformed (1c). The transfer function represents the mapping of inputs u to outputs y . As a rational matrix-valued function of a complex variable, it can be approximated in different ways. In rational interpolation methods, V , W are computed so that

$$\frac{d^j}{ds^j} G(s_k) = \frac{d^j}{ds^j} \hat{G}(s_k), \quad k = 1, \dots, K, \quad j = 0, \dots, J_k,$$

for K interpolation points s_k and derivatives up to order J_k at each point. Here, \hat{G} denotes the transfer function of (2) and (3), defined by $\hat{A} = W^T A V$, $\hat{B} = W^T B$, and $\hat{C} = C V$.

In the nonlinear case, a further question is how to obtain functions \hat{f} and \hat{g} allowing for fast evaluation. Simply setting $\hat{f}(t, x, u, p) = W^T f(t, V\hat{x}, u, p)$ obviously does not lead to faster simulation in general. Therefore, dedicated methods, such as (discrete) empirical interpolation, are needed to obtain a “reduced” \hat{f} and \hat{g} .

2 An Example

As an example consider the mathematical model of a microgyroscope: a device used in stability control of vehicles. Finite-element discretization of this particular model leads to a linear time-invariant system of $n = 34\,722$ linear ordinary differential equations with $d = 4$ parameters, $m = 1$ input, and $q = 12$ outputs. Using a reduced-order model of size $r = 289$, a parameter study involving two parameters (defining x - and y -axes in figure 1) and the excitation frequency ω (i.e., the parametric transfer function $G(s, p)$ is evaluated for $s = i\omega$ with varying ω) could be accelerated by a factor of approximately 90 without significant loss of accuracy. The output y was computed with an error of less than 0.01% in the whole frequency and parameter domain. Figure 1 shows the response surfaces of the full and reduced-order models at one frequency for variations of two parameters.

II.27 Multiscale Modeling

Fadil Santosa

To accurately model physical, biological, and other phenomena, one is often confronted with the need to capture complex interactions occurring at distinct temporal and spatial scales. In the language of multiscale modeling, temporal scales are usually differentiated by slow, medium, and fast timescales. Spatially, the phenomena are separated into micro-, meso-, and

macroscales. In modeling the deformation of solids, for instance, the microscale phenomena could be atomistic interactions occurring on a femtosecond (10^{-15} second) timescale. At the mesoscopic scale, one could be interested in the behavior of the constituent macromolecules, e.g., a tangled bundle of polymers. Finally, at the macroscopic scale, one might be interested in how a body, whose size could be in meters, deforms under an applied force. The challenge in multiscale modeling is that the interactions at one scale communicate with interactions at other scales. Thus, in the example given, the question we wish to answer is how the applied forces affect the atomistic interactions, and how those interactions impact the behavior of the macromolecules, which in turn affects how the overall shape of the body deforms.

Multiscale modeling is a rapidly developing field because of its enormous importance in applications. The range of applications is staggering. It has been applied in geophysics, biology, chemistry, meteorology, materials science, and physics.

We give another concrete example that arises in solid mechanics. Suppose we have a block of pure aluminum whose crystalline structure is known. How can we calculate its elastic properties, i.e., its Lamé modulus and Poisson ratio, *ab initio* from knowledge of its atomistic structure? Such a calculation would start by considering Schrödinger's equation for the multiparticle system. By solving for the ground states of the system, one can then extract the desired macroscopic properties of the bulk aluminum.

A classical example of multiscale modeling in applied mathematics is the HOMOGENIZATION METHOD [II.17], which allows for extraction of effective properties of composite materials. Consider the steady-state distribution of temperature in a rod of length ℓ made up of a material with rapidly oscillating conductivity. The conductivity is described by a periodic function $a(y) > 0$, such that $a(y+1) = a(y)$. A small-scale ε is introduced to denote the actual period in the medium. The governing equation for temperature $u(x)$ is

$$\left(a\left(\frac{x}{\varepsilon}\right)u'\right)' = f, \quad 0 < x < \ell,$$

where a prime denotes differentiation with respect to x . Here, f is the heat source distribution, with x measuring distance along the rod. To solve the problem, the solution u is developed in powers of ε . The macroscopic behavior of u is identified with the zeroth order. This solution will be smooth as the small rapid oscillations are ignored.

Current research in multiscale modeling focuses on bridging the phenomena at the different scales and developing efficient numerical methods. There are efforts to develop rigorous multiscale models that agree with their continuum counterparts. CONTINUUM MODELS [IV.26] are macroscale models derived from first principles and where the material properties are usually measured. Other efforts concentrate more on developing accurate simulations, such as modeling the properties of Kevlar starting from the polymers in the resin and the carbon fibers used. All research in this area involves some numerical analysis and scientific computing.

II.28 Nonlinear Equations and Newton's Method

Marcos Raydan

Nonlinear equations appear frequently in the mathematical modeling of real-world processes. They are usually written as a zero-finding problem: find $x_j \in \mathbb{R}$, for $j = 1, 2, \dots, n$, such that

$$f_i(x_1, \dots, x_n) = 0 \quad \text{for } i = 1, 2, \dots, n,$$

where the f_i are given functions of n variables. This system of equations is nonlinear if at least one of the functions f_i depends nonlinearly on at least one of the variables. Using vector notation, the problem can also be written as find $x = [x_1, \dots, x_n]^T \in \mathbb{R}^n$ such that

$$F(x) = [f_1(x), \dots, f_n(x)]^T = 0.$$

If every function f_i depends linearly on all the variables, then it is usually written as a linear system of equations $Ax = b$, where $b \in \mathbb{R}^n$ and A is an $n \times n$ matrix.

The existence and uniqueness of solutions for nonlinear systems of equations is more complicated than for linear systems of equations. For solving $Ax = b$, the number of solutions must be either zero, infinity, or one (when A is nonsingular), whereas $F(x) = 0$ can have zero, infinitely many, or any finite number of solutions. Fortunately, in practice, it is usually sufficient to find a solution of the nonlinear system for which a reasonable initial approximation is known.

Even in the simple one-dimensional case ($n = 1$), most nonlinear equations cannot be solved by a closed formula, i.e., using a finite number of operations. A well-known exception is the problem of finding the roots of polynomials of degree less than or equal to four, for which closed formulas have been known for

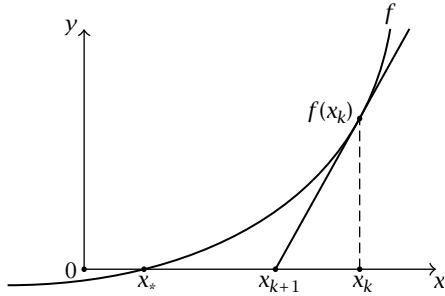

Figure 1 One iteration of Newton's method in one dimension for $f(x) = 0$.

centuries. As a consequence, in general iterative methods must be used to produce increasingly accurate approximations to the solution. One of the oldest iterative schemes, which has played an important role in the numerical methods literature for solving $F(x) = 0$, is Newton's method.

1 Newton's Method

Newton's method for solving nonlinear equations was born in one dimension. In that case, the problem is find $x \in \mathbb{R}$ such that $f(x) = 0$, where $f: \mathbb{R} \rightarrow \mathbb{R}$ is differentiable in the neighborhood of a solution x_* . Starting from a given x_0 , on the k th iteration Newton's method constructs the tangent line passing through the point $(x_k, f(x_k))$,

$$M_k(x) = f(x_k) + f'(x_k)(x - x_k),$$

and defines the next iterate, x_{k+1} , as the root of the equation $M_k(x) = 0$ (see figure 1). Hence, from a given $x_0 \in \mathbb{R}$, Newton's method generates the sequence $\{x_k\}$ of approximations to x_* given by

$$x_{k+1} = x_k - f(x_k)/f'(x_k).$$

Notice that the tangent line or linear model $M_k(x)$ is equal to the first two terms of the Taylor series of f around x_k .

Newton's idea in one dimension can be extended to n -dimensional problems. In \mathbb{R}^n the method approximates the solution of a square nonlinear system of equations by solving a sequence of square linear systems. As in the one-dimensional case, on the k th iteration the idea is to define x_{k+1} as a zero of the linear model given by

$$M_k(x) = F(x_k) + J(x_k)(x - x_k),$$

where the map $F: \mathbb{R}^n \rightarrow \mathbb{R}^n$ is assumed to be differentiable in a neighborhood of a solution x_* and where $J(x_k)$ is the $n \times n$ Jacobian matrix with entries $J_{ij}(x_k) = \partial f_i / \partial x_j(x_k)$ for $1 \leq i, j \leq n$. Therefore, starting at a given $x_0 \in \mathbb{R}^n$, Newton's method carries out for $k = 1, 2, \dots$ the following two steps.

- Solve $J(x_k)s_k = -F(x_k)$ for s_k .
- Set $x_{k+1} = x_k + s_k$.

Notice that Newton's method is scale invariant: if the method is applied to the nonlinear system $AF(x) = 0$, for any nonsingular $n \times n$ matrix A , the sequence of iterates is identical to the ones obtained when it is applied to $F(x) = 0$. Another interesting theoretical feature is its impressively fast local convergence. Under some standard assumptions—namely that $J(x_*)$ is nonsingular, $J(x)$ is Lipschitz continuous in a neighborhood of x_* , and the initial guess x_0 is sufficiently close to x_* —the sequence $\{x_k\}$ generated by Newton's method converges *quadratically* to x_* ; i.e., there exist $c > 0$ and $\hat{k} \geq 0$ such that for all $k \geq \hat{k}$,

$$\|x_{k+1} - x_*\| \leq c \|x_k - x_*\|^2.$$

Hence Newton's method is theoretically attractive, but it may be difficult to use in practice for various reasons, including the need to calculate the derivatives, the need to have a good initial guess to guarantee convergence, and the cost of solving an $n \times n$ linear system per iteration.

2 Practical Variants

If the derivatives are not available, or are too expensive to compute, they can be approximated by finite differences. A standard option is to approximate the j th column of $J(x_k)$ by a forward difference quotient: $(F(x_k + h_k e_j) - F(x_k)) / h_k$, where e_j denotes the j th unit vector and $h_k > 0$ is a suitable small number. Notice that, when using this finite-difference variant, the map F needs to be evaluated $n + 1$ times per iteration, once for each column of the Jacobian and one for the vector x_k . Therefore, this variant is attractive when the evaluation of F is not expensive.

Another option is to extend the well-known one-dimensional secant method to the n -dimensional problem $F(x) = 0$. The main idea, in these so-called *secant* or *QUASI-NEWTON METHODS* [IV.11 §4.2], is to generate not only a sequence of iterates $\{x_k\}$ but also a sequence of matrices $\{B_k\}$ that approximate $J(x_k)$ and satisfy the secant equation $B_k s_{k-1} = y_{k-1}$, where $s_{k-1} = x_k - x_{k-1}$

and $y_{k-1} = F(x_k) - F(x_{k-1})$. In this case, an initial matrix $B_0 \approx J(x_0)$ must be supplied. Clearly, infinitely many $n \times n$ matrices satisfy the secant equation. As a consequence, a wide variety of quasi-Newton methods (e.g., Broyden's method) with different properties have been developed.

When using Newton's method, or any of its derivative-free variants, a linear system needs to be solved at each iteration. This linear system can be solved by direct methods (e.g., LU or QR factorization), but if n is large and the Jacobian matrix has a sparse structure, it may be preferable to use an iterative method (e.g., a KRYLOV SUBSPACE METHOD [IV.10 §9]). For that, note that x_k can be used as the initial guess for the solution at iteration $k+1$. One of the important features of these so-called inexact variants of Newton's method is that modern iterative linear solvers do not require explicit knowledge of the Jacobian; instead, they require only the matrix-vector product $J(x_k)z$ for any given vector z . This product can be approximated using a forward finite difference:

$$J(x_k)z \approx (F(x_k + h_k z) - F(x_k)) / h_k.$$

Hence, inexact variants of Newton's method are also suitable when derivatives are not available. In all the discussed variants, the local *q-quadratic convergence* is in general lost, but *q-superlinear convergence* can nevertheless be obtained, i.e., $\|x_{k+1} - x_*\| / \|x_k - x_*\| \rightarrow 0$.

Finally, in general Newton's method converges only locally, so it requires globalization strategies to be practically effective. The two most popular and best-studied options are line searches and trust regions. In any case, a merit function $\hat{f}: \mathbb{R}^n \rightarrow \mathbb{R}^+$ must be used to evaluate the quality of all possible iterates. When solving $F(x) = 0$, the natural choice is $\hat{f}(x) = F(x)^T F(x)$.

II.29 Orthogonal Polynomials

Polynomials $p_0(x), p_1(x), \dots$, where p_i has degree i , are *orthogonal polynomials* on an interval $[a, b]$ with

Table 1 Parameters in the three-term recurrence (1) for some classical orthogonal polynomials.

Polynomial	$[a, b]$	$w(x)$	a_j	b_j	c_j
Chebyshev	$[-1, 1]$	$(1 - x^2)^{-1/2}$	2	0	1
Legendre	$[-1, 1]$	1	$\frac{2j+1}{j+1}$	0	$\frac{j}{j+1}$
Hermite	$(-\infty, \infty)$	e^{-x^2}	2	0	$2j$
Laguerre	$[0, \infty)$	e^{-x}	$-\frac{1}{j+1}$	$\frac{2j+1}{j+1}$	$\frac{j}{j+1}$

respect to a nonnegative weight function $w(x)$ if

$$\int_a^b w(x) p_i(x) p_j(x) dx = 0, \quad i \neq j,$$

that is, if all distinct pairs of polynomials are orthogonal on $[a, b]$ with respect to w . For a given weight function and interval, the orthogonality conditions determine the polynomials p_i uniquely up to a constant factor.

An important property of orthogonal polynomials is that they satisfy a three-term recurrence relation

$$p_{j+1}(x) = (a_j x + b_j) p_j(x) - c_j p_{j-1}(x), \quad j \geq 1. \quad (1)$$

The weight functions, interval, and recurrence coefficients for some classical orthogonal polynomials are summarized in table 1, in which it is assumed the normalization $p_0(x) = 1$, with $p_1(x) = x$ for the Chebyshev and Legendre polynomials, $p_1(x) = 2x$ for the Hermite polynomials, and $p_1(x) = 1 - x$ for the Laguerre polynomials.

Orthogonal polynomials have many interesting properties and find use in many different settings, e.g., in numerical integration, Krylov subspace methods, and the theory of continued fractions. In this volume they arise in LEAST-SQUARES APPROXIMATION [IV.9 §3.3], NUMERICAL SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS [IV.13 §6], RANDOM-MATRIX THEORY [IV.24], and as SPECIAL FUNCTIONS [IV.7 §7]. See SPECIAL FUNCTIONS [IV.7 §7] for more information.

II.30 Shocks

Barbara Lee Keyfitz

1 What Are Shocks?

“Shocks” (or “shock waves”) is another name for the field of quasilinear hyperbolic PDEs, or CONSERVATION LAWS [II.6]. When the mathematical theory of supersonic flow was in its infancy, the first text on the subject named it this way; and the first modern monograph to

focus on the mathematical theory of quasilinear hyperbolic PDEs also used this terminology. Shocks are a dominant feature of the subject, for, as noted with reference to the BURGERS EQUATION [III.4] (see also PARTIAL DIFFERENTIAL EQUATIONS [IV.3 §3.6]), solutions to initial-value problems, even with smooth data, are not likely to remain smooth for all time. We return to the derivation to see what happens when solutions are not differentiable.

In the derivation of a system in one space dimension,

$$\mathbf{u}_t + \mathbf{f}(\mathbf{u})_x = 0, \quad (1)$$

one typically invokes the conservation of each component u_i of \mathbf{u} . The rate of change of u_i over a control length $[x, x+h]$ is the net flux across the endpoints:

$$\partial_t \int_x^{x+h} u_i(y, t) dy = f_i(\mathbf{u}(x, t)) - f_i(\mathbf{u}(x+h, t)). \quad (2)$$

Under the assumption that \mathbf{u} is differentiable, the mean value theorem of calculus yields (1) in the limit $h \rightarrow 0$. However, (2) is also useful in a different case. If \mathbf{u} approaches two different limits, $\mathbf{u}_L(X(t), t)$ and $\mathbf{u}_R(X(t), t)$, on the left and right sides of a curve of discontinuity, $x = X(t)$, then taking the limit $h \rightarrow 0$ in (2) with x and $x+h$ straddling the curve $X(t)$ yields a relationship among \mathbf{u}_L , \mathbf{u}_R , and the derivative of the curve:

$$\begin{aligned} X'(t)(\mathbf{u}_R(X(t), t) - \mathbf{u}_L(X(t), t)) \\ = \mathbf{f}(\mathbf{u}_R(X(t), t)) - \mathbf{f}(\mathbf{u}_L(X(t), t)). \end{aligned} \quad (3)$$

This is known as the (generalized) Rankine–Hugoniot relation. The quantity $X'(t)$ measures the speed of propagation of the discontinuity at $X(t)$.

Because solutions of conservation laws are not expected to be continuous for all time, even when the initial data are smooth, it is necessary to allow shocks in any formulation of what is meant by a “solution” of (1). Conservation law theory states that a solution of (1) may contain countably many shocks, the functions $X(t)$ may be no smoother than Lipschitz continuous, and there may be countably many points in physical (x, t) -space at which shock curves intersect. In the case of conservation laws in more than one space dimension, the notion of a “shock curve” can be generalized to that of a “shock surface” by supposing that the solution is piecewise differentiable on each side of such a surface. One obtains an equation similar to (3) that relates the states on either side of the surface to the normal to the surface at each point. However, as distinct from the case in a single space dimension, it is not known

whether all solutions have this structure, or whether more singular behavior is possible.

2 Entropy, Admissibility, and Uniqueness

Although allowing for weak solutions, in the form of solutions containing shocks, is forced upon us by both mathematical considerations (they arise from almost all data) and physical considerations (they are seen in all the fluid systems modeled by conservation laws), a new difficulty arises: if shocks are admitted as solutions to a conservation law system, there may be *too many* solutions (this is also known, somewhat illogically, as “lack of uniqueness”). Here is a simple example, involving the Burgers equation. If at $t = 0$ we are given

$$u(x, 0) = \begin{cases} 0, & x \leq 0, \\ 1, & x > 0, \end{cases}$$

then

$$u(x, t) = \begin{cases} 0, & x \leq \frac{1}{2}t, \\ 1, & x > \frac{1}{2}t, \end{cases}$$

is a shock solution in the sense of (3). But

$$u(x, t) = \begin{cases} 0, & x \leq 0, \\ x/t, & 0 < x \leq t, \\ 1, & x > t, \end{cases}$$

is also a solution, and in fact it is the latter, which is described as a “rarefaction wave,” that is correct, while the former, known as a “RAREFACTION SHOCK [V.20 §2.2],” can be ruled out on both mathematical and physical grounds. A fluid that is rarefying (that is, one in which the force of pressure is decreasing), be it a gas or traffic, spreads out gradually and erases the initial discontinuity, while a fluid that is being compressed forms a shock.

Another mode of reasoning, which has both a mathematical and a physical basis, goes as follows. Suppose η is a convex function of \mathbf{u} for which another function $q(\mathbf{u})$ exists such that

$$\eta(\mathbf{u})_t + q(\mathbf{u})_x = 0 \quad (4)$$

whenever \mathbf{u} is a smooth solution of (1). When this is the case, we say that (1) “admits a convex entropy.” A calculation (easy for the Burgers equation and true in general) shows that we should not expect (4) to be satisfied (in the weak sense, as an additional Rankine–Hugoniot relation like (3)) in regions containing shocks. But since η is convex, imposing the requirement that η decrease in time when shocks are present forces a bound on

solutions. For systems of conservation laws in a single space dimension, this condition, which admits some shocks and not others as weak solutions, is sufficient to guarantee uniqueness.

There are a number of other ways to formulate admissibility conditions for shocks, including modifying the system with so-called viscosity terms to make it parabolic,

$$u_t + \mathbf{f}(\mathbf{u})_x = \varepsilon \mathbf{u}_{xx}, \quad (5)$$

and then admitting only shocks that are limits, as $\varepsilon \rightarrow 0$, of classical solutions of this semilinear parabolic system.

3 Shock Profiles

To a fluid dynamicist, the viscous equation (5) is more than an artifice to obtain uniqueness of solutions by winnowing out shocks that fail some test. The hyperbolic system (1) may be regarded as an approximation to a more realistic physical situation that takes into account viscosity, heat transfer effects, and even the mean free path of particles (for a gas). If, for example, viscous effects are included, the right-hand side of (5) takes the form $B\mathbf{u}_{xx}$, where $B = B(\mathbf{u})$ is a matrix that is typically diagonal, typically positive-semidefinite, and typically small when the system is measured on the length scale of interest. In particular, the hyperbolic system (1) gives a good description of a flow on that length scale. However, across a shock there is a rapid change in \mathbf{u} , or at least in some of its components, and the hyperbolic approximation is not adequate. One approach here is to use the hyperbolic system to uncover the macroscopic features of the shock—the speed $c = X'$ and the states on either side, using (3)—and then to formulate a traveling wave problem for the solution inside the shock. That is, one uses techniques from dynamical systems to study solutions $\mathbf{u}(\xi) = \mathbf{u}(x - ct)$ of

$$-cu' + A(\mathbf{u})\mathbf{u}' = B(\mathbf{u})\mathbf{u}'',$$

$$\mathbf{u}(-\infty) = \mathbf{u}_L, \quad \mathbf{u}(\infty) = \mathbf{u}_R,$$

where A is the Jacobian matrix of the flux function f .

II.31 Singularities

P. A. Martin

The word “singularity” has a variety of meanings in mathematics but it usually means a place or point where something bad happens. For example, the function $f(x) = 1/x$ is not defined at $x = 0$; it has a singularity at $x = 0$: it is “singular” there. In this simple example, $f(x)$ is unbounded (infinite) at $x = 0$, but this need not be a defining property of a singularity. Thus, in COMPLEX ANALYSIS [IV.1], $f(z)$ is said to have a singularity at a point z_0 when f is not differentiable at z_0 . For example, $f_1(z) = 1/(z - 1)^2$ has a singularity at $z = 1$, and $f_2(z) = z^{1/2}$ has a singularity at $z = 0$. Note that $f_1(z)$ is unbounded at $z = 1$, whereas $f_2(0) = 0$. In complex analysis, singularities of $f(z)$ are exploited to good effect, especially in the calculus of residues.

Before describing more benefits of singularities, let us consider some of the trouble that they may cause. Elementary examples occur in the evaluation of definite integrals when the integrand is unbounded at some point in the range of integration. For example, consider $I = \int_0^1 x^\alpha dx$, where α is a parameter. Integrating, $I = 1/(\alpha + 1)$ provided $\alpha > -1$; the integral diverges for $\alpha \leq -1$. (When $\alpha = -1$, use $\int x^{-1} dx = \log|x|$.) When $\alpha < 0$, the integrand $f(x) = x^\alpha$ is unbounded as $x \rightarrow 0$ through positive values. Nevertheless, even though $f(x)$ has a singularity at $x = 0$, the singularity is integrable when $-1 < \alpha < 0$, meaning that the area under the graph, $y = f(x)$, $0 < x < 1$, is finite; the area is infinite when $\alpha \leq -1$.

In the example just described we were able to evaluate the integral I exactly, and this enabled us to examine the effect of the parameter α . In practice, we may have to compute the value of an integral numerically using a quadrature rule (such as the trapezium rule or Simpson’s rule). When the integrand has a singularity, we are often obliged to use a specialized rule tailored to that specific kind of singularity or to use a substitution designed to remove the singularity. Generally, a blend of analytical and numerical techniques is needed so as to mollify the effects of the singularity.

Similar difficulties can occur in many other problems, such as when solving boundary-value problems for a PARTIAL DIFFERENTIAL EQUATION [IV.3] (PDE). For a specific example, consider LAPLACE’S EQUATION [III.18], $\nabla^2 u = 0$, in the region $r > 0$, $0 < \theta < \beta$, where r and θ are plane polar coordinates and the angle β satisfies $0 < \beta < 2\pi$. We shall refer to this region as a

wedge. If we have boundary conditions $u = 0$ on both sides of the wedge, $\theta = 0$ and $\theta = \beta$, one solution is $u(r, \theta) = r^\nu \sin(\nu\theta)$, where $\nu = \pi/\beta$. This solution is zero at the tip of the wedge (where $r = 0$), but derivatives of u may be unbounded there; for example, if we take $\beta = \frac{4}{3}\pi$, then $\nu = \frac{3}{4}$ and the gradient of u is unbounded at $r = 0$. This singular behavior is typical at corners and often degrades the performance of numerical methods for solving PDEs. In fact, it is not even necessary to have a corner, as a change in boundary condition can have the same effect. For example, take $\beta = \pi$, so that the wedge becomes the half-plane $y > 0$, and then require that $u = 0$ at $\theta = 0$ and $\partial u / \partial \theta = 0$ at $\theta = \pi$. Then one solution is $u = r^{1/2} \sin(\theta/2)$, and this has an unbounded gradient at $r = 0$, which is the point on the straight edge $y = 0$ where the boundary condition changes. This phenomenon was built into the *Motz problem*, devised in the 1940s for testing numerical methods; it is still in use today.

Returning to the wedge, take $\beta = 2\pi$ so that the wedge becomes the whole plane with a slit along the positive x -axis. The two sides of the slit are defined by $\theta = 0$ and $\theta = 2\pi$. Suppose that the boundary conditions are $\partial u / \partial \theta = 0$ at $\theta = 0$ and $\theta = 2\pi$. One solution of $\nabla^2 u = 0$ is then $u = r^{1/2} \cos(\theta/2)$, and this has an unbounded gradient at $r = 0$. This solution is of interest in the MECHANICS OF SOLIDS [IV.32], where the slit represents a crack, u is a displacement, and the gradient of u is related to the elastic stresses. The linear theory of elasticity predicts that the stresses are given approximately by $r^{-1/2} K(\theta)$ when r (the distance from the crack tip) is small, where K can be calculated. The form of the singular behavior, namely $r^{-1/2}$, is given by a local analysis near the crack tip, but the multiplier K , known as the *stress intensity factor*, requires knowledge of the geometry of the cracked body and the applied loads. Physically, the stresses cannot be infinite: the linear theory of elasticity breaks down at crack tips. A more accurate theory might involve plastic effects or consideration of atomic structures. However, useful predictions about when a cracked object will break as the applied loads are increased can be made by examining K . This is at the heart of engineering theories of *fracture mechanics*. It is another example where the singular behavior can be exploited.

Returning to mathematics, consider Laplace's equation in three dimensions, $\nabla^2 u = 0$. One solution is

$$G(x, y, z; x_0, y_0, z_0) = G(P, P_0) = R^{-1},$$

where

$$R = \{(x - x_0)^2 + (y - y_0)^2 + (z - z_0)^2\}^{1/2}.$$

Here we can regard (x, y, z) and (x_0, y_0, z_0) as being the coordinates of points P and P_0 , respectively, and we have $\nabla^2 G = 0$ for fixed P_0 , provided $P \neq P_0$. As R is the distance between P and P_0 , we see that G is singular as $P \rightarrow P_0$. The function G is an example of a *Green function*, named after George Green. (It is conventional to abandon the rules of English grammar and to speak of “a Green's function”; opposing this widespread misuse appears futile.) One use of G comes when we want to solve Poisson's equation, $\nabla^2 u = f$, where f is a given function. Thus

$$u(P_0) = -\frac{1}{4\pi} \int G(P, P_0) f(P) dP,$$

where the integration is over all P . Notice that G could be replaced by $A/R + H(P, P_0)$, where A is a constant and H is any solution of $\nabla^2 H = 0$. In principle, H can be chosen so that G satisfies additional conditions, such as boundary conditions; indeed, this was how Green conceived of his function, as the electrostatic field inside a conductor due to a point charge. However, in practice, it is usual to use a simple G and then to impose boundary conditions on u by solving an INTEGRAL EQUATION [IV.4]. We note that the alternative terminology *fundamental solution* is often used, meaning a simple singular solution of a governing PDE.

Singularities can occur in many other contexts. We mention two. Suppose we want to solve an initial-value problem for a nonlinear PDE, where the initial state at time $t = 0$ is specified and the goal is to calculate the solution as t increases. It is then possible that the solution becomes unbounded as $t \rightarrow t_c$, where t_c is some finite critical time. This is known as “blow-up”: there is a finite-time singularity at $t = t_c$ (see PARTIAL DIFFERENTIAL EQUATIONS [IV.3 §3.6]). There is much interest within FLUID DYNAMICS [IV.28] in the existence or otherwise of finite-time singularities because it is thought that they may be relevant in understanding the nature of TURBULENCE [V.21].

Finally, we cannot end an article on singularities without mentioning cosmology. It is generally accepted that the Big Bang theory gives a model for how the universe evolves, starting from an initial singularity. Some cosmologists believe that the universe will end with a singularity; the trouble caused by this singularity (if it exists) is unlikely to bother readers of this article.

II.32 The Singular Value Decomposition

Nicholas J. Higham

One of the most useful matrix factorizations is the *singular value decomposition* (SVD), which is defined for an arbitrary rectangular matrix $A \in \mathbb{C}^{m \times n}$. It takes the form

$$A = U\Sigma V^*, \quad \Sigma = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_p) \in \mathbb{R}^{m \times n}, \quad (1)$$

where $p = \min(m, n)$, Σ is a diagonal matrix with diagonal elements $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_p \geq 0$, and $U \in \mathbb{C}^{m \times m}$ and $V \in \mathbb{C}^{n \times n}$ are unitary. The σ_i are the *singular values* of A , and they are the nonnegative square roots of the p largest eigenvalues of A^*A . The columns of U and V are the left and right *singular vectors* of A , respectively.

Postmultiplying (1) by V gives $AV = U\Sigma$ since $V^*V = I$, which shows that the i th columns of U and V are related by $Av_i = \sigma_i u_i$ for $i = 1:p$. Similarly, $A^*u_i = \sigma_i v_i$ for $i = 1:p$. A geometrical interpretation of the former equation is that the singular values of A are the lengths of the semiaxes of the hyperellipsoid $\{Ax : \|x\|_2 = 1\}$.

Assuming that $m \geq n$ for notational simplicity, from (1) we have

$$A^*A = V(\Sigma^*\Sigma)V^*, \quad (2)$$

with $\Sigma^*\Sigma = \text{diag}(\sigma_1^2, \sigma_2^2, \dots, \sigma_n^2)$, which shows that the columns of V are eigenvectors of the matrix A^*A with corresponding eigenvalues the squares of the singular values of A . Likewise, the columns of U are eigenvectors of the matrix AA^* .

The SVD reveals a great deal about the matrix A and the key subspaces associated with it. The rank, r , of A is equal to the number of nonzero singular values, and the range and the null space of A are spanned by the first r columns of U and the last $n - r$ columns of V , respectively.

The SVD reveals not only the rank but also how close A is to a matrix of a given rank, as shown by a classic 1936 theorem of Eckart and Young.

Theorem 1 (Eckart–Young). Let $A \in \mathbb{C}^{m \times n}$ have the SVD (1). If $k < r = \text{rank}(A)$, then for the 2-norm and the Frobenius norm,

$$\min_{\text{rank}(B)=k} \|A - B\| = \|A - A_k\| = \begin{cases} \sigma_{k+1}, & \text{2-norm,} \\ \sqrt{\sum_{i=k+1}^r \sigma_i^2}, & \text{F-norm,} \end{cases}$$

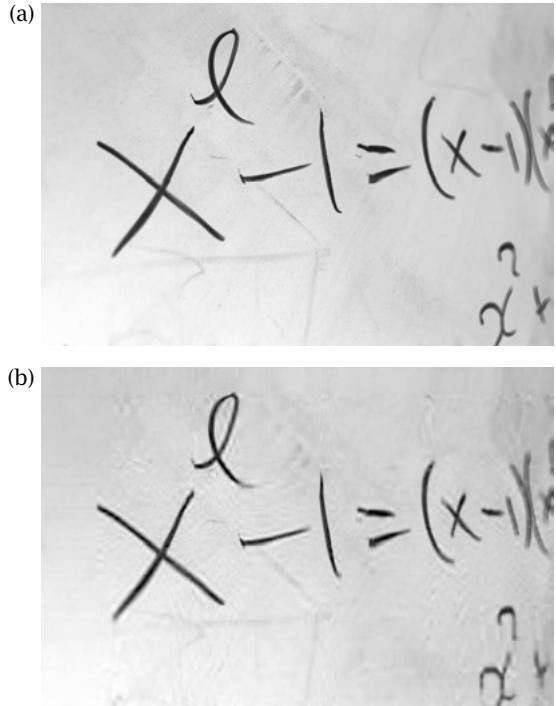

Figure 1 Photo of a blackboard, inverted so that white and black are interchanged in order to show more clearly the texture of the board: (a) original 1067×1600 image; (b) image compressed using rank-40 approximation A_{40} computed from SVD.

where

$$A_k = UD_kV^*, \quad D_k = \text{diag}(\sigma_1, \dots, \sigma_k, 0, \dots, 0).$$

In many situations the matrices that arise are necessarily of low rank but errors in the underlying data make the matrices actually obtained of full rank. The Eckart–Young result tells us that in order to obtain a lower-rank matrix we are justified in discarding (i.e., setting to zero) singular values that are of the same order of magnitude as the errors in the data.

The SVD (1) can be written as an outer product expansion

$$A = \sum_{i=1}^p \sigma_i u_i v_i^*,$$

and A_k in the Eckart–Young theorem is given by the same expression with p replaced by k . If $k \ll p$ then A_k requires much less storage than A and so the SVD can provide *data compression* (or *data reduction*). As an example, consider the monochrome image in figure 1(a) represented by a 1067×1600 array of RGB

values ($R = G = B$ since the image is monochrome). Let $A \in \mathbb{R}^{1067 \times 1600}$ contain the values from any one of the three channels. The singular values of A range from 8.4×10^4 down to 1.3×10^1 . If we retain only the singular values down to the 40th, $\sigma_{40} = 2.1 \times 10^3$ (a somewhat arbitrary cutoff since there is no pronounced gap in the singular values), we obtain the image in figure 1(b). The reduced SVD requires only 6% of the storage of the original matrix. Some degradation is visible in the compressed image (and more can be seen when it is viewed at 100% size on screen), but it retains all the key features of the original image. While this example illustrates the power of the SVD, image compression is in general done much more effectively by the JPEG SCHEME [VII.7 §5].

A pleasing feature of the SVD is that the singular values are not unduly affected by perturbations. Indeed, if A is perturbed to $A + E$ then no singular value of A changes by more than $\|E\|_2$.

The SVD is a valuable tool in applications where two-sided orthogonal transformations can be carried out without “changing the problem,” as it allows the matrix of interest to be diagonalized. Foremost among such problems is the LINEAR LEAST-SQUARES PROBLEM [IV.10 §7.1] $\min_{x \in \mathbb{C}^n} \|b - Ax\|_2$.

The SVD was first derived by Beltrami in 1873. The first reliable method for computing it was published by Golub and Kahan in 1965; this method applies two-sided unitary transformations to A and does not form and solve the equation (2), or its analogue for AA^* . Once software for computing the SVD became readily available, in the 1970s, the use of the SVD proliferated. Among the wide variety of uses of the SVD are for TEXT MINING [VII.24], deciphering encrypted messages, and image deblurring.

II.33 Tensors and Manifolds

Mark R. Dennis

We know that the surface of the Earth is curved, despite the fact that it appears flat. This is easily understood

from the fact that the Earth’s radius of curvature is over 6000 km, vast on a human scale. This picture motivates the mathematical definition of a *manifold* (properly a *Riemannian manifold*): a space that appears to be Euclidean locally in a neighborhood of each point (or pseudo-Euclidean, as defined below) but globally may have curvature, such as the surface of a sphere.

Manifolds are most simply defined in terms of the coordinate systems on them, and of course there are uncountably many such systems. *Tensors* are mathematical objects defined on manifolds, such as vector fields, which are in a natural sense independent of the coordinate system used to define them and their components. The importance of tensors in physics stems from the fact that the description of physical phenomena ought to be independent of any coordinate system we choose to impose on space and hence should be tensorial.

Our description of manifolds and tensors will be rather informal. For instance, we will picture vector or tensor fields as defining a vector or tensor at each point of the manifold itself rather than more abstractly as a section of the appropriate tangent bundle. In applications, tensors are frequently used in the study of GENERAL RELATIVITY AND COSMOLOGY [IV.40], which involves describing the dynamics of matter and fields using any reference frame (coordinate system), assuming space-time is a four-dimensional pseudo-Riemannian curved manifold, as described below.

An n -dimensional manifold is a topological space such that a neighborhood around each point is equivalent (i.e., homeomorphic) to a neighborhood of a point in n -DIMENSIONAL EUCLIDEAN SPACE [I.2 §19.1]. More formally, it can be defined as the set of smooth coordinate systems that can be defined on the space, together with transformation rules between them. In a neighborhood around each point, a coordinate system can always be found that looks locally Cartesian, regardless of any global curvature (which can cause the system to fail to be Cartesian at other points).

In practice, each coordinate system on a Riemannian manifold has a *metric*, defined below, which is possibly position dependent. This enables inner products between pairs of vectors at each point in the space to be defined. The situation is complicated by the fact that, at each point, most coordinate systems are *oblique*, as in figure 1. The following description uses “index notation,” which suggests the explicit choice of

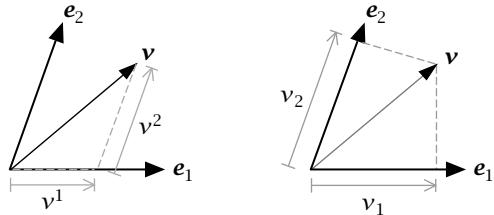

Figure 1 The components of a vector \mathbf{v} in an oblique basis of unit vectors $\{\mathbf{e}_1, \mathbf{e}_2\}$: contravariant components v^1, v^2 follow from the parallelogram rule, and covariant components v_1, v_2 are found by dropping perpendiculars onto the basis vectors. For basis vectors with arbitrary lengths, each covariant component is the length shown on the diagram multiplied by the norm of the corresponding basis vector.

a coordinate system. However, such expressions are always valid since all tensorial expressions should be the same in every coordinate system; that is, they are *covariant*. Explicitly coordinate-free formulations exist, although they require a greater familiarity with differential geometry than is assumed here and require the definition of much new notation.

Consider a vector \mathbf{v} in n -dimensional Euclidean space with oblique coordinate axes locally defined by linearly independent but not necessarily orthonormal basis vectors $\mathbf{e}_j, j = 1, \dots, n$. The *contravariant* components of \mathbf{v} , represented with upper indices v^j for $j = 1, \dots, n$, are defined by the parallelogram law; that is,

$$\mathbf{v} = \sum_{j=1}^n v^j \mathbf{e}_j \quad (v^j \text{ contravariant}).$$

Throughout this article, we will assume that the symbol v^j represents the *vector itself*, and not simply the components. This will also apply to objects with multiple indices.

The *covariant* components v_j , represented with lower indices, are those defined by the scalar product with the basis vectors (i.e., formally, covariant components are the components of the vectors in the dual space to the tangent vector space, with “covariant” here not to be confused with the sense previously), i.e.,

$$v_j = \mathbf{v} \cdot \mathbf{e}_j, \quad j = 1, \dots, n \quad (v_j \text{ covariant}).$$

If the \mathbf{e}_j are orthonormal, then the covariant components v_j are the same as the contravariant v^j . The components of the *metric tensor* g_{ij} for the coordinate system at this point are then given by $g_{ij} = \mathbf{e}_i \cdot \mathbf{e}_j$, with $g^{ij} \equiv (g_{ij})^{-1}$, the inverse of g_{ij} considered as a matrix.

All of the geometry of the local basis is encoded in g_{ij} ; for instance, covariant and contravariant components are found from each other using the metric tensor to “raise” and “lower” indices, such as $v^i = g^{ij} v_j$ and $v_i = g_{ij} v^j$. In these expressions, and for the remainder of the article, we adopt the *Einstein summation convention*; that is, when an index symbol is repeated, once each in an upper (contravariant) and a lower (covariant) position, we assume that the indices are summed from 1 to n . The summed index symbol i, j, \dots is itself arbitrary, i.e., a “dummy index.”

This procedure generalizes the inner product to oblique axes, defining *inner multiplication*, or *index contraction*. As usual in linear algebra, objects with multiple indices can be defined, e.g., $T^{ij} = u^i v^j + p^i q^j$ for vectors u^j, v^j, p^j, q^j . Forming a product of objects such as $u^i v^j$ without contracting the indices is referred to as *outer multiplication*, and in coordinate-free form, $u^i v^j$ is written as $\mathbf{u} \otimes \mathbf{v}$.

The components of the position vector, in terms of the chosen coordinate system, are denoted x^i , i.e., in Cartesian coordinates $x^1 = x, x^2 = y, \dots$. Differentiation with respect to a set of contravariant indices is in fact covariant, as can easily be verified from a Taylor expansion by a small displacement δx^i of a scalar field $f(x^i)$ around a chosen point x^i :

$$f(x^i + \delta x^i) = f(x^i) + \delta x^i \partial_i f + O((\delta x)^2).$$

The term $\delta x^i \partial_i f$ is first order in δx^i , so it must be the same in all coordinate systems; since δx^i is contravariant, $\partial_i \equiv \partial/\partial x^i$ must be covariant.

As coordinate systems on curved manifolds are not typically orthonormal everywhere, we must assume in general that the components of a vector are different from those of its dual (which is used to take inner products). Any vector object may be represented with upper or lower indices, which are related by the metric tensor. Objects with multiple indices, such as the metric tensor itself, can also have both indices upper, both lower, or a mixture. In fact, since g^{ij} is the matrix inverse of g_{ij} , the matrix representation of the mixed metric tensor $g_i^k = g_{ij} g^{jk}$ is the identity matrix and so is often written δ_i^k , to be understood as a generalization of the usual Kronecker symbol with mixed upper and lower indices.

With this formalism an alternative coordinate system has components x'^j , the different system being represented by the prime on the coordinate symbol; at each point, the linear transformation between the systems is

given by the Jacobian $\partial x^i / \partial x^{j'} \equiv \Lambda_{j'}^i$; therefore, a vector's contravariant components are transformed to the new system by $v^{i'} = \Lambda_j^{i'} v^j$. The inverse transformation $\Lambda_{i'}^j$ not only transforms contravariant coordinates back from the primed to the unprimed system but also transforms unprimed covariant components to the primed system, i.e., $v_{i'} = \Lambda_{i'}^j v_j$. This equivalence guarantees that the squared length of the vector is independent of the coordinate system, i.e.,

$$v_{i'} v^{i'} = v_j \Lambda_i^{i'} \Lambda_k^{i'} v^k = v_j \delta_k^i v^k = v_j v^j,$$

where δ_k^i is the Kronecker symbol with one upper index and one lower index (both unprimed), which may be thought of as representing the identity transformation from the unprimed coordinate system to itself.

A general *tensor* is therefore a (possibly) multicomponent object, all of whose components transform between coordinate systems according to the local Jacobian transformation, namely,

$$T^{i' j' \dots}_{\quad k' \ell' \dots} = \Lambda_i^{i'} \Lambda_j^{j'} \dots \Lambda_{k'}^k \Lambda_{\ell'}^\ell \dots T^{i j \dots}_{\quad k \ell \dots}$$

A *scalar* is a tensorial object with no indices, a *vector* has one index, and in general a tensor with m distinct indices is said to have *rank* m . The ordering of the indices of a tensor is of course important, and this is maintained regardless of whether they appear in upper or lower positions. The *principle of covariance* (either special covariance or general covariance), due to Einstein, states that physical laws should be expressible in tensorial form, that is, they should be covariant under the class of coordinate transformations being considered.

Although it is tempting to identify tensors such as g_{ij} as arrays of numbers in particular coordinate systems, a tensor on a manifold is in fact properly defined independently of any particular coordinate system, and instead its tensoriality follows from its indices transforming in the appropriate way under coordinate transformations.

Coordinate derivatives $\partial_i v_j$ (also written $v_{j,i}$) should not be expected to be tensorial, as they follow the possibly curved coordinate lines of the arbitrarily chosen coordinate system. The *covariant derivative*

$$\nabla_i v_j = v_{i;j} \equiv \partial_i v_j - \Gamma_{ij}^k v_k \quad (1)$$

is tensorial, where the *connection coefficients* or *Christoffel symbols* Γ_{ij}^k denote a nontensorial object defined in terms of coordinate derivatives of the metric tensor ($\Gamma_{ij}^k \equiv 2^{-1} g^{kl} \partial_j g_{il} + \partial_i g_{lj} - \partial_l g_{ij}$), whose combination with the coordinate derivative in (1) does indeed

yield a tensor. Covariant derivatives of general tensors pick up a Γ term for each index (e.g., $T_{i\ell,j} = T_{i\ell,j} - \Gamma_{ij}^k T_{k\ell} - \Gamma_{\ell j}^m T_{im}$). The derivative of a scalar is therefore automatically tensorial.

No part of the discussion up to this point explicitly involves the manifold's curvature. Indeed, a complicated coordinate system may have nonzero connection coefficients and yet describe Euclidean space. The tensoriality of the covariant derivative is an expression of the *parallel transport* of a vector along a curve. A *geodesic* on a manifold is a curve that is as straight as possible, given that the manifold may be curved. Such a curve can be constructed by parallel transporting a vector as a tangent vector along a curve; a geodesic curve $z^i(s)$, parametrized by s , therefore satisfies the geodesic equation

$$\frac{d^2 z^k}{ds^2} + \Gamma_{ij}^k \frac{dz^i}{ds} \frac{dz^j}{ds} = 0,$$

which generalizes the equation for a Euclidean straight line in Cartesian coordinates (for which the connection is zero), and is in general nonlinear.

Curvature exists around a point on a manifold when there exists a vector that, upon being parallel transported from the point around some infinitesimal closed path back to the point, does not return to its original direction. This is equivalent to the *failure of covariant derivatives to commute*. For any vector field v_i ,

$$\nabla_j \nabla_k v_i - \nabla_k \nabla_j v_i = R^\ell_{ijk} v_\ell, \quad (2)$$

defining the *Riemann curvature tensor* R^ℓ_{ijk} . This tensor has rank 4: the indices j and k are related to the plane defined by the derivatives (i.e., the closed path), and i is related to the original direction of the vector, whose change in direction is related to ℓ . The Riemann curvature tensor has many symmetries, such as $R_{\ell ijk} = -R_{i\ell jk} = R_{jk\ell i}$, with the result that, although a general rank-4 tensor has n^4 components, only $n^2(n^2 - 1)/12$ of the Riemann tensor's components are independent: one for $n = 2$, six for $n = 3$, twenty for $n = 4$, etc. A manifold where the curvature tensor vanishes everywhere is said to be *flat*.

The symmetric, rank-2 “trace” of the Riemann tensor, $R_{ik} \equiv R^j_{ijk}$, is known as the *Ricci tensor*. It plays a crucial role in the theory of general relativity, as the part of the curvature of the space-time manifold affected by energy-momentum and the cosmological constant. Its trace $R \equiv g^{ik} R_{ik}$ is called the *curvature scalar*.

In many applications it is mathematically easier to restrict the class of coordinate systems being considered in order to gain mathematical tractability at

the cost of generality. For example, in problems of CLASSICAL MECHANICS [IV.19] in three-dimensional flat Euclidean space described by a position vector \mathbf{r} , it is conventional to work with *Cartesian tensors*; all coordinate systems are Cartesian, and the transformations between them are simply rotations and translations. In this case, covariant and contravariant indices transform in the same way, so the metric becomes the Kronecker symbol in all systems $g_{ij} = \delta_{ij}$ (the indices are both lower here, appropriate for a metric tensor).

Examples of Cartesian tensors include the inertia tensor of a solid body with density $\rho(\mathbf{r})$,

$$I_{ij} = \int_{\text{body}} \rho(\mathbf{r})(r^k r_k \delta_{ij} - r_i r_j) d^3 r,$$

which relates the rotating body's angular momentum $L_i = I_{ij}\omega^j$ to its angular velocity ω^j . Another example that is important for continuum mechanics is a body's Cauchy stress tensor σ_{ij} ; at each point, $f_j = \sigma_{ij}n^i$ is the force acting on a surface perpendicular to the unit vector n^i .

The tensorial framework for space-time was introduced into physics by Einstein, who applied it to the four-dimensional manifold of space-time events, in which all vectors become four-dimensional 4-vectors. In this formalism, *time* becomes a spatial coordinate $ct = x^0$ (or, in older literature, x^4), where c is the speed of light (approximately 3×10^8 meters per second), so that physical laws satisfy the *principle of special relativity* (or special covariance); they take the same form in all inertial frames, which are regarded effectively as orthonormal coordinate systems on flat space-time. This generalization of Newton's first law of mechanics was necessary to accommodate Maxwell's equations of electrodynamics, famously requiring all inertial observers to agree on the value of c . In Einstein's theory, all inertial observers agree on the value of $x^2 + y^2 + z^2 - c^2 t^2$, written more compactly via the summation convention as $\eta_{ab}x^a x^b$, or $x^a x_a$; this is the "space-time separation" of the event $x^a = (ct, x, y, z)$ from the space-time origin, where η_{ab} is the *Minkowski tensor* with the form $\text{diag}(-1, +1, +1, +1)$. Conventionally, indices a, b, \dots are used to denote four-dimensional space-time indices $0, \dots, 3$, whereas indices i, j, \dots are used to denote spatial indices $1, 2, 3$. The different continuous symmetries of Euclidean, Newtonian, and Minkowski space-time are discussed in INVARIANTS AND CONSERVATION LAWS [II.21].

The four-dimensional flat manifold that admits the Minkowski tensor η_{ab} at each point is called *Minkowski*

space. Notably, η_{ab} has some negative as well as positive entries (as such it is *pseudo-Euclidean*); Minkowski space has many similarities geometrically to Euclidean space. However, the crucial difference is that the squared length $x^a x_a$ of a space-time 4-vector may be positive, negative, or zero.

In special relativity, therefore, space-time is represented by Minkowski space, a flat pseudo-Riemannian manifold. Space-time coordinate transformations on Minkowski space are called *Lorentz transformations*. The choice of the overall sign of the tensor η_{ab} (i.e., $\text{diag}(-1, +1, +1, +1)$ or $\text{diag}(+1, -1, -1, -1)$) is a convention, and it is common, particularly in the literature on relativistic quantum theory, to use the opposite sign to that chosen here (it is also common to represent the four space-time indices by Greek characters α, μ, \dots , reserving Roman characters for the space-like indices). The *signature* of a metric is the sum of signs of its entries in a coordinate system when it is diagonal: in a Euclidean space it is n , but in Minkowski space it is 2 (or -2, depending on the sign convention). The neighborhood of each point in a Riemannian manifold admits a coordinate system that is locally Euclidean. Manifolds in which the neighborhood of each point admits a coordinate system with metric signature not equal to n , such as Minkowski space, are said to be *pseudo-Riemannian*.

In *general relativity*, Einstein proposed the *principle of general covariance*, i.e., that physical laws be tensorial with respect to *all observers* (i.e., all frames on space-time), not just the inertial ones (for which tensors in special relativity become analogous to the restriction in Euclidean space to Cartesian tensors). In general relativity, therefore, space-time is no longer required to be flat (i.e., the neighborhood of each point locally looks like Minkowski space), allowing for the possibility that at larger length scales, space-time itself may be curved. The EINSTEIN FIELD EQUATIONS [III.10] relate the Ricci curvature of a manifold to the distribution of matter, energy, and momentum in space-time, thereby fundamentally tying the nature of space and time to the phenomena that occupy it.

II.34 Uncertainty Quantification

Youssef Marzouk and Karen Willcox

Uncertainty quantification (UQ) involves the quantitative characterization and management of uncertainty in a broad range of applications. It employs both computational models and observational data, together with theoretical analysis. UQ encompasses many different tasks, including uncertainty propagation, sensitivity analysis, statistical inference and model calibration, decision making under uncertainty, experimental design, and model validation. UQ therefore draws upon many foundational ideas and techniques in applied mathematics and statistics (e.g., approximation theory, error estimation, stochastic modeling, and Monte Carlo methods) but focuses these techniques on complex models (e.g., of physical or sociotechnical systems) that are primarily accessible through computational simulation. UQ has become an essential aspect of the development and use of predictive computational simulation tools.

Modeling endeavors may contain multiple sources of uncertainty. A widely used classification contrasts *aleatory* or irreducible uncertainty, resulting from some inherent variability, with *epistemic* or reducible uncertainty that reflects a lack of knowledge. The more detailed classification of uncertainties below was proposed in the seminal work of Kennedy and O'Hagan, and it provides a useful foundation on which to establish mathematical approaches.

Parameter uncertainty refers to uncertain inputs to or parameters of a model. For example, parameters representing physical properties (permeability, porosity) of the Earth may be unknown in a computational model of the subsurface. *Parametric variability* captures the uncertainty due to uncontrolled or unspecified conditions in inputs or parameters. For example, aircraft design must account for uncertain operating conditions that arise from varying atmospheric conditions and gust encounters. *Residual variability* describes the uncertainty due to intrinsic random variation in the underlying physics being modeled or induced by behavior at physical scales that are not resolved by the model. Examples of residual variability include the uncertainty due to using models of turbulence that approximate the effects of the small scales that are not resolved. *Code uncertainty* refers to the uncertainty associated with not knowing the output of a computer model given any particular configuration until the code is run. For

example, a Gaussian process emulator used as a surrogate for a higher-fidelity model has code uncertainty at parameter values away from those at which the emulator was calibrated. *Observation error* is the uncertainty associated with actual observations and measurements; it plays an important role in model calibration and inverse problems. *Model discrepancy* captures the uncertainty due to limitations of and assumptions in the model. This uncertainty is present in almost every model used in science and engineering.

This article takes a probabilistic view of all these sources of uncertainty. While other approaches, e.g., interval analysis, fuzzy set theory, and Dempster-Shafer theory, have also been employed to analyze particular UQ problems, the probabilistic approach to UQ offers a particularly rich and flexible structure, and has seen extensive development over the past two decades.

The challenge of *model validation* is closely related to UQ. A recent National Academy of Sciences report defines validation as “the process of determining the degree to which a model is an accurate representation of the real world from the perspective of the intended uses of the model.” This process therefore involves assessing how the sources of uncertainty described above contribute to any prediction of interest. Quantifying model discrepancy is a particularly challenging aspect of the validation process; posterior predictive checks, cross validation, and other ways of assessing model error are important in this regard. In situations where data are few in number or where the model is intended for use in an extrapolatory setting, however, traditional techniques for model checking may not apply. This is important and somewhat uncharted territory, for which new mathematical and statistical approaches are being developed.

1 Characterizing Uncertainty

Probabilistic approaches characterize uncertain quantities using probability density or mass functions. These approaches require the specification of sufficient information to endow model inputs with probability distributions. This information can be drawn from various types of prior knowledge, including historical databases, physical constraints, previous computations, and the elicitation of expert opinion. The principle of maximum entropy is sometimes used to map from a few specified characteristics of the uncertainty (e.g., minimum and maximum values, or mean,

variance, and other moments) to a probability distribution by determining the maximum entropy distribution that is compatible with the specified constraints. Inferential approaches, described below, can update probabilistic characterizations of uncertain quantities by conditioning these quantities on new observational data.

2 Forward Propagation of Uncertainty

Forward propagation of uncertainty addresses how uncertainty in model inputs translates into uncertainty in model outputs. The goal is often to provide distributional information (output means and variances, event probabilities) in support of uncertainty assessment or decision making. The most flexible method for estimating distributional information is Monte Carlo simulation, which draws random samples from the joint distribution of inputs and evaluates the output value corresponding to each input sample. Expectations over the output distribution are then estimated from these samples. Monte Carlo estimates converge slowly, typically requiring many samples to achieve acceptable levels of accuracy; the error in a simple Monte Carlo estimator converges as $O(N^{-1/2})$, where N is the number of Monte Carlo samples. Variance-reduction techniques, such as importance sampling and the use of control variates, are therefore of great interest in UQ. Also, quasi-Monte Carlo approaches can offer faster convergence rates than random (or pseudorandom) sampling, while maintaining good scalability with respect to the number of uncertain parameters.

Approaches that rely on polynomial chaos and other spectral representations of random quantities, such as stochastic Galerkin and stochastic collocation methods, are important and widely used alternatives to Monte Carlo simulation. By exploiting the regularity of the input-output relationship induced by a model, these approaches can provide greater accuracy and efficiency than Monte Carlo simulation for moderate numbers of parameters. They can also provide more information about this input-output relationship, including sensitivity indices and approximations that are useful in inverse problems (see below). Stochastic spectral techniques have been developed for many classes of partial differential equations with random parameters or input data, as well as for more general black-box models. Methods for identifying and exploiting sparsity in polynomial representations, for evaluating the model on sparse grids in high-dimensional parameter

spaces, and for performing dimension reduction have proven quite successful in expanding the range and size of problems to which spectral techniques can be successfully applied.

3 Sensitivity Analysis

Sensitivity analysis aims to elucidate how the uncertain inputs of a system contribute to system output uncertainty. Variance-based sensitivity analysis apportions the variance of an output quantity of interest among contributions from each of the system inputs and their interactions. This apportionment is based on the law of total variance, which for a given output quantity of interest Q and a given factor X_i is written as

$$\text{Var}(Q) = \mathbb{E}[\text{Var}(Q|X_i)] + \text{Var}(\mathbb{E}[Q|X_i]).$$

From this, a main effect sensitivity index is defined as the expected fraction of the variance of Q that would be removed if the variance of X_i were reduced to zero:

$$S_i = \frac{\text{Var}(\mathbb{E}[Q|X_i])}{\text{Var}(Q)}.$$

The results of a global sensitivity analysis can be used for *factor prioritization* (identifying those inputs where future research is expected to bring the largest reduction in variance) and *factor fixing* (identifying those inputs that may be fixed to a deterministic value without substantially affecting probabilistic model outputs). Algorithms for computing main and total effect sensitivity indices may rely on Monte Carlo or quasi-Monte Carlo sampling, sparse quadrature, or post-processing of the stochastic spectral expansions described above.

4 Inverse Problems and Data Assimilation

INVERSE PROBLEMS [IV.15] arise from indirect observation of a quantity of interest. For example, one may wish to estimate certain parameters of a system given limited and noisy observations of the system's outputs. From the UQ perspective, one seeks not only a point estimate of the parameters but also a quantitative assessment of their uncertainty. UQ in inverse problems can therefore be addressed through the perspective of statistical inference. The statistical inference problems that arise in this context typically involve a likelihood function that contains a complex physical model (described by ordinary or partial differential equations) and inversion "parameters" that are in fact functions and hence are infinite dimensional.

The Bayesian statistical approach provides a natural route to quantifying uncertainty in inverse problems by characterizing the posterior probability distribution. And yet the application of Bayesian inference to inverse problems raises a number of important computational challenges and foundational issues. From the computational perspective, important tasks include the design of Markov chain Monte Carlo sampling schemes for complicated and high-dimensional posterior distributions; the construction of controlled approximations to the likelihood function or forward model, whether through statistical emulation, model reduction, or function approximation; and the development of more efficient alternative algorithms, including variational approaches, for characterizing the posterior distribution. From the foundational perspective, important efforts center on incorporating model error or model discrepancy into the solution of the inverse problem and subsequent predictions, and on designing classes of prior distributions that are sufficiently rich or expressive to capture available information about the inversion parameters, while ensuring that the Bayesian formulation is well-posed and discretization invariant. We also note that not all methods for characterizing uncertainty in the inversion parameters and subsequent predictions are Bayesian; many frequentist methods for uncertainty assessment (using, for example, Tikhonov regularized estimators) have also been developed.

Data assimilation encompasses a related set of problems for which the goal is to estimate the time-evolving *state* of a dynamical system, given a sequence of observations. Applications include ocean modeling and NUMERICAL WEATHER PREDICTION [V.18]. Observations are typically available sequentially, and one therefore seeks algorithms that can be applied recursively—updating the state estimates as new data become available. When one's goal is to condition the state at time t on observations received up to time t , the inference problem is known as *filtering*; when the state at time t is conditioned on observations up to some time $T > t$, the problem becomes one of *smoothing*. For linear models and Gaussian error distributions, the recursive Kalman formulas for filtering and smoothing apply. For nonlinear models and non-Gaussian distributions, a host of other algorithms can be used to approximate the posterior distribution. Chief among these are ensemble methods, including ensemble Kalman filters and smoothers, and weighted particle methods, including many types of particle filters and smoothers.

Practical applications of data assimilation involve high-dimensional states and chaotic dynamics, and the development of efficient and accurate probabilistic approaches for such problems is an active area of research.

5 Decision Making under Uncertainty

The results of uncertainty analysis and inference are often a prelude to *designing* a system, executing some *control* action, or otherwise making a decision, perhaps in an iterative fashion. Optimization techniques that account for uncertainty are therefore an important component of an end-to-end UQ approach. For example, robust optimization methods define an objective function that can incorporate both the mean of some performance metric and its variance, thus making a trade between absolute performance and variability. Multiobjective formulations allow this trade-off to be controlled and explored completely. One can also introduce chance constraints that specify an acceptable level of reliability for a system (e.g., by requiring the probability of failure to be less than a specified value); in the engineering literature, these are known as reliability-based design-optimization approaches. More general approaches to decision making under uncertainty use the framework of decision theory to incorporate the probabilistic background of any choice, e.g., choosing the action that maximizes some expected utility. Even questions of optimal *experimental design* can be cast in this framework: choosing where to place a sensor or how to interrogate a system, before the outcome of the experiment is known and while other uncertainties remain in the model, is yet another instance of decision making under uncertainty.

II.35 Variational Principle

A variational principle is a method in the CALCULUS OF VARIATIONS [IV.6] for determining a function by identifying it as a minimum or maximum of a *functional*, which is a function that maps functions into scalars. An example of a functional on a HILBERT SPACE [I.2 §19.4] H is the mapping from $f \in H$ to the inner product $\langle f, g \rangle$, where g is any fixed element in H . In particular, $\int_0^1 f(x) dx$ is a functional on $C[0, 1]$.

Many partial differential equations (PDEs) have the property that their solution is a minimum of a certain Lagrangian functional. The PDE is known as the EULER-LAGRANGE EQUATION [III.12] (see also PARTIAL DIFFERENTIAL EQUATIONS [IV.3 §4.3]) of the functional.

In matrix analysis an example of a variational principle is the expression $\lambda_1 = \max_{x \neq 0} x^* Ax / (x^* x)$ for the largest eigenvalue of a Hermitian matrix A , which is a particular case of the COURANT-FISCHER THEOREM [IV.10 §5.4]. The expression $x^* Ax / (x^* x)$ is called a *Rayleigh quotient*, and generalizations of it arise in the Rayleigh-Ritz approximation problem of finding optimal approximate eigenvectors of A given an approximate invariant subspace.

II.36 Wave Phenomena

Waves are everywhere. We immediately think of waves on the ocean, sound waves, electromagnetic waves such as light and radio, and seismic waves caused by earthquakes. Less obviously, there are waves of traffic on busy roads, ultrasonic waves used to image the insides of our bodies, and the Mexican wave around a football stadium.

From these examples, we all have a good idea of what a wave is, but it is not so easy to define a wave. Perhaps the key property is *propagation*: disturbances are propagated. Think of the Mexican wave; people in the crowd stand and sit in an organized manner so as to generate a disturbance that propagates around the stadium. Notice that the people do not propagate! Similarly, in a sound wave air particles move about their equilibrium positions. Electromagnetic waves do not require a medium in order to exist; they can propagate through empty space whereas sound waves cannot.

In addition to propagating disturbances, waves are often associated with the transfer of energy, and this is one reason they are useful. Waves can also interact with objects (giving rise to reflection, refraction, diffraction, or scattering), or even with other waves.

For a simple formula, suppose that the x -axis points to the right. A disturbance $u(x, t)$ at position x and time t will be a wave propagating to the right if it has the form

$$u(x, t) = f(x - ct),$$

where f is a function of one variable and c is a constant (the speed of propagation, or the *phase speed*). For an explanation, see the article on the WAVE EQUATION [III.31]. In this very simple one-dimensional example, the disturbance propagates without change of shape. In reality, the shape may change as the wave propagates (think of ocean waves approaching and then breaking on a beach).

Wave phenomena continue to fascinate and provoke the creation of new mathematics.

Part III

Equations, Laws, and Functions of Applied Mathematics

III.1 Benford's Law

Theodore P. Hill

Benford's law, also known as the *first-digit law* or the *significant-digit law*, is the empirical observation from statistical folklore that in many naturally occurring tables of numerical data the leading significant digits are not equally likely. In particular, more than 30% of the leading significant (nonzero) digits are 1 and less than 5% are 9.

1 The First-Digit Law

Benford's law asserts that, instead of being uniformly distributed, as might be expected, the first significant decimal digit often tends to follow the logarithmic distribution

$$\text{Prob}(D_1 = d) = \log_{10} \left(\frac{d+1}{d} \right), \quad d = 1, 2, \dots, 9,$$

so

$$\text{Prob}(D_1 = 1) = \log_{10}(2) = 0.3010\dots,$$

$$\text{Prob}(D_1 = 2) = \log_{10}(3/2) = 0.1760\dots,$$

⋮

$$\text{Prob}(D_1 = 9) = \log_{10}(10/9) = 0.04575\dots,$$

where D_1 represents the first significant decimal digit (e.g., $D_1(0.0203) = D_1(203) = 2$).

2 History

The earliest known reference to this logarithmic distribution is a short article in 1881 by polymath Simon Newcomb in the *American Journal of Mathematics*, and the article contained not only the first-digit law above

but also the second-digit law. This paper was forgotten, and in 1938 Frank A. Benford published an article containing the same first- and second-digit laws, as well as extensive empirical evidence of the law in tables ranging from baseball statistics to square-root tables and atomic weights. This article attracted much attention but Newcomb's note continued to be overlooked for decades and the name "Benford" came to be associated with the significant-digit law. Since then, over 700 articles have appeared on applications, statistical tests, and mathematical proofs of Benford's law.

3 Empirical Evidence

Many common tables of numerical data do not follow Benford's law. For example, the proportion of positive integers that begin with 1, i.e., $\{1, 10, 11, \dots, 19, 100, 101, \dots, 199, 1000, 1001, \dots\}$, oscillates between $\frac{1}{9}$ and $\frac{5}{9}$ as the sample size increases. The prime numbers also do not follow Benford's law. Similarly, many tables of real-world data, such as telephone numbers and lottery numbers, do not follow Benford's law.

On the other hand, in addition to Benford's original empirical data, an abundance of subsequent empirical evidence of Benford's law has appeared in a wide range of fields. This includes numbers gleaned from newspaper articles and almanacs, tables of physical constants and half-lives of radioactive substances, stock markets and financial data, demographic and geographical data, scientific calculations, eBay prices, and the collection of all numbers on the Internet, as reflected by magnitudes of Google hits on numbers.

4 Applications

One of the main applications of Benford's law has been for fraud detection. Since certain types of true tax data have been found to be a close fit to Benford's

law (e.g., about 30% of the numbers begin with 1), chi-squared goodness-of-fit tests have been used successfully to detect fraud or error by checking conformance of the first digits of the data to Benford's law. Benford's law goodness-of-fit tests have also been used to identify anomalous signals in data. This has been employed, for example, to detect mild earthquakes, and to evaluate the detection efficiency of lightning location networks.

The output of numerical algorithms and other digital computer calculations often follows Benford's law, and based on a hypothesis of the output following Benford's law it is possible to obtain improved estimates of expected roundoff errors, and of likelihoods of overflow and underflow errors.

Benford's law has also been used as an effective teaching tool, to introduce students to basic concepts in statistics such as goodness-of-fit tests and basic data-collection methods, and to demonstrate tools in MATHEMATICA.

5 The General-Digit Law

The general form of Benford's law is a statement about the joint distribution of all decimal digits, namely:

$$\begin{aligned} \text{Prob}(D_1 = d_1, D_2 = d_2, \dots, D_m = d_m) \\ = \log_{10} \left(1 + \left(\sum_{j=1}^m 10^{m-j} d_j \right)^{-1} \right) \end{aligned}$$

holds for all m -tuples (d_1, d_2, \dots, d_m) , where d_1 is an integer in $\{1, 2, \dots, 9\}$ and, for $j \geq 2$, d_j is an integer in $\{0, 1, \dots, 9\}$. Here D_2, D_3, D_4 , etc., represent the second, third, fourth, etc., significant decimal digits, e.g., $D_2(0.0203) = 0, D_3(0.0203) = 3$.

Thus, for example, this general form of Benford's law implies that

$$\begin{aligned} \text{Prob}(D_1 = 3, D_2 = 1, D_3 = 4) &= \log_{10}(315/314) \\ &= 0.001380\dots \end{aligned}$$

A corollary of the general form of Benford's law is that the significant digits are dependent and not independent, as one might expect.

Letting $S(x)$ denote the (floating-point) *significand* (see FLOATING-POINT ARITHMETIC [II.13]) of the positive number x , e.g., $S(0.0203) = S(2.03 \times 10^{-2}) = 2.03$, a more compact form of the general Benford's law is

$$\text{Prob}(S < t) = \log_{10} t \quad \text{for all } 1 \leq t < 10.$$

Analogs of Benford's law for nondecimal bases b are obtained by simply replacing the decimal base by the new base, both in the significant digits or significand and in the logarithm.

6 The Mathematical Framework

One of the main tools used to study Benford's law is the fact that a data set X (e.g., a sequence, function, or random variable) is Benford if and only if $\log X$ is uniformly distributed modulo 1, that is, if and only if the fractional part of $\log X$ is uniformly distributed between 0 and 1.

Two key characterizations of Benford's law are *scale invariance* and *base invariance*. The Benford distribution is the only distribution of significant digits that does not change under multiplicative changes of scale. For example, if a data set originally in euros or meters follows Benford's law, conversion of the data into dollars or feet will also follow Benford's law. Similarly, the Benford distribution is the only distribution of significant digits that is continuous and invariant under changes of base.

7 Sequences and Functions

Many common sequences follow Benford's law exactly. That is, the proportion of times that particular significant digits appear in the elements of the sequence converges to the exact Benford's law probabilities. For example, the sequence of powers of 2 (and of 3 or 5), the Fibonacci and Lucas numbers, and the sequence of factorials $1!, 2!, 3!, 4!, \dots = 1, 2, 6, 24, \dots$ all follow Benford's law exactly.

Sequences exhibiting exponential growth (or decay) generally obey Benford's law for almost all starting points and almost all bases. Similarly, many general classes of algorithms, including Newton's method, and multidimensional systems such as Markov chains can also be shown to obey Benford's law. Continuous functions with exponential or super-exponential growth or decay also typically exhibit Benford's law behavior, and thus wide classes of initial-value problems obey Benford's law exactly.

8 Random Variables and Probability Distributions

None of the classical probability distributions—uniform, exponential, normal, Pareto, etc.—is arbitrarily close to Benford's law for *any* values of the parameters, although the standard Cauchy distribution comes quite close. On the other hand, it is easy to construct distributions that satisfy Benford's law exactly, such as the continuous distribution on $[1, 10)$ with density proportional to $1/x$. Some of the basic probabilistic Benford's law results are given below.

- X is Benford if and only if $1/X$ is Benford.
- If a random variable X has a density, then the powers X^n of X converge in distribution to Benford's law (i.e., $P(S(X^n) < t) \rightarrow \log t$).
- If X is Benford and Y is positive and independent of X , then XY is Benford.
- The product of independent and identically distributed continuous random variables converges in distribution to Benford's law.
- If random samples are taken from probability distributions chosen at random (in an unbiased way), the combined sample will converge to Benford's law.

III.2 Bessel Functions

P. A. Martin

F. W. Bessel (1784–1846) was a German astronomer. In an analysis of planetary motions, published in 1826, he investigated properties of the integral

$$J_n(z) = \frac{1}{2\pi} \int_0^{2\pi} \cos(n\theta - z \sin \theta) d\theta.$$

(He denoted the integral by I_z^n .) Schlömilch (1856) regarded $J_n(z)$ as coefficients in the expansion

$$\exp\{(z/2)(t - 1/t)\} = \sum_{n=-\infty}^{\infty} t^n J_n(z); \quad (1)$$

the left-hand side is called a *generating function*. Both approaches are convenient when n is an integer. Another approach, which generalizes more easily, is via an ordinary differential equation,

$$z^2 w''(z) + zw'(z) + (z^2 - \nu^2)w(z) = 0, \quad (2)$$

in which the independent variable, z , and the parameter ν can be complex. Solutions of *Bessel's equation* (2) can be constructed by the method of Frobenius. One of these is

$$J_\nu(z) = \sum_{m=0}^{\infty} \frac{(-1)^m (z/2)^{\nu+2m}}{m! \Gamma(\nu + m + 1)},$$

which is known as the *Bessel function of the first kind*. Here, Γ denotes the GAMMA FUNCTION [III.13]. If ν is not an integer, $J_{-\nu}(z)$ gives a second, linearly independent, solution of (2). However, when $\nu = n$, an integer, we have $J_n(z) = (-1)^n J_{-n}(z)$ (to see this, replace t by $-1/t$ in (1)), so a new solution is required. It is

$$Y_\nu(z) = \frac{J_\nu(z) \cos \nu \pi - J_{-\nu}(z)}{\sin \nu \pi},$$

with $Y_n = \lim_{\nu \rightarrow n} Y_\nu$. This defines the *Bessel function of the second kind*.

The functions $J_\nu(z)$ and $Y_\nu(z)$ are examples of SPECIAL FUNCTIONS [IV.7 §9] of two variables, ν and z . In elementary applications, ν is an integer, z is real, and both are nonnegative. For example, the vibrational modes of a circular membrane of radius a (such as a drumhead) have the form

$$J_n(kr) \cos(n\theta) \cos(\omega t),$$

where r and θ are plane polar coordinates, t is time, ω is frequency, $k = \omega/c$, c is the speed of sound in the membrane (it is a constant depending on what the membrane is made from), and ka is chosen as any one of the positive zeros of $J_n(x)$ (there are infinitely many).

Much is known about the properties of Bessel functions. The standard reference is G. N. Watson's 800-page book *A Treatise on the Theory of Bessel Functions* (Cambridge University Press, Cambridge, 2nd edn, 1944). However, a good place to start is chapter 10 of *NIST Handbook of Mathematical Functions* (Cambridge University Press, Cambridge, 2010), edited by F. W. J. Olver, D. W. Lozier, R. F. Boisvert, and C. W. Clark. (An electronic version of the book is available at <http://dlmf.nist.gov>.)

III.3 The Black-Scholes Equation

The Black-Scholes equation is a linear parabolic partial differential equation of the form

$$\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV = 0.$$

It is associated with the problem of pricing a financial option whose value is $V = V(S, t)$. The underlying asset has price $S \geq 0$ at time $t \in [0, T]$, where T is the expiry time of the option. The equation also involves the volatility σ and the interest rate r . Appropriate boundary conditions must be added in order to determine V uniquely. Under appropriate changes of variable the Black-Scholes equation transforms into the DIFFUSION

(HEAT) EQUATION [III.8]. The Black–Scholes equation is used in the derivation of the BLACK–SCHOLES OPTION PRICING FORMULA [IV.14 §2.2].

III.4 The Burgers Equation

The one-dimensional *Burgers equation* is a nonlinear PARTIAL DIFFERENTIAL EQUATION [IV.3] (PDE) for $u(x, t)$,

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = \nu \frac{\partial^2 u}{\partial x^2}, \quad (1)$$

where ν is a positive constant. It is named after J. M. Burgers (1895–1981), although the importance of (1) had been first recognized (1915) by Bateman in his study of the NAVIER–STOKES EQUATIONS [III.23] as the viscosity $\nu \rightarrow 0$.

When $\nu = 0$, (1) simplifies to

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = 0. \quad (2)$$

This is known as the *inviscid Burgers equation*, although the word “inviscid” is sometimes omitted.

There is a connection between (1) and the DIFFUSION EQUATION [III.8] known as the *Cole-Hopf transformation*. Thus, if $w(x, t)$ solves

$$\frac{\partial^2 w}{\partial x^2} = \frac{1}{\nu} \frac{\partial w}{\partial t},$$

then

$$u = -\frac{2\nu}{w} \frac{\partial w}{\partial x}$$

solves (1). This is an example of solving a nonlinear PDE using solutions of a related linear PDE.

The Cole-Hopf transformation can be used to show that, if (1) is solved with specified initial conditions at $t = 0$, then the solution is smooth for all x and for all $t > 0$. On the other hand, the inviscid Burgers equation (2) can have discontinuous solutions (“shocks”). We can say that the presence of the diffusive term on the right-hand side of (1) “regularizes” the problem and prevents shocks from appearing. Energy is removed because $\nu > 0$.

If we change the sign of the diffusive term, energy is added. To compensate for this, another term can be appended. One PDE of this kind is the *Kuramoto–Sivashinsky equation*,

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} = -\frac{\partial^2 u}{\partial x^2} - \frac{\partial^4 u}{\partial x^4}.$$

It is encountered in the modeling of several physical phenomena, it has been studied extensively, and it has many interesting kinds of solutions.

III.5 The Cahn–Hilliard Equation

Amy Novick-Cohen

1 The Equation

The partial differential equation for $u = u(x, t) \in \mathbb{R}$,

$$u_t = M\Delta(-u + u^3 + \varepsilon^2\Delta u), \quad (x, t) \in Q_T,$$

is known as the Cahn–Hilliard equation. Here, $\Delta := \sum_{i=1}^N \frac{\partial^2}{\partial x_i^2}$ and $Q_T = \Omega \times (0, T)$, where $\Omega \subset \mathbb{R}^N$, $T > 0$. It was proposed in 1958 by John W. Cahn and John E. Hilliard to describe phase separation in binary alloys. In that context, u represents the locally defined mass fraction of one of the two components of the binary alloy, M is the “mobility,” and ε measures the effective length scale of the interatomic forces.

2 Structure

Equation (1) may be written in the coupled form

$$\left. \begin{aligned} u_t &= \nabla \cdot (M \nabla \mu), & (x, t) \in Q_T, \\ \mu &= f'(u) - \varepsilon^2 \Delta u, & (x, t) \in Q_T, \end{aligned} \right\} \quad (1)$$

where $\mu = \mu(x, t)$ is the “chemical potential,” and $f(u) := \frac{1}{4}(1 - u^2)^2$ has minima at $u = \pm 1$ and is referred to as a “double-well potential.”

Typically, $\Omega \subset \mathbb{R}^N$ is a bounded domain, $N = 3$, and periodic or Neumann and no flux boundary conditions ($\hat{n} \cdot \nabla u = \hat{n} \cdot \nabla \mu = 0$ along $\partial\Omega$ for $\hat{n} \perp \partial\Omega$) are imposed. In both these cases, integrating (1) over Ω , and then integrating by parts, yields that

$$\frac{d}{dt} \int_{\Omega} u(x, t) dx = 0,$$

which may be interpreted as stating that mass is conserved in the system.

Multiplying the first equation in (1) by μ and then integrating over Ω , we get

$$\frac{d}{dt} \int_{\Omega} (f(u) + \frac{1}{2}\varepsilon^2 |\nabla u|^2) dx = - \int_{\Omega} M |\nabla \mu|^2 dx,$$

which describes energy dissipation in the system.

3 Dynamics

It is often reasonable to assume that

$$u(x, 0) = \bar{u} + \tilde{u}(x, 0),$$

where $\bar{u} \in \mathbb{R}$ and $\tilde{u}(x, 0)$ is a small disturbance or “perturbation” of \bar{u} that satisfies $\int_{\Omega} \tilde{u}(x, 0) dx = 0$. The subsequent dynamics can be described by an early “spinodal” regime followed by a late “coarsening” regime. During the spinodal or “linear” regime, the

Cahn–Hilliard dynamics is dominated by its linearization about \bar{u} . Spatial perturbations of sufficiently long wavelength grow, while shorter-wavelength perturbations decay exponentially. Locally spatially uniform domains begin to form. The larger domains start to grow at the expense of the smaller domains; this behavior is known as “coarsening.” The coarsening dynamics can be described via a free boundary problem for the motion of the interfaces, $\Gamma(t)$, which partition Ω into locally uniform subdomains. In this free boundary problem, known as the “Mullins–Sekerka” problem, the normal velocity of $\Gamma(t)$ is proportional to the jump in the normal derivative across $\Gamma(t)$ of μ , the chemical potential. Moreover, $\mu = \kappa$ along $\Gamma(t)$, where κ denotes the mean curvature of $\Gamma(t)$, and $\Delta\mu = 0$ away from the interfaces, in $\Omega \setminus \Gamma(t)$. The late-time dynamics predict that the average size of the uniform subdomains grows at a rate proportional to $t^{1/3}$.

4 Applications

Although the mass-conservative Cahn–Hilliard equation was conceived as a model for phase separation in binary alloys, the features of its dynamics, with an early linear regime followed by a late coarsening regime, make it an appropriate model in a wide range of settings. It has been used to describe pattern formation in populations, structure formation in biofilms, galaxy formation, as well as in image processing.

5 Generalizations

Many generalizations of the Cahn–Hilliard equation have been suggested. These include conserved phase field models (models that couple the Cahn–Hilliard equation with thermal effects), models for simultaneous phase separation and ordering (models coupling Cahn–Hilliard and Allen–Cahn equations), models coupling the Cahn–Hilliard equation with hydrodynamics effects, phase field crystal models (generalization that include crystalline anisotropy effects), and more.

III.6 The Cauchy–Riemann Equations

Let $u(x, y)$ and $v(x, y)$ be two real functions of two real variables, x and y . The *Cauchy–Riemann equations* are

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}. \quad (1)$$

These equations arise in COMPLEX ANALYSIS [IV.1]: if $f(z) = u(x, y) + iv(x, y)$ is an analytic function of $z = x + iy$, where u and v are real, then u and v satisfy the Cauchy–Riemann equations.

Eliminating v from (1) shows that LAPLACE'S EQUATION [III.18] is satisfied by u :

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0;$$

v satisfies the same equation.

In plane potential flow of a fluid, u is identified as a *velocity potential* and v as a *stream function*. If we define vectors $\mathbf{n} = (n_1, n_2)$ and $\mathbf{t} = (-n_2, n_1)$, so that $\mathbf{n} \cdot \mathbf{t} = 0$, from (1) we have

$$\mathbf{n} \cdot \operatorname{grad} u = \mathbf{t} \cdot \operatorname{grad} v.$$

If we take \mathbf{n} as being a unit normal vector to a curve C , then \mathbf{t} is a unit tangent vector. In fluid flow, a typical boundary condition is zero normal velocity on C , $\mathbf{n} \cdot \operatorname{grad} u = 0$. This derivative condition on u can then be replaced by $v = \text{const.}$ on C , a condition that is often easier to enforce.

III.7 The Delta Function and Generalized Functions

P. J. Upton

The Dirac δ function, denoted by $\delta(x)$ and named after its inventor, the twentieth-century theoretical physicist P. A. M. Dirac, may be thought of as a function that is so tightly peaked about the value $x = 0$ that it is zero everywhere except at $x = 0$ and yet its integral $\int_{-\infty}^{\infty} \delta(x) dx = 1$. This means that, strictly speaking, $\delta(x)$ is not a function at all, since its value at $x = 0$ is ill defined. However, as will become clear later on, the “function” $\delta(x)$ can be used as a convenient shorthand notation for the limit of a sequence of well-defined functions, $g_n(x)$, as $n \rightarrow \infty$. The δ function is used widely across physical applied mathematics, to model, for example, impulses in mechanics and electric circuit theory, and point-like charge distributions in electromagnetism or gravity.

So why define such a strange object as $\delta(x)$? One answer is that many physical situations can be described well using the δ function. For example, in one-dimensional mechanics a particle with mass m may be subject to a force $f(t)$ present for *only* a very short time interval $-t_0 < t < t_0$. Consider the total *impulse* defined by the integral

$$\int_{-t_0}^{t_0} f(t) dt = \int_{-t_0}^{t_0} m \frac{dv}{dt} dt = mv(t_0) - mv(-t_0),$$

where the first equality follows from Newton's second law, and $v(t)$ is the velocity of the particle at time t . Suppose that the force acts in such a way that it causes the particle, initially at rest, to move off with constant velocity and its momentum set to unity, so that $v(-t_0) = 0$ and $mv(t_0) = 1$. Furthermore, we require that the force acts over such a tiny time interval that t_0 is practically zero. In other words, the force acts *instantaneously*, as might be expected if $f(t)$ were the result of a sudden hammer blow or kick, and the precise form of $f(t)$ when $-t_0 < t < t_0$ does not significantly affect the outcome. In order to model this kick, $f(t)$ must be zero everywhere except at $t = 0$ but with unit total integral, corresponding to a unit impulse. We are therefore led to a δ function as a model for an *impulsive force*. The subsequent motion (or *response*) of a particle due to an impulsive force is an important function of t . It is an *initial-value Green function*, $G(t)$, named after the early nineteenth-century mathematical physicist George Green. Green functions are, more generally, the solutions of nonhomogeneous differential equations with a δ function as the source term.

1 Basic Properties

As discussed above, the δ function has the property that

$$\int_a^b \delta(x) dx = \begin{cases} 1 & \text{if } a < 0 < b, \\ 0 & \text{if } 0 \notin [a, b]; \end{cases}$$

cases where $a = 0$ or $b = 0$ will not be considered. The δ function is not strictly a function at all, as $x = 0$ is in the domain of the "function" yet $\delta(0)$ cannot be assigned a value in the codomain. Strictly speaking, $\delta(x)$ has a meaning only when it appears under an integral sign, in which case the following important basic property is satisfied:

$$\int_{-\infty}^{\infty} f(x) \delta(x) dx = f(0) \quad (1)$$

for a sufficiently well-behaved function $f(x)$. The identity $\int_{-\infty}^{\infty} \delta(x) dx = 1$ is a special case of (1).

2 Green Functions

Linear initial-value problems, such as those in which we seek the position of a particle, $x(t)$, at time t , involve solving a differential equation $Lx = f(t)$, where L is a linear differential operator and $f(t)$ some arbitrary force. The general solution is given by $x = x_c + x_p$. Here, x_c is the complementary function and it solves $Lx_c = 0$, while x_p , the particular integral, can be expressed in terms of a Green function, $G(t)$, that is, the response to the impulsive force $\delta(t)$. Thus, with $LG = \delta(t)$, we have $x_p(t) = \int_0^{\infty} G(t-t')f(t')dt'$.

The δ function defined on \mathbb{R}^3 , where

$$\delta(\mathbf{r}) = \delta(x)\delta(y)\delta(z) \quad \text{for } \mathbf{r} = (x, y, z) \in \mathbb{R}^3,$$

can be used to model a point-like charge distribution. This then enables the determination of the potential, $\phi(\mathbf{r})$, $\mathbf{r} \in \mathbb{R}^3$, for general charge distributions, $\rho(\mathbf{r})$, which requires solving POISSON'S EQUATION [III.18] $-\Delta\phi = \rho(\mathbf{r})$ (Δ denotes the Laplace operator). Again, this can be done using a Green function, $G(\mathbf{r})$, which solves $-\Delta G = \delta(\mathbf{r})$, so that $G(\mathbf{r})$ is the potential for a point-like charge, from which we find that $G(\mathbf{r}) = 1/(4\pi|\mathbf{r}|)$, i.e., the Coulomb potential, and that $\phi(\mathbf{r}) = \int_{\mathbb{R}^3} G(\mathbf{r}-\mathbf{r}')\rho(\mathbf{r}')d\mathbf{r}'$.

When treating problems involving both time evolution and spatial variation, such as in quantum theory and the theory of Brownian motion, the Green function depends on time as well as position. In these cases, $G(t, \mathbf{r})$ is often referred to as a *propagator*.

3 Delta-Convergent Sequences

The δ function can be constructed by taking a limit of a sequence of well-defined functions $g_n(x)$ as $n \rightarrow \infty$. If g_n is *smooth* (that is, differentiable at all orders) for all n , then the sequence is said to define a *generalized function*. In addition, for all n , we insist on the condition $\int_{-\infty}^{\infty} g_n(x) dx = 1$. An example of such a δ -convergent sequence is given by the sequence of Gaussian functions

$$g_n(x) = \frac{n}{\sqrt{2\pi}} e^{-(nx)^2/2}, \quad n \geq 1. \quad (2)$$

Examples of this $g_n(x)$ are plotted in figure 1(a). As n increases, the functions $g_n(x)$ get more strongly peaked (both narrower and taller) about $x = 0$. Indeed, from the expression in (2) it follows that as $n \rightarrow \infty$, $g_n(x) \rightarrow 0$ for $x \neq 0$ but $g_n(0) \rightarrow \infty$, as expected if the limit is $\delta(x)$. Also, $\int_{-\infty}^{\infty} g_n(x) dx = 1$, $n \geq 1$, must hold, in view of the expression $\int_{-\infty}^{\infty} e^{-x^2} dx = \sqrt{\pi}$ for the integral of a Gaussian function. Thus, taking into

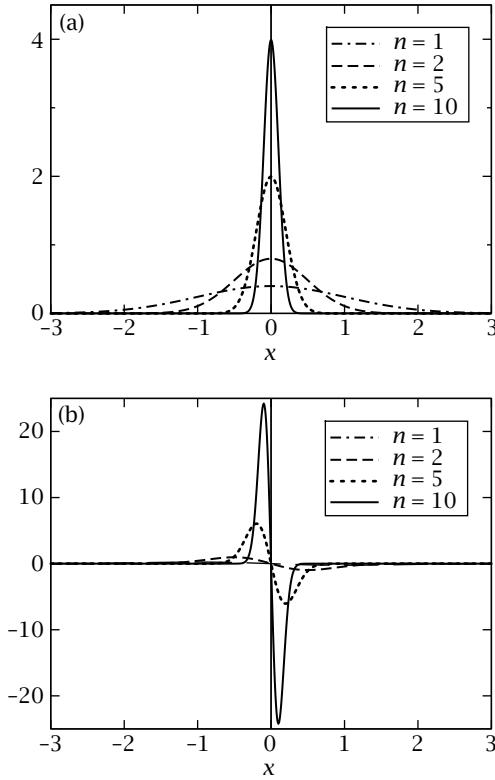

Figure 1 (a) The functions $g_n(x)$ as defined in (2). (b) Their derivatives $g'_n(x)$ for $n = 1, 2, 5$, and 10. These sequences converge to $\delta(x)$ and $\delta'(x)$, respectively.

account these properties of $g_n(x)$ in (2), it begins to look plausible that $g_n(x) \rightarrow \delta(x)$ (in some sense) as $n \rightarrow \infty$. Indeed, one can prove that for sufficiently well-behaved functions $f(x)$ (such as Lipschitz-continuous functions), the limit

$$\lim_{n \rightarrow \infty} \int_{-\infty}^{\infty} g_n(x) f(x) dx = f(0) \quad (3)$$

holds. Hence, the limit of $g_n(x)$ as $n \rightarrow \infty$ satisfies the basic property of the δ function given by (1), at least for Lipschitz-continuous functions. But with a different δ -convergent sequence, $g_n(x)$, $n \geq 1$, one can prove that (3) holds for all continuous functions $f(x)$. In this case, the functions $g_n(x)$ are smooth but *compactly supported*, that is, nonzero only on bounded intervals of \mathbb{R} .

4 Derivatives of the Delta Function

One can define a generalized function corresponding to the derivative of the delta function, $\delta'(x)$, through a

(δ' -convergent) sequence of functions, $g'_n(x)$, $n \geq 1$. An example of such a sequence is illustrated in figure 1(b), where $g'_n(x)$ is the derivative of $g_n(x)$ given by (2). Such a process has an appealing physical interpretation. Just as we can think of $\delta(x)$ as a model for a one-dimensional charge distribution of a point-like electric charge, we can regard $\delta'(x)$ as that of an electric dipole consisting of two oppositely signed point-like charges that are infinitesimally close together. From the limiting properties of $g'_n(x)$, one can show that the dipole moment of this charge distribution is given by $\int_{-\infty}^{\infty} x \delta'(x) dx = -1$. Indeed, this is a special case of the more general result for derivatives of general order k ,

$$\int_{-\infty}^{\infty} \delta^{(k)}(x) f(x) dx = (-1)^k f^{(k)}(0),$$

for sufficiently well-behaved functions $f(x)$.

5 Toward a Rigorous Theory

A rigorous theory of generalized functions, also called *distributions*, can be constructed by defining them as *continuous linear functionals*, $T(\varphi)$, on the space of all smooth, compactly supported test functions $\varphi(x)$ on \mathbb{R} . The derivative of $T(\varphi)$ is defined by $dT(\varphi)/dx = -T(\varphi')$. If $T(\varphi)$ can be expressed in the form $T(\varphi) = \int_{-\infty}^{\infty} g(x) \varphi(x) dx$, where $g(x)$ is a well-defined locally integrable function, then $T(\varphi)$ is said to be a *regular* generalized function; otherwise, it is called *singular*. The δ function is the singular generalized function defined by $T(\varphi) = \varphi(0)$. So, regular generalized functions assign a functional $T(\varphi)$ to each well-defined function $g(x)$. But, by extending the range of allowed $T(\varphi)$ to include singular generalized functions, one can think of $g(x)$ as being part of a much larger set, hence the term “generalized” function.

Another approach to the rigorous treatment of the δ function, and one that is particularly useful in probability theory, is to regard it as a *measure*. The Dirac δ measure centered at a point $a \in \mathbb{R}$, denoted by δ_a , acts on sets $A \subset \mathbb{R}$ and is defined by the property that $\delta_a(A) = 1$ if $a \in A$ and $\delta_a(A) = 0$ otherwise. A measure-theoretic version of the basic property (1) then follows from $\int_{\mathbb{R}} f(x) \delta_a(dx) = f(a)$.

III.8 The Diffusion Equation

The one-dimensional *diffusion* (or *heat*) *equation* is a PARTIAL DIFFERENTIAL EQUATION [IV.3] (PDE) for $u(x, t)$,

$$\frac{\partial^2 u}{\partial x^2} = \frac{1}{k} \frac{\partial u}{\partial t}, \quad (1)$$

where k is a constant. It is classified as a linear second-order homogeneous parabolic equation.

The diffusion equation has solutions that are separated, $u(x, t) = e^{yx} e^{y^2 kt}$, where y is an arbitrary constant. There are also nonseparable solutions such as $u(x, t) = t^{-1/2} e^{-\phi}$, where $\phi(x, t) = x^2/(4kt)$.

Equation (1) describes the conduction of heat along a bar of metal and many other diffusion processes. In financial mathematics, there is a famous PDE known as the BLACK-SCHOLES EQUATION [III.3]

$$\frac{\partial V}{\partial t} + \frac{1}{2} \sigma^2 S^2 \frac{\partial^2 V}{\partial S^2} + rS \frac{\partial V}{\partial S} - rV = 0, \quad (2)$$

where σ and r are constants and the independent variables are S and t . Solutions of this PDE can be constructed from solutions of the diffusion equation. Thus, the substitutions $u(x, t) = e^{\alpha x + \beta t} V$ and $e^x = S$ in (1) show that V solves (2) if we take $k = -\frac{1}{2}\sigma^2$, $\alpha = -\frac{1}{2}(1 + r/k)$, and $\beta = \frac{1}{4}k(1 - r/k)^2$.

THE BURGERS EQUATION [III.4] is another PDE that can be solved using solutions of (1).

III.9 The Dirac Equation

Mark R. Dennis

In quantum theory, the Dirac equation is the relativistic counterpart to SCHRÖDINGER'S EQUATION [III.26], representing the space-time dependence of an electron wave packet. It is one of the most fundamental equations in physics, combining the formalism of quantum physics with special relativity, and its solutions naturally lead to the concept of antimatter.

In QUANTUM MECHANICS [IV.23], when considering the wave function $\Psi(\mathbf{r}, t)$ of a quantum particle, quantities such as position in 3-space \mathbf{r} , time t , momentum \mathbf{p} , and energy $E > 0$ are related to multiplication operators or the product of differential operators multiplied by the imaginary unit i times the quantum of action, Planck's constant \hbar . These include the energy operator $i\hbar\partial_t$ and the momentum operator with components $-i\hbar\partial_j$, with ∂_j for $j = 1, 2, 3$ denoting derivatives on the spatial coordinates of \mathbf{r} . The Schrödinger equation

$i\hbar\partial_t\Psi = \hat{H}\Psi$ thus expresses equality of the energy operator and a Hamiltonian operator \hat{H} when each acts on the quantum wave function $\Psi(\mathbf{r}, t)$. However, in special relativity, the energy-momentum relationship is

$$E^2 = |\mathbf{p}|^2 c^2 + m^2 c^4 \quad (1)$$

for a particle of rest mass m , with constant c the speed of light. We will refer to the quantum particle of interest as an “electron” and denote its electric charge by e .

The *Klein-Gordon equation* is one possible quantum equation corresponding to (1),

$$c^{-2} \partial_t^2 \varphi - \nabla^2 \varphi + \frac{m^2 c^2}{\hbar^2} \varphi = 0, \quad (2)$$

for a generally complex-valued wave function $\varphi(\mathbf{r}, t)$. However, there are physical problems in interpreting a solution of (2) as the relativistic counterpart of a Schrödinger wave function: unlike the Schrödinger equation, (2) involves the second derivative of time, so two initial conditions at $t = 0$ are required to specify a solution (whereas only one is required for the Schrödinger equation), and there are problems with defining a continuity equation for $|\varphi|^2$ as a probability density. Furthermore, (2) does not include the two components of electron spin. Therefore, to write down a quantum mechanical partial differential equation (PDE) corresponding to (1) that is first order in time, one must find an appropriate square root of the overall operator acting on the left-hand side of (2).

Paul Dirac famously resolved this problem algebraically, proposing the Dirac equation

$$i\hbar\partial_t\psi = \sum_{j=1}^3 \alpha_j c \hat{p}_j \psi + \beta mc^2 \psi. \quad (3)$$

Unlike the Schrödinger and Klein-Gordon equations, (3) is a vector-matrix equation, where $\psi \equiv \psi(\mathbf{r}, t)$ is a wave function with four complex components, called a *Dirac spinor* (the components are not related to four-dimensional space-time), and α_j , β are the 4×4 *Dirac matrices*, most commonly written in block form:

$$\beta = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad \alpha_j = \begin{pmatrix} 0 & \sigma_j \\ \sigma_j & 0 \end{pmatrix}, \quad j = 1, 2, 3.$$

Here, 0 and 1 denote the 2×2 zero and identity matrices, and the σ_j denote the three Pauli matrices:

$$\sigma_1 = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}.$$

The square of each Dirac matrix so defined is the identity matrix, and otherwise the matrices anticommute; that is, if $i \neq j$ then $\alpha_j \alpha_k + \alpha_k \alpha_j = \alpha_j \beta + \beta \alpha_j = 0$. These properties imply that the square of the operators on

the left- and right-hand sides of (3) gives the operator equivalent of (1). Thus, the α_j , β matrices themselves form a Clifford algebra, known as the *Dirac algebra*.

When considering solutions in the nonrelativistic, low-velocity limit $|\mathbf{p}|/m \ll c$, the *Dirac equation* asymptotically approaches the Schrödinger equation for a two-component spin (in the first two components of the Dirac spinor; the second two are vanishingly small), recovering the familiar nonrelativistic quantum behavior of the electron. Dirac therefore found a relativistic, quantum PDE that is first order in space and time, albeit requiring the quantum electron to be described by the four-component Dirac spinor ψ , each component of which, in fact, satisfies the Klein-Gordon equation (2). The fact that the Pauli spin matrices—previously included ad hoc in the Schrödinger equation to explain the behavior of the electron's quantum mechanical spin—appear naturally in the Dirac algebra has been seen as one of the great successes of the Dirac equation as the fundamental quantum equation for the electron.

Although a matrix-vector equation, the form (3) of the Dirac equation is similar to the Schrödinger equation, and indeed the operator $\sum_{j=1}^3 \alpha_j c \hat{p}_j + \beta mc^2$ is referred to as the *Dirac Hamiltonian*. The Dirac equation may also be written in a relativistically covariant form, by defining the set of four *gamma matrices* $\gamma^0 = \beta$, $\gamma^j = \gamma^0 \alpha_j$, enabling (3) to be rewritten as

$$i\hbar \sum_{a=0}^3 \gamma^a \partial_a \psi = mc\psi, \quad (4)$$

with $\partial_0 = c^{-1} \partial_t$. Usually, this form of the Dirac equation is written in the Einstein summation convention (omitting explicit summation symbols for repeated 4-vector components, as in the article on **TENSORS AND MANIFOLDS** [II.33]).

It is natural to define a current 4-vector $j^a \equiv \psi^\dagger \gamma^0 \gamma^a \psi$, where $a = 0, \dots, 3$, and ψ^\dagger is the adjoint (conjugate transpose) of ψ . The 0-component $\psi^\dagger \psi$ is the nonnegative-definite probability associated with the Dirac particle described by ψ , and the other components $\psi^\dagger \alpha_j \psi$ give a 3-velocity field, and hence the electric current on multiplication by e . The 4-divergence of this current vanishes: $\sum_a \partial_a j^a = 0$. This is interpreted as both the local conservation of probability and, after multiplication by e , the local conservation of the electric charge distribution determined by ψ . The 3-velocity so defined is different from the 3-momentum, $\psi^\dagger \hat{p}_j \psi$, $j = 1, 2, 3$. This distinction between velocity and momentum gives rise to some surprising aspects

of Dirac particles, such as the difference between quantum numbers associated with the electron's magnetic moment (related to velocity) and its angular momentum (related to momentum). For the remainder of this article we will adopt the convention in relativistic quantum theory of working in units where the constants c and \hbar are unity.

The Dirac equation, being a PDE for a multicomponent wave field dependent on space and time compatible with special relativity, is comparable to the set of **MAXWELL'S EQUATIONS** [III.22], which has similar properties (particularly in the case when $m = 0$, which is sometimes referred to as *Weyl's equation*). In particular, it has four linearly independent plane-wave solutions, of the form $\exp(i(-Et + \mathbf{p} \cdot \mathbf{r}))$ times the constant unnormalized Dirac spinors

$$\begin{aligned} \psi_{\text{pw}}^1 &= (E + m, 0, p_3, p_1 + ip_2), \\ \psi_{\text{pw}}^2 &= (0, E + m, p_1 - ip_2, -p_3), \\ \psi_{\text{pw}}^3 &= (-p_3, -(p_1 + ip_2), -E + m, 0), \\ \psi_{\text{pw}}^4 &= (-(p_1 - ip_2), p_3, 0, -E + m). \end{aligned}$$

The solutions involving ψ_{pw}^1 and ψ_{pw}^2 are interpreted as electron plane waves in spin up and spin down states, respectively, especially in the nonrelativistic regime $p \ll m$. However, ψ_{pw}^3 , ψ_{pw}^4 appear to be *negative energy solutions*, reflecting the fact that the relativistic energy relation (1), involving only E^2 , should mathematically admit negative energies as well as positive energies.

The existence of negative energy solutions is one of the most striking aspects of the Dirac equation (similar solutions also exist for the Klein-Gordon equation (2)), not least because physically they appear to preclude energetic ground states; it suggests that relativistic electrons may constantly decay to successively lower energies without bound, at odds with our physical experience. Dirac himself proposed the following resolution to this problem: the negative energies are already filled with a *Dirac sea* of electrons. Free electrons cannot then occupy these filled negative energy states and must have nonnegative energy. The existence of this postulated Dirac sea has the further consequences that a negative energy electron might, through some process, become excited into a positive energy state, leaving a positively charged “hole” in the sea whose plane-wave components act according to the negative energy solutions ψ_{pw}^3 and ψ_{pw}^4 (in a similar way to “holes” appearing in filled valence bands in semiconductors). Dirac originally identified these “positive charge electrons” as

protons, despite the fact that a proton has a mass that is very different from the electron mass m . However, *positrons*, which appeared to have the same mass as electrons but opposite charge, were discovered experimentally by Anderson in 1932, just four years after Dirac's theory. This prediction of a new kind of particle earned Dirac the Nobel Prize in Physics in 1933, shared with Schrödinger.

To incorporate the interaction between an electron and the electromagnetic field, the momentum operator \hat{p}_j must be replaced with the appropriate canonical momentum for a charged particle moving in a field from the Lorentz force equation (as in CLASSICAL MECHANICS [IV.19]). In a scalar potential V and vector potential A , giving a 4-potential A_a , this replacement in (3), (4) requires replacing the usual partial derivatives with the gauge-covariant derivative

$$\partial_a \rightarrow D_a \equiv \partial_a + ieA_a, \quad a = 0, 1, 2, 3.$$

Finding self-consistent solutions of Maxwell's equations and the Dirac equation with interactions is analytically difficult. Nevertheless, very good approximations are possible that agree well with experiment, particularly in quantum electrodynamics, which is a systematic quantum approach to solving systems with many electrons interacting quantum mechanically with the electromagnetic field. Quantum electrodynamics, like other quantum field theories, requires a more sophisticated mathematical approach based on the Dirac and Maxwell equations and relates the negative energy solutions of the Dirac and Klein-Gordon equations to positive energy states of *antimatter* (i.e., positrons are "anti-electrons"). Despite many mathematical complications, this theory successfully describes the evolution of many interacting quantum particles, including the possibility of their creation and annihilation in a fluctuating vacuum.

III.10 Einstein's Field Equations

Malcolm A. H. MacCallum

Einstein's general theory of relativity generalizes Newton's gravity theory to one compatible with special relativity. It models space and time points as a (pseudo-)Riemannian four-dimensional manifold (see TENSORS AND MANIFOLDS [II.33]) with a metric g_{ab} of signature ± 2 (the sign choice is conventional). Test particles move on space-time's geodesics. This formulation ensures the "weak equivalence principle" or "universality of free fall," which states that free fall under gravity depends only on a body's initial position and momentum. The other fundamental part of the theory is Einstein's field equations (EFEs), which relate the metric to the matter present. For more on the theory and its applications see GENERAL RELATIVITY AND COSMOLOGY [IV.40].

By considering a "gedanken" experiment in which bodies released at relative rest in a laboratory freely falling toward the Earth will appear to move toward one another, Einstein recognized that geodesics that are initially parallel meet due to gravity. This is described by the metric's curvature. To generalize Newton's theory, the curvature must be related to the space-time distribution of the energy-momentum tensor of the matter content, T^{ab} .

T^{ab} is assumed to obey $T^{ab}_{;b} = 0$, the generalization to curved space of the Noetherian conservation laws obtained when the matter obeys a variational principle. Here, " $;b$ " denotes a covariant derivative with respect to the b index, while " $,b$ " will denote a partial derivative below.

The formulas relating the metric, the connection Γ^a_{bc} , and the Riemannian curvature, in coordinate components, are

$$\Gamma^a_{bc} = \frac{1}{2}g^{ad}(g_{bd,c} + g_{dc,b} - g_{bc,d}),$$

$$R^a_{bcd} = \Gamma^a_{bd,c} - \Gamma^a_{bc,d} + \Gamma^e_{bd}\Gamma^a_{ec} - \Gamma^e_{bc}\Gamma^a_{ed},$$

where g^{ad} is the inverse of g_{bc} .

Taking a weak-field, slow-motion limit, comparison of the geodesic equation with Newtonian free fall identifies corrections to an approximating flat (special-relativistic) metric with the Newtonian gravitational potential Φ . One therefore wants to find equations relating the second derivative of the metric to T_{ab} . Defining the Ricci tensor R_{ab} and the Ricci scalar R by

$$R_{bd} := R^a_{bad}, \quad R := g^{ab}R_{ab},$$

the EFEs

$$G_{ab} := R_{ab} - \frac{1}{2}Rg_{ab} = \kappa T_{ab} + \Lambda g_{ab} \quad (1)$$

achieve this relation. Here, Λ is a constant and G_{ab} is called the Einstein tensor.

To agree with the Newtonian limit, the constant κ has to be $8\pi G/c^4$, where G is the Newtonian constant of gravitation and c the speed of light.

The full curvature can be expressed, in four dimensions, as

$$R^{ab}_{cd} = C^{ab}_{cd} - \frac{1}{3}R\delta^a_{[c}\delta^b_{d]} + 2\delta^a_{[c}R^b_{d]},$$

where square brackets denote antisymmetrization, so that, for any tensor, $T_{[ab]} := \frac{1}{2}(T_{ab} - T_{ba})$. The Weyl tensor C^a_{bcd} thus defined is conformally invariant and describes tidal gravitational forces and gravitational waves. Its value depends on distant matter and the boundary conditions: it is nonlocally determined by certain first-order differential equations, the Bianchi identities, with a source given by derivatives of R_{ab} .

There are a number of other ways to write (1). A first-order system arises by taking the metric and its connection as variables. Tetrad bases are widely used in place of coordinate bases. The EFEs themselves are given by a variational principle (assuming that T_{ab} is), with the G_{ab} part coming from an action $\int R\sqrt{-g} d^4x$, where $g = \det(g_{ab})$.

Calculating in coordinates, the ten components of (1) each have on the order of 10^4 terms in components of g_{ab} , they are quasilinear in second derivatives of g_{ab} , and they are nonlinear of degree 8 in g_{ab} itself (after clearing denominators). The tensorial EFEs are therefore a set of coupled nonlinear inhomogeneous partial differential equations. Lovelock proved that in four dimensions, G_{ab} is the only symmetric divergence-free tensorial concomitant of g_{ab} that is linear in second derivatives, so the EFEs are the unique field equations of this character.

No general solution is known, except in the sense of the integral form given by Sciama, Waylen, and Gilman, but many specific solutions have been found. Their local geometry can be completely characterized by components of the curvature tensor and its covariant derivatives.

General relativity shares with other physical theories the property that the evolution is unique given initial values of the field and its first derivative. In this case these are the induced metric on an initial space-like surface, and its derivative off the surface (the first and second “fundamental forms”). Four of the EFEs

constrain these initial values, the remaining equations giving six second-order evolution equations. The constraint equations are elliptic and the evolution equations hyperbolic; the characteristic speed is that of light.

Existence and uniqueness theorems have been obtained for the evolution equations in this form. Typically, the functions that appear lie in appropriate Sobolev spaces.

As well as such Cauchy problems, the EFEs can be studied in a “2 + 2” formalism, where data is given on a pair of intersecting two-dimensional characteristic surfaces.

It was recently recognized that the EFEs in standard form are only weakly hyperbolic, which explained problems that had arisen in numerical integrations, and strongly hyperbolic reformulations are now available that allow fully four-dimensional numerical computations (see NUMERICAL RELATIVITY [V.15]).

In both numerical and analytic studies, important problems such as the generation of gravitational waves require characterization of isolated bodies. This is achieved by defining *asymptotic flatness*, when at spatial or light-like (null) infinity the geometry approaches that of special relativity’s empty Minkowski space. A conformal transformation by a factor Ω is used in the precise definition; this transformation preserves null directions and gives a single point, denoted by i^0 , at spatial infinity. The definition, which is abbreviated as AEFANSI (for “asymptotically empty and flat at null and spatial infinity”), specifies the behavior of Ω and the Ricci tensor near i^0 .

Space-times may have more than one asymptotic infinity (see, for example, the Kruskal diagram in GENERAL RELATIVITY AND COSMOLOGY [IV.40]). *Weakly asymptotically simple* (WAS) space-times are those for which only one asymptotic region need be considered. There is a large class of WAS space-times for which null infinity is smooth, for which fields such as the Weyl tensor can be expanded in inverse powers of a radial distance r , and for which there is an asymptotic symmetry, the Bondi–Metzner–Sachs group. These results have been generalized to cases where $\log r$ terms appear in expansions; it is conjectured that only a rather restricted set of cases avoids such terms.

There is no locally defined energy of the gravitational field in general relativity; such an energy could not be compatible with the local special relativistic limit required by the principle of equivalence. However, asymptotically flat spaces do possess globally

defined energies, using integrals at infinity—the *ADM energy* for a spatial infinity (named after the formalism introduced by Arnowitt, Deser, and Misner) and the *Trautman–Bondi energy* for a future null infinity—thus enabling definition of the total gravitational energy of an isolated system.

The ADM energy has been proved to be nonnegative—assuming both that the matter that is present obeys the dominant energy condition that $T^{ab}v_a v_b \geq 0$ and that T^{ab} is space-like for all time-like vectors v^a —and it is zero only in Minkowski space. The Trautman–Bondi energy is monotone decreasing with time, as radiation carries energy away, and agrees with ADM energy in its past limit and hence must also be nonnegative (as can also be proved directly). These results show in particular that gravitational waves carry energy. However, the waves cannot carry away more energy than an isolated system has initially, as total energy would then become negative. The positive energy results also imply that there is no analogue of the possibility, present in Newtonian gravity theory, that negative gravitational potential energy could be greater than the positive energy of the field's source.

III.11 The Euler Equations

P. A. Martin

The motion of a fluid is well modeled by the NAVIER-STOKES EQUATIONS [III.23]. An underlying assumption is that the fluid is viscous (meaning that it is sticky, in the sense that there is some resistance to shearing motions). Assume further that the fluid is incompressible (meaning that the density is constant). Then, if the viscous effects are removed from the Navier-Stokes equations (even though real fluids are always viscous to some extent), the result is known as the *Euler equations*.

To state them, let $\mathbf{x} = (x_1, x_2, x_3)$ be the position vector of a point in the fluid and let $\mathbf{u}(\mathbf{x}, t) = (u_1, u_2, u_3)$ be the fluid velocity at \mathbf{x} at time t . Then

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} + \frac{1}{\rho} \nabla p = \mathbf{0}, \quad (1)$$

where $p(\mathbf{x}, t)$ is the pressure and ρ is the density. The vector equation (1) is to be solved together with the incompressibility constraint, which is

$$\nabla \cdot \mathbf{u} = 0. \quad (2)$$

There are thus four partial differential equations (PDEs) for the four unknowns, u_1 , u_2 , u_3 , and p . These form the incompressible Euler equations for inviscid (zero-viscosity) flows; there are also *compressible Euler equations* for flows in which the fluid density is not constant but has to be calculated. If body forces are acting (the most important of these is gravity), there would be an extra term on the right-hand side of (1).

To clarify the notation used in (1) and (2), we can write them in component form:

$$\frac{\partial u_i}{\partial t} + \sum_{j=1}^3 u_j \frac{\partial u_i}{\partial x_j} + \frac{1}{\rho} \frac{\partial p}{\partial x_i} = 0, \quad \sum_{j=1}^3 \frac{\partial u_j}{\partial x_j} = 0,$$

where $i = 1, 2, 3$. Alternatively, if we use $\mathbf{x} = (x, y, z)$ and $\mathbf{u} = (u, v, w)$, we can write out Euler's equations explicitly:

$$\begin{aligned} \frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + w \frac{\partial u}{\partial z} + \frac{1}{\rho} \frac{\partial p}{\partial x} &= 0, \\ \frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + w \frac{\partial v}{\partial z} + \frac{1}{\rho} \frac{\partial p}{\partial y} &= 0, \\ \frac{\partial w}{\partial t} + u \frac{\partial w}{\partial x} + v \frac{\partial w}{\partial y} + w \frac{\partial w}{\partial z} + \frac{1}{\rho} \frac{\partial p}{\partial z} &= 0, \\ \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} &= 0. \end{aligned}$$

An important special case arises when the motion is *irrotational*, which means that the vorticity $\nabla \times \mathbf{u} = \mathbf{0}$. In this case, $\mathbf{u} = \nabla \phi$ for some scalar (potential) function ϕ . From (2), $\nabla^2 \phi = 0$; that is, ϕ solves LAPLACE'S EQUATION [III.18]. Moreover, the nonlinear PDEs (1) reduce to a formula for p that is known as *Bernoulli's equation*.

Irrational flows of inviscid incompressible fluids have been studied extensively since the nineteenth century. However, it is also known that the underlying assumptions are too restrictive in some circumstances because they lead to some results that do not agree with our experience. Perhaps the most glaring example is the *d'Alembert paradox*, a mathematical theorem asserting that irrotational flow of an inviscid incompressible fluid about a rigid body generates no drag

force on the body. The conventional way to overcome the paradox is to bring back viscosity but only inside a thin BOUNDARY LAYER [II.2] attached to the body (see also FLUID MECHANICS [IV.28 §7.2]).

III.12 The Euler-Lagrange Equations

Paul Glendinning

The function $y(x)$ with derivative $y' = dy/dx$ that maximizes or minimizes the integral

$$\int F(y, y', x) dx$$

with given endpoints satisfies the Euler-Lagrange equation

$$\frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) - \frac{\partial F}{\partial y} = 0. \quad (1)$$

There are many variants of this equation to deal with further complications, e.g., if y or x or both are vectors, and more details are given in CALCULUS OF VARIATIONS [IV.6], but this simple version is sufficient to demonstrate the power and ubiquity of variational problems of this form.

If $F = F(y, y')$ has no explicit x -dependence (x is said to be *absent*), then the Euler-Lagrange equations can be simplified by finding a first integral. Using (1) it is straightforward to show that

$$\frac{d}{dx} \left(y' \frac{\partial F}{\partial y'} - F \right) = 0,$$

and hence that

$$y' \frac{\partial F}{\partial y'} - F = A \quad (2)$$

for some constant A .

Application 1: Potential Forces

Classical mechanics can be formulated as a problem of minimizing the integral of a function called the *Lagrangian*, \mathcal{L} , which is the kinetic energy minus the potential energy. For a particle moving in one dimension with position q (so the dependent variable q plays the role of y above and time t plays the role of the independent variable x) in a potential $V(q)$, the Lagrangian is $\mathcal{L} = \frac{1}{2}m\dot{q}^2 - V(q)$ and the Euler-Lagrange equation (1) is simply Newton's law for the acceleration, $m\ddot{q} = -V'(q)$ (where the prime denotes differentiation with respect to q), while the autonomous version (2) shows that $\frac{1}{2}m\dot{q}^2 + V(q)$ is constant, which is the conservation of energy (see CLASSICAL MECHANICS [IV.19]).

The power of this approach (and a related version due to Hamilton) is such that much of modern theoretical physics revolves round a generalization called an *action*.

Application 2: The Catenary

The problem of determining the curve describing the rest state of a heavy chain or cable with fixed endpoints can also be solved using the Euler-Lagrange formulation, although the original seventeenth-century solution uses simple mechanics. In the rest state the chain will assume a shape $y = y(x)$ that minimizes the potential energy $g \int y ds$, where g is the acceleration due to gravity and s is the arc length along the chain. The length of the chain is $\int ds$, and since this length is assumed to be constant, L say, $\int ds = L$. This acts as a constraint on the solutions of the energy-minimization problem and so the full problem can be approached by introducing a LAGRANGE MULTIPLIER [I.3 §10], λ . Scaling out the constant g and noting that $ds = \sqrt{1 + y'^2} dx$, the shape of the curve minimizes

$$\int y \sqrt{1 + y'^2} dx - \lambda \left(\int \sqrt{1 + y'^2} dx - L \right). \quad (3)$$

(The second term represents the constraint and is zero when the constraint is satisfied.) The Euler-Lagrange equation with

$$F(y, y', \lambda) = \sqrt{1 + y'^2} - \lambda \sqrt{1 + y'^2}$$

can now be used since the λL term of (3) is constant with respect to variations in y . The Euler-Lagrange equation is supplemented by an additional equation obtained by extremizing with respect to the Lagrange multiplier, i.e., setting the derivative of (3) with respect to λ to zero, but this is just the length constraint again. Since x is absent, (2) implies that

$$(y - \lambda) \left(\frac{y'^2}{\sqrt{1 + y'^2}} - \sqrt{1 + y'^2} \right) = A.$$

Tidying up the left-hand side and rearranging gives $A^2(1 + y'^2) = (y - \lambda)^2$. Rewriting this as an expression for y' gives a differential equation that can be solved by separation of variables to give

$$y - \lambda = A \cosh \left(\frac{x - B}{A} \right),$$

where B is a further constant of integration. This is the catenary curve, and the constants are determined by the endpoints of the chain and the constraint that the total length is L .

III.13 The Gamma Function

Euler's gamma function, Γ , is defined by

$$\Gamma(x) = \int_0^\infty t^{x-1} e^{-t} dt, \quad x > 0.$$

One integration by parts shows that

$$\Gamma(x+1) = x\Gamma(x), \quad x > 0.$$

A direct calculation gives $\Gamma(1) = 1$, and then an inductive argument gives $\Gamma(n) = (n-1)!$ when n is any positive integer. For this reason, the alternative notation $x! = \Gamma(x+1)$ is also used.

Much is known about Γ and its properties. It is classified as a SPECIAL FUNCTION [IV.7] of one variable. According to Davis (1959), of all special functions, Γ "is undoubtedly the most fundamental." It is also ubiquitous, appearing in countless applications. In COMPLEX ANALYSIS [IV.1], $\Gamma(z)$ is defined as a function of a complex variable, z , for all $z \neq 0, -1, -2, \dots$.

An alternative but equivalent definition of Γ is

$$\Gamma(x) = \frac{e^{-yx}}{x} \prod_{n=1}^{\infty} \frac{n}{n+x} e^{x/n},$$

where $y = 0.5772\dots$ is Euler's constant, defined by

$$y = \lim_{n \rightarrow \infty} \left(1 + \frac{1}{2} + \frac{1}{3} + \dots + \frac{1}{n} - \log n \right).$$

The definition of Γ as an infinite product shows clearly that $\Gamma(x)$ is not defined when $x = 0, -1, -2, \dots$, and it reveals the singular nature at these points.

III.14 The Ginzburg–Landau Equation

S. Jonathan Chapman

The Ginzburg–Landau equations were written down in 1950 to describe the change of phase of a superconducting material in the presence of a magnetic field. They are partial differential equations for the complex-valued superconducting order parameter Ψ and the (real-valued) magnetic vector potential A . The parameter Ψ can be thought of as a kind of macroscopic wave function and is such that $|\Psi|^2$ is the number density of superconducting electrons, while A is such that the magnetic field is $\text{curl } A$.

In their normalized form the equations are

$$\begin{aligned} \left(\frac{1}{\kappa} \nabla - iA \right)^2 \Psi &= (|\Psi|^2 - 1)\Psi, \\ \text{curl}^2 A &= \frac{i}{2\kappa} (\Psi^* \nabla \Psi - \Psi \nabla \Psi^*) - |\Psi|^2 A, \end{aligned}$$

where $i = \sqrt{-1}$, κ is a material constant known as the Ginzburg–Landau parameter, and the asterisk denotes complex conjugation.

1 The Ginzburg–Landau Free Energy

The Ginzburg–Landau equations arise from minimizing the Ginzburg–Landau free energy. For small applied magnetic fields the superconducting solution ($|\Psi| = 1$) has a lower energy than the nonsuperconducting (normal) solution ($\Psi = 0$), while for high applied magnetic fields the normal solution has the lower energy. At the critical magnetic field H_c , the two states have the same energy, and a normal-superconducting transition region is possible.

The main aim in developing the Ginzburg–Landau equations was to determine the energy of such a transition region (the so-called surface energy), since this determines the scale of the pattern of normal and superconducting domains when both are present. In particular, it was desirable to demonstrate that the surface energy was positive. In fact, it turns out that the surface energy is positive only if $\kappa < 1/\sqrt{2}$. Values of the Ginzburg–Landau parameter above this threshold were dismissed at the time as being unphysical.

2 Type-II Superconductors

A few years later, in 1957, Abrikosov published solutions of the equations for values of $\kappa > 1/\sqrt{2}$ that had a quite different structure. When surface energy is negative, a normal region shrinks until it is just a point. However, the scale of the solution is prevented from being infinitely fine by the complex nature of the order parameter; each zero of Ψ has a winding number that is a topological invariant. Abrikosov's solutions are of the form $\Psi = f(r)e^{in\theta}$, $A = A(r)\mathbf{e}_\theta$, where r and θ are polar coordinates, the integer n is the winding number, and \mathbf{e}_θ is the unit vector in the azimuthal direction. The electric current associated with such a solution is

$$\mathbf{j} = -f^2 \left(A - \frac{n}{\kappa r} \right) \mathbf{e}_\theta,$$

which is why these solutions are known as superconducting vortices. Such solutions demonstrate the quantum nature of superconductivity on a macroscopic

scale. Superconductors with $\kappa > 1/\sqrt{2}$ are now known as type-II superconductors, while those with $\kappa < 1/\sqrt{2}$ are known as type-I superconductors.

For type-II superconductors, the critical magnetic field H_c splits into two critical fields, H_{c1} and H_{c2} . Below H_{c1} the superconducting state is energetically preferred, above H_{c2} the normal state is preferred, but in between H_{c1} and H_{c2} a mixed state comprising a periodic array of superconducting vortices exists.

Following Abrikosov's work this lattice of vortices was demonstrated experimentally. It is an amazing triumph of the Ginzburg-Landau theory that it predicted the existence of such structures, not only before they had been observed experimentally but when the very idea of them was disturbing. Almost all technological applications of superconductivity involve type-II superconductors in the vortex state.

III.15 Hooke's Law

P. A. Martin

Strictly, Hooke's law is not a law, as it is readily and frequently violated. Nevertheless, it can be a useful approximation, it can be generalized, and it leads to ideas of *elasticity* and *constitutive equations*.

In 1678, Robert Hooke (1635–1703) described his experiments in which he fixed one end of a long vertical wire to the ceiling and hung various weights to the other end. When there are no hanging weights, the wire has length L , say. When a weight of mass m is added, the wire extends by an amount ℓ , so that the new length is $L + \ell$. If the weight is removed, the wire's length returns to L : this is the signature of elastic behavior. Hooke also showed that doubling the mass (from m to $2m$) gives double the extension. He inferred that the restoring force exerted by the wire on the mass, F , is proportional to the displacement of the mass from its equilibrium position,

$$F = k\ell,$$

where k is the constant of proportionality, the *spring constant*. This is Hooke's law. Hooke also did experiments on the stretching and compression of springs and on the lateral deflections of wooden beams. He

asserted that his law was applicable to "every springing body" and that it could be used to understand vibrations of such bodies.

To see this, return to the mass m hanging on the wire. In equilibrium, its weight is balanced by the restoring force, $mg = k\ell$, where g is the acceleration due to gravity. If the mass is pulled down further and then released, it will oscillate about its equilibrium position. In detail, if the mass is displaced by an amount x , the downward force on the mass is $mg - k(\ell + x) = -kx$, so, by Newton's second law, force = mass × acceleration, the equation of motion is $-kx = m(d^2x/dt^2)$. As $k = mg/\ell$, we obtain $d^2x/dt^2 = -\omega^2x$, where $\omega = (g/\ell)^{1/2}$. This differential equation for $x(t)$ has the general solution $x = x_0 \cos(\omega t + \delta)$, where x_0 and δ are arbitrary constants. The oscillating mass exhibits *simple harmonic motion* with frequency ω .

Hooke's law is an approximation. It models the mechanical behavior of his wire and many other elastic bodies: doubling the load doubles the extension. It is a linear approximation, where the constant of proportionality can be found by experiment; recall that $k = mg/\ell$. However, there will be limits to the validity of Hooke's law: if a very large load is applied, the wire will extend plastically (which means that the wire's length will not return to L if the load is removed) and then it might break.

Returning to Hooke's experiments, suppose we hang a mass m on a wire of length $2L$; the extension doubles to 2ℓ . This implies that k must be proportional to L^{-1} (the left-hand side of $mg = k \times \text{extension}$ has not changed). Similarly, if we suspend the mass by two wires in parallel, each of length L , we see half the extension; we can say that k must be proportional to A , the cross-sectional area of the wire. Thus, we rewrite Hooke's law as

$$\frac{F}{A} = \frac{kL}{A} \frac{\ell}{L}.$$

The dimensionless quantity ℓ/L is the extension per unit length of wire; it is a measure of *strain* in the wire. The quantity F/A is the force per unit area; it is a measure of *stress* in the wire. The quantity kL/A does not depend on L or A ; it depends on what the wire is made from, so it is a *material constant*. Therefore, we write

$$\sigma = E\varepsilon, \quad (1)$$

stating that the stress, σ , is proportional to the strain, ε . The material constant E is known as *Young's modulus*. The formula (1) is a basic assumption in the one-

dimensional theory of the strength of materials. Suitably generalized, it is fundamental to the linear theory of elasticity.

Hooke's law is a *constitutive relation*: it is a model of how certain materials behave when they are subjected to forces. Constitutive relations are part of all continuum theories. Hooke's law is useful for elastic materials, but, as we saw for the oscillating mass, there is no damping; the oscillations do not decay with time. Incorporating damping leads to viscoelastic models. For fluids, it is common to replace Hooke's law with a relation between stresses and velocities; this leads to the Navier-Stokes equations.

Developing and selecting constitutive relations requires an interplay between good modeling of experimental observations, essential mathematical properties (such as causality and frame indifference), and simplicity.

III.16 The Korteweg-de Vries Equation

Willy A. Hereman

1 Historical Perspective

In 1895 Diederik Korteweg (1848–1941) and Gustav de Vries (1866–1934) derived a partial differential equation (PDE) that models the “great wave of translation” that naval engineer John Scott Russell had observed in the Union Canal in 1834.

Assuming that the wave propagates in the X -direction, the evolution of the surface elevation $\eta(X, T)$ above the undisturbed water depth h at time T can be modeled by the Korteweg-de Vries (KdV) equation:

$$\frac{\partial \eta}{\partial T} + \sqrt{gh} \frac{\partial \eta}{\partial X} + \frac{3}{2} \frac{\sqrt{gh}}{h} \eta \frac{\partial \eta}{\partial X} + \frac{1}{2} h^2 \sqrt{gh} \left(\frac{1}{3} - \frac{T}{\rho gh^2} \right) \frac{\partial^3 \eta}{\partial X^3} = 0, \quad (1)$$

where g is the gravitational acceleration, ρ is the density, and T is the surface tension. The dimensionless parameter $T/\rho gh^2$, called the *Bond number*, measures the relative strengths of surface tension and the gravitational force. Equation (1) is valid for long waves of relatively small amplitude, $|\eta|/h \ll 1$.

In dimensionless variables, (1) can be written as

$$u_t + \alpha u u_x + u_{xxx} = 0, \quad (2)$$

where subscripts denote partial derivatives. The term $\sqrt{gh}\eta_X$ in (1) has been removed by an elementary transformation. Conversely, a linear term in u_x can be added to (2). The parameter α can be scaled to any

real number. Commonly used values are $\alpha = \pm 1$ and $\alpha = \pm 6$.

The term u_t describes the time evolution of the wave. Therefore, (2) is called an *evolution equation*. The nonlinear term $\alpha u u_x$ accounts for steepening of the wave. The linear dispersive term u_{xxx} describes spreading of the wave.

It is worth noting that the KdV equation had already appeared in seminal work on water waves published by Joseph Boussinesq about twenty years earlier.

2 Solitary Waves and Periodic Solutions

The balance of the steepening and spreading effects gives rises to a stable solitary wave,

$$u(x, t) = \frac{\omega - 4k^3}{\alpha k} + \frac{12k^2}{\alpha} \operatorname{sech}^2(kx - \omega t + \delta), \quad (3)$$

where the wave number k , the angular frequency ω , and the phase δ are arbitrary constants. Requiring that $\lim_{x \rightarrow \pm\infty} u(x, t) = 0$ for all t leads to $\omega = 4k^3$, in which case (3) reduces to

$$u(x, t) = 12(k^2/\alpha) \operatorname{sech}^2(kx - 4k^3 t + \delta). \quad (4)$$

This hump-shaped solitary wave of finite amplitude $12k^2/\alpha$ travels to the right at constant phase speed $v = \omega/k = 4k^2$, and it models Scott Russell's “great wave of translation” that traveled without change of shape over a fairly long distance.

As shown by Korteweg and de Vries, (2) also has a periodic solution:

$$u(x, t) = \frac{\omega - 4k^3(2m - 1)}{\alpha k} + 12(k^2/\alpha)m \operatorname{cn}^2(kx - \omega t + \delta; m). \quad (5)$$

They called this the *cnoidal wave* solution because it involves Jacobi's elliptic cosine function, cn , with modulus m , $0 < m < 1$. In the limit $m \rightarrow 1$, $\operatorname{cn}(\xi; m) \rightarrow \operatorname{sech} \xi$ and (5) reduces to (3).

3 Modern Developments

The solitary wave was, for many years, considered an unimportant curiosity in the field of nonlinear waves. That changed in 1965, when Zabusky and Kruskal realized that the KdV equation arises as the continuum limit of a one-dimensional anharmonic lattice used by Fermi, Pasta, and Ulam in 1955 to investigate how energy is distributed among the many possible oscillations in the lattice. Since taller solitary waves travel

faster than shorter ones, Zabusky and Kruskal simulated the collision of two waves in a nonlinear crystal lattice and observed that each retains its shape and speed after collision. Interacting solitary waves merely experience a phase shift, advancing the faster wave and retarding the slower one. In analogy with colliding particles, they coined the word “solitons” to describe these elastically colliding waves.

To model water waves that are weakly nonlinear, weakly dispersive, and weakly two-dimensional, with all three effects being comparable, Kadomtsev and Petviashvili (KP) derived a two-dimensional version of (2) in 1970:

$$(u_t + 6uu_x + u_{xxx})_x + 3\sigma^2 u_{yy} = 0, \quad (6)$$

where $\sigma^2 = \pm 1$ and the y -axis is perpendicular to the direction of propagation of the wave (along the x -axis).

The KdV and KP equations, and the NONLINEAR SCHRÖDINGER EQUATION [III.26]

$$iu_t + u_{xx} + \kappa|u|^2 u = 0 \quad (7)$$

(where κ is a constant and $u(x, t)$ is a complex-valued function), are famous examples of so-called completely integrable nonlinear PDEs. This means that they can be solved with the inverse scattering transform, a nonlinear analogue of the Fourier transform.

The inverse scattering transform is not applied to (2) directly but to an auxiliary system of linear PDEs,

$$\psi_{xx} + (\lambda + \frac{1}{6}\alpha u)\psi = 0, \quad (8)$$

$$\psi_t + \frac{1}{2}\alpha u_x \psi + \alpha u \psi_x + 4\psi_{xxx} = 0, \quad (9)$$

which is called the *Lax pair* for the KdV equation. Equation (8) is a linear Schrödinger equation for an eigenfunction ψ , a constant eigenvalue λ , and a potential $(-\alpha u)/6$. Equation (9) governs the time evolution of ψ . The two equations are compatible, i.e., $\psi_{xxt} = \psi_{txx}$, if and only if $u(x, t)$ satisfies (2). For given $u(x, 0)$ decaying sufficiently fast as $|x| \rightarrow \infty$, the inverse scattering transform solves (8) and (9) and finally determines $u(x, t)$.

4 Properties and Applications

Scientists remain intrigued by the rich mathematical structure of completely integrable nonlinear PDEs. These PDEs can be written as infinite-dimensional bi-Hamiltonian systems and have additional, remarkable features. For example, they have an associated Lax pair, they can be written in Hirota’s bilinear form, they admit Bäcklund transformations, and they have the Painlevé property. They have an infinite number of conserved

quantities, infinitely many higher-order symmetries, and an infinite number of soliton solutions.

As well as being applicable to shallow-water waves, the KdV equation is ubiquitous in applied science. It describes, for example, ion-acoustic waves in a plasma, elastic waves in a rod, and internal waves in the atmosphere or ocean. The KP equation models, for example, water waves, acoustic waves, and magnetoelastic waves in anti-ferromagnetic materials. The nonlinear Schrödinger equation describes weakly nonlinear and dispersive wave packets in physical systems, e.g., light pulses in optical fibers, surface waves in deep water, Langmuir waves in a plasma, and high-frequency vibrations in a crystal lattice. Equation (7) with an extra linear term $V(x)u$ to account for the external potential $V(x)$ also arises in the study of Bose-Einstein condensates, where it is referred to as the time-dependent Gross-Pitaevskii equation.

III.17 The Lambert W Function

Robert M. Corless and David J. Jeffrey

1 Definition and Basic Properties

For a given complex number z , the equation

$$w e^w = z$$

has a countably infinite number of solutions, which are denoted by $W_k(z)$ for integers k . Each choice of k specifies a *branch* of the Lambert W function. By convention, only the branches $k = 0$ (called the *principal* branch) and $k = -1$ are real-valued for any z ; the range of every other branch excludes the real axis, although the range of $W_1(z)$ includes $(-\infty, -1/e]$ in its closure. Only $W_0(z)$ contains positive values in its range (see figure 1). When $z = -1/e$ (the only nonzero branch point), there is a double root $w = -1$ of the basic equation $we^w = z$. The conventional choice of branches assigns

$$W_0(-1/e) = W_{-1}(-1/e) = -1$$

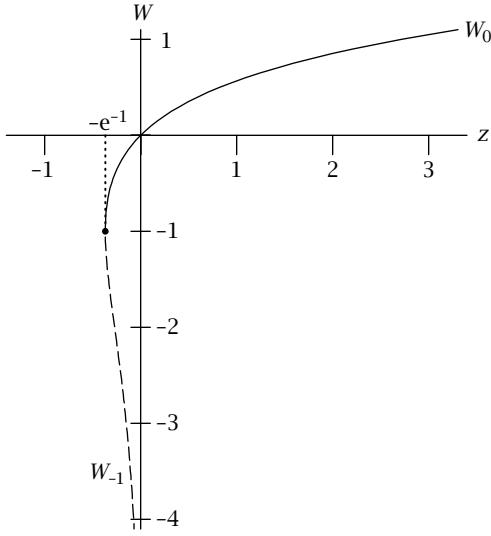

Figure 1 Real branches of the Lambert W function. The solid line is the principal branch W_0 ; the dashed line is W_{-1} , which is the only other branch that takes real values. The small filled circle at the branch point corresponds to the one in figure 2.

and implies that $W_1(-1/e - i\varepsilon^2) = -1 + O(\varepsilon)$ is arbitrarily close to -1 because the conventional branch choice means that the point -1 is on the border between these three branches. Each branch is a single-valued complex function, analytic away from the branch point and branch cuts.

The set of all branches is often referred to, loosely, as the Lambert W “function”; but of course W is multivalued. Depending on context, the symbol $W(z)$ can refer to the principal branch ($k = 0$) or to some unspecified branch. Numerical computation of any branch of W is typically carried out by Newton’s method or a variant thereof. Images of $W_k(re^{i\theta})$ for various k , r , and θ are shown in figure 2.

In contrast to more commonly encountered multi-branched functions, such as the inverse sine or cosine, the branches of W are not linearly related. However, by rephrasing things slightly, in terms of the *unwinding number*

$$\mathcal{K}(z) := \frac{z - \ln(e^z)}{2\pi i}$$

and the related *single-valued* function

$$\omega(z) := W_{\mathcal{K}(z)}(e^z),$$

which is called the *Wright ω function*, we do have the somewhat simple relationship between branches that $W_k(z) = \omega(\ln_k z)$, where $\ln_k z$ denotes $\ln z + 2\pi ik$ and

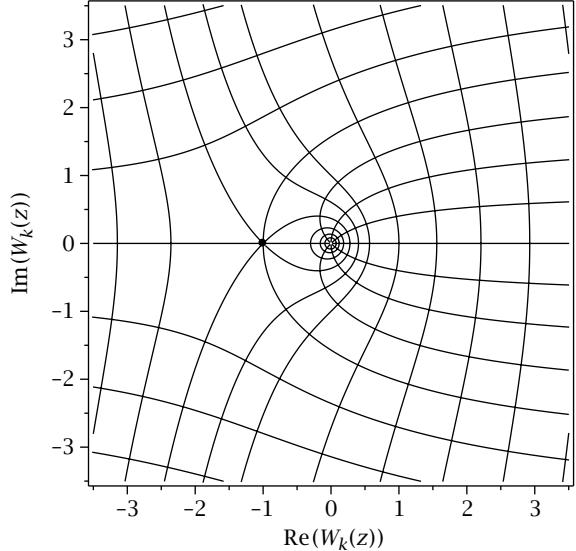

Figure 2 Images of circles and rays in the z -plane under the maps $z \rightarrow W_k(z)$. The circle with radius e^{-1} maps to a curve that goes through the branch point, as does the ray along the negative real axis. This graph was produced in Maple by numerical evaluation of $\omega(x + iy) = W_{\mathcal{K}(iy)}(e^{x+iy})$ first for a selection of fixed x and varying y , and then for a selection of fixed y and varying x . These two sets produce orthogonal curves as images of horizontal and vertical lines in x and y under ω or, equivalently, images of circles with constant $r = e^x$ and rays with constant $\theta = y$ under W .

$\ln z$ is the principal branch of the logarithm, having $-\pi < \text{Im}(\ln z) \leq \pi$.

The Wright ω function helps to solve the equation $y + \ln y = z$. We have that, if $z \neq t \pm i\pi$ for $t < -1$, then $y = \omega(z)$. If $z = t - i\pi$ for $t < -1$, then there is no solution to the equation; if $z = t + i\pi$ for $t < -1$, then there are two solutions: $\omega(z)$ and $\omega(z - 2\pi i)$.

1.1 Derivatives

Implicit differentiation yields

$$W'(z) = e^{-W(z)} / (1 + W(z))$$

as long as $W(z) \neq -1$. The derivative can be simplified to the *rational* differential equation

$$\frac{dW}{dz} = \frac{W}{z(1 + W)}$$

if, in addition, $z \neq 0$. Higher derivatives follow naturally.

1.2 Integrals

Integrals containing $W(x)$ can often be performed analytically by the change of variable $w = W(x)$, used in an inverse fashion: $x = we^w$. Thus,

$$\int \sin W(x) dx = \int (1+w)e^w \sin w dw,$$

and integration using usual methods gives

$$\frac{1}{2}(1+w)e^w \sin w - \frac{1}{2}we^w \cos w,$$

which eventually gives

$$\begin{aligned} \int 2 \sin W(x) dx &= \left(x + \frac{x}{W(x)} \right) \sin W(x) \\ &\quad - x \cos W(x) + C. \end{aligned}$$

More interestingly, there are many *definite* integrals for $W(z)$, including one for the principal branch that is due to Poisson and is listed in the famous table of integrals by D. Bierens de Haan. The following integral, which is of relatively recent construction and which is valid for z not in $(-\infty, -1/e]$, can be computed with spectral accuracy by the trapezoidal rule:

$$\frac{W(z)}{z} = \frac{1}{2\pi} \int_{-\pi}^{\pi} \frac{(1-v \cot v)^2 + v^2}{z + v \csc v e^{-v \cot v}} dv.$$

1.3 Series and Generating Functions

Euler was the first to notice, using a series due to Lambert, that what we now call the Lambert W function has a convergent series expansion around $z = 0$:

$$W(z) = \sum_{n \geq 1} \frac{(-n)^{n-1}}{n!} z^n.$$

Euler knew that this series converges for $-1/e \leq z \leq 1/e$. The nearest singularity is the branch point $z = -1/e$.

W can also be expanded in series about the branch point. The series at the branch point can be expressed most cleanly using the *tree function* $T(z) = -W(-z)$ rather than W or w , but keeping with W we have

$$W_0(-e^{-1-z^2/2}) = - \sum_{n \geq 0} (-1)^n a_n z^n,$$

$$W_{-1}(-e^{-1-z^2/2}) = - \sum_{n \geq 0} a_n z^n,$$

where the a_n are given by $a_0 = a_1 = 1$ and

$$a_n = \frac{1}{(n+1)a_1} \left(a_{n-1} - \sum_{k=2}^{n-1} k a_k a_{n+1-k} \right).$$

These give an interesting variation on STIRLING'S FORMULA [IV.7 §3] for the asymptotics of $n!$. Euler's integral

$$n! = \int_0^\infty t^n e^{-t} dt$$

is split at the maximum of the integrand ($t = n$), and each integral is transformed using the substitutions $t = -nW_k(-e^{-1-z^2/2})$, where $k = 0$ is used for $t \leq n$ and $k = -1$ otherwise. The integrands then simplify to $t^n e^{-t} = n^n e^{-n} e^{-nz^2/2}$ and the differentials dt are obtained as series from the above expansions. Term-by-term integration leads to

$$n! \sim \frac{n^{n+1}}{e^n} \sum_{k \geq 0} (2k+1) a_{2k+1} \left(\frac{2}{n} \right)^{k+1/2} \Gamma(k + \frac{1}{2}),$$

where Γ is the gamma function.

Asymptotic series for $z \rightarrow \infty$ have been known since de Bruijn's work in the 1960s. He also proved that the asymptotic series are actually convergent for large enough z . The series begin as follows: $W_k(z) \sim \ln_k(z) - \ln(\ln_k(z)) + o(\ln \ln_k z)$. Somewhat surprisingly, these series can be reversed to give a simple (though apparently useless) expansion for the logarithm in terms of compositions of W :

$$\begin{aligned} \ln z &= W(z) + W(W(z)) + W(W(W(z))) + \dots \\ &\quad + W^{(N)}(z) + \ln W^{(N)}(z) \end{aligned}$$

for a suitably restricted domain in z . The series obtained by omitting the term $\ln W^{(N)}(z)$ is not convergent as $N \rightarrow \infty$, but for fixed N if we let $z \rightarrow \infty$ the approximation improves, although only tediously slowly.

2 Applications

Because W is a so-called implicitly elementary function, meaning it is defined as an implicit solution of an equation containing only elementary functions, it can be considered an "answer" rather than a question. That it solves a simple rational differential equation means that it occurs in a wide range of mathematical models. Out of many applications, we mention just two favorites.

First, a serious application. W occurs in a chemical kinetics model of how the human eye adapts to darkness after exposure to bright light: a phenomenon known as bleaching. The model differential equation is

$$\frac{d}{dt} O_p(t) = \frac{K_m O_p(t)}{\tau(K_m + O_p(t))},$$

and its solution in terms of W is

$$O_p(t) = K_m W \left(\frac{B}{K_m} e^{B/K_m - t/\tau} \right),$$

where the constant B is the initial value of $O_p(0)$, that is, the amount of initial bleaching. The constants K_m and τ are determined by experiment. The solution

in terms of W enables more convenient analysis by allowing the use of known properties.

The second application we mention is nearly frivolous. W can be used to explore solutions of the so-called astrologer's equation, $\dot{y}(t) = ay(t+1)$. In this equation, the rate of change of y is supposed to be proportional to the value of y one time unit into the *future*. Dependence on past times instead leads to **DELAY DIFFERENTIAL EQUATIONS** [I.2 §12], which of course are of serious interest in applications, and again W is useful there in much the same way as for this frivolous problem.

Frivolity can be educational, however. Notice first that, if $e^{\lambda t}$ satisfies the equation, then $\lambda = ae^\lambda$, and therefore $\lambda = -W_k(-a)$. For the astrologer's equation, any function $y(t)$ that can be expressed as a *finite* linear combination $y(t) = \sum_{k \in M} c_k e^{-W_k(-a)t}$ for $0 \leq t \leq 1$ and some finite set M of integers then solves the astrologer's equation for all time. Thus, perfect knowledge of $y(t)$ on the time interval $0 \leq t \leq 1$ is sufficient to predict $y(t)$ for all time. However, if the knowledge of $y(t)$ is imperfect, even by an infinitesimal amount (omitting a single term $\varepsilon e^{-W_k(-a)t}$, say, where K is some large integer), then since the real parts of $-W_K(-a)$ go to infinity as $K \rightarrow \infty$ by the first two terms of the logarithmic series for W_k given above, the “true” value of $y(t)$ can depart arbitrarily rapidly from the prediction. This seems completely in accord with our intuitions about horoscopes.

Returning to serious applications, we note that the tree function $T(z)$ has huge combinatorial significance for all kinds of enumeration. Many instances can be found in Knuth's selected papers, for example. Additionally, a key reference to the tree function is a note by Borel in *Comptes Rendus de l'Académie des Sciences* (volume 214, 1942; reprinted in his *Oeuvres*). The generating function for probabilities of the time between periods when a queue is empty, given Poisson arrivals and service time σ , is $T(\sigma e^{-\sigma} z)/\sigma$.

3 Solution of Equations

Several equations containing algebraic quantities together with logarithms or exponentials can be manipulated into either the form $y + \ln y = z$ or $w e^w = z$, and hence solved in terms of the Lambert W function. However, it appears that not every exponential polynomial equation—or even most of them—can be solved in this way. We point out one equation, here, that starts with a nested exponential and can be solved in terms

of branch *differences* of W : a solution of

$$z + v \csc v e^{-v \cot v} = 0$$

is $v = (W_k(z) - W_\ell(z))/(2i)$ for some pair of integers k and ℓ ; moreover, every such pair generates a solution. This bi-infinite family of solutions has accumulation points of zeros near odd multiples of π , which in turn implies that the denominator in the above definite integral for $W(z)/z$ has essential singularities at $v = \pm\pi$. This example underlines the importance of the fact that the branches of W are not trivially related.

Another equation of popular interest occurs in the analysis of the limit of the recurrence relation

$$a_{n+1} = z^{a_n}$$

starting with, say, $a_0 = 1$. This sequence has $a_1 = z$, $a_2 = z^z$, $a_3 = z^{z^z}$, and so on. If this limit converges, it does so to a solution of the equation $a = z^a$. By inspection, the limit that is of interest is $a = -W(-\ln z)/\ln z$. Somewhat surprisingly, this recurrence relation—which defines the so-called tower of exponentials—diverges for small enough z , even if z is real. Specifically, the recurrence converges for $e^{-e} \leq z \leq e^{1/e}$ if z is real and diverges if $z < e^{-e} = 0.0659880\dots$. This fact was known to Euler. The detailed convergence properties for complex z were settled only relatively recently. Describing the regions in the complex plane where the recurrence relation converges to an n -cycle is made possible by a transformation that is itself related to W : if $\zeta = -W(-\ln z)$, then the iteration converges if $|\zeta| < 1$, and also if $\zeta = e^{i\theta}$ for θ equal to some *rational* multiple of π , say $m\pi/k$. Regions where the iteration converges to a k -cycle may touch the unit circle at those points.

4 Retrospective

The Lambert W function crept into the mathematics literature unobtrusively, and it now seems natural there. There is even a matrix version of it, although the solution of the matrix equation $S e^S = A$ is not always $W(A)$.

Hindsight can, as it so often does, identify the presence of W in writings by Euler, Poisson, and Wright and in many applications. Its implementation in Maple in the early 1980s was a key step in its eventual popularity.

Indeed, its recognition and naming supports Alfred North Whitehead's opinion that:

By relieving the brain of all unnecessary work, a good notation sets it free to concentrate on more advanced problems.

III.18 Laplace's Equation

P. A. Martin

In 1789, Pierre-Simon Laplace (1749–1827) wrote down an equation,

$$\frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} + \frac{\partial^2 V}{\partial z^2} = 0, \quad (1)$$

that now bears his name. Today, it is arguably the most important partial differential equation (PDE) in mathematics.

The left-hand side of (1) defines the *Laplacian* of V , denoted by $\nabla^2 V$ or ΔV :

$$\nabla^2 V = \Delta V = \nabla \cdot \nabla V = \operatorname{div} \operatorname{grad} V.$$

Laplace's equation, $\nabla^2 V = 0$, is classified as a linear homogeneous second-order elliptic PDE for $V(x, y, z)$. The inhomogeneous version, $\nabla^2 V = f$, where f is a given function, is known as *Poisson's equation*. The fact that there are three independent variables (x , y , and z) in (1) can be indicated by calling it the *three-dimensional Laplace equation*. The two-dimensional version,

$$\nabla^2 V \equiv \frac{\partial^2 V}{\partial x^2} + \frac{\partial^2 V}{\partial y^2} = 0, \quad (2)$$

also has important applications; it is a PDE for $V(x, y)$. There is a natural generalization to n independent variables. Usually, the number of terms in $\nabla^2 V$ is determined by the context.

1 Harmonic Functions

Solutions of Laplace's equation are known as *harmonic functions*. It is easy to see (one of Laplace's favorite phrases) that there are infinitely many different harmonic functions.

A short list of solutions, $V(x, y)$, for (2) follows:

- there are polynomial solutions, such as 1 , x , y , xy , and $x^2 - y^2$;
- there are solutions such as $e^{\alpha x} \cos \alpha y$ and $e^{\alpha x} \times \sin \alpha y$, where α is an arbitrary parameter; and
- $\log r$, θ , $r^\alpha \cos \alpha \theta$, and $r^\alpha \sin \alpha \theta$ are solutions, where $x = r \cos \theta$ and $y = r \sin \theta$ define plane polar coordinates, r and θ .

Further solutions can be found by differentiating or integrating any solution with respect to x or y ; for example, $(\partial/\partial x) \log r = x/r^2$ is harmonic. One can also differentiate or integrate with respect to any parameter; for example,

$$\int_{\alpha_1}^{\alpha_2} g(\alpha) e^{\alpha x} \sin \alpha y \, d\alpha$$

is harmonic, where $g(\alpha)$ is an arbitrary (integrable) function of the parameter α and the integration could be over the real interval $\alpha_1 < \alpha < \alpha_2$ or along a contour in the complex α -plane.

A list of solutions, $V(x, y, z)$, for (1) follows:

- any solution of (2) also solves (1);
- there are polynomial solutions, such as xyz and $x^2 + y^2 - 2z^2$;
- there are solutions such as $e^{yz} \cos \alpha x \cos \beta y$, where $y^2 = \alpha^2 + \beta^2$ and α and β are arbitrary parameters;
- $e^{\alpha z} J_n(\alpha r) \cos n\theta$ is a solution, where $x = r \cos \theta$, $y = r \sin \theta$, and J_n is a Bessel function; and
- R^{-1} is a solution, where $R = (x^2 + y^2 + z^2)^{-1/2}$ is a spherical polar coordinate.

Again, further solutions can be obtained by differentiating or integrating any solution with respect to x , y , z , or any parameter. For example, if i , j , and k are any nonnegative integers,

$$V(x, y, z) = \frac{\partial^{i+j+k}}{\partial x^i \partial y^j \partial z^k} \frac{1}{R}$$

is harmonic; it is known as a *Maxwell multipole*.

As Laplace's equation is linear and homogeneous, more solutions can be constructed by superposition; if V_1 and V_2 satisfy $\nabla^2 V = 0$, then so does $AV_1 + BV_2$, where A and B are arbitrary constants.

2 Boundary-Value Problems

Although Laplace's equation has many solutions, it is usual to seek solutions that also satisfy boundary conditions. A basic problem is to solve $\nabla^2 V = 0$ inside a

bounded region D subject to $V = g$ (a given function) on the boundary of D , ∂D . This boundary-value problem (BVP) is known as the *interior Dirichlet problem*. Under certain mild conditions, this problem has exactly one solution. This solution can be constructed explicitly (by the method of separation of variables) when D has a simple shape, such as a circular disk or a rectangle in two dimensions, and a ball or a cube in three dimensions. For more complicated geometries, progress can be made by reducing the BVP to a boundary integral equation around ∂D , or by solving the BVP numerically, using finite elements, for example.

Other BVPs can be formulated. For example, instead of specifying V on ∂D , the normal derivative of V , $\partial V / \partial n$, could be given (this is the *interior Neumann problem*). One could specify a linear combination of V and $\partial V / \partial n$ at each point on ∂D , or one could specify V on part of ∂D and $\partial V / \partial n$ on the rest of ∂D (this is the *mixed problem*). One could specify both V and $\partial V / \partial n$ on part of ∂D but give no information on the rest of ∂D ; this is called the *Cauchy problem*. There are also exterior versions of all these problems, where the goal is to solve $\nabla^2 V = 0$ in the unbounded region outside ∂D ; for such problems, one also has to specify the behavior of V “at infinity,” far from ∂D .

3 Applications

Laplace's 1789 application of (1) was to gravitational attraction and the rings of Saturn. Gravitational forces can be written as $\mathbf{F} = \text{grad } V$, where $\nabla^2 V = 0$ outside regions containing matter. In general, vector fields that can be written as the gradient of a scalar are called *conservative*; the scalar, V , is called a *potential*. Equivalently, conservative fields \mathbf{F} satisfy $\text{curl } \mathbf{F} = \mathbf{0}$: they are *irrotational*.

The velocity \mathbf{v} for the motion of an incompressible (constant-density) fluid satisfies the *continuity equation*, $\text{div } \mathbf{v} = 0$. If the motion is irrotational, then there exists a *velocity potential* ϕ such that $\mathbf{v} = \text{grad } \phi$. The continuity equation then shows that $\nabla^2 \phi = 0$.

Similar equations are encountered in electrostatics and magnetostatics. For example, in empty space, the electric field, \mathbf{E} , satisfies $\text{div } \mathbf{E} = 0$ and $\text{curl } \mathbf{E} = \mathbf{0}$. Thus, we can write $\mathbf{E} = \text{grad } \varphi$, where the potential φ solves $\nabla^2 \varphi = 0$.

4 Analytic Function Theory

In this section we use $z = x + iy$ to denote a complex variable. Let $f(z) = u(x, y) + iv(x, y)$ be a function

of z . If f is analytic (that is, a differentiable function of z), u and v satisfy the *Cauchy-Riemann equations*:

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}.$$

Eliminating v between these equations shows that $u(x, y)$ satisfies the two-dimensional Laplace equation, (2); $v(x, y)$ solves the same PDE. The real and imaginary parts of an analytic function are said to be *harmonic*.

This connection between functions of a complex variable and two-dimensional harmonic functions leads to powerful methods for solving BVPs for (2), especially when CONFORMAL MAPPINGS [II.5] are employed.

5 Generalizations

The Laplacian occurs in PDEs other than Laplace's equation. Here are a few examples:

$$\begin{aligned} \nabla^2 u &= c^{-2}(\partial^2 u / \partial t^2), && \text{the wave equation,} \\ \nabla^2 u &= k^{-1}(\partial u / \partial t), && \text{the heat/diffusion equation,} \\ \nabla^2 u + k^2 u &= 0, && \text{the Helmholtz equation,} \\ \nabla^2 u + i\ell(\partial u / \partial t) &= Wu, && \text{the Schrödinger equation.} \end{aligned}$$

In these equations, c , k , ℓ , and W are given (the first three are often constants) and t is time. One reason that ∇^2 occurs frequently is that space is often assumed to be isotropic, meaning that there is no preferred direction. Thus, in (1), x , y , and z are Cartesian coordinates, but the value of $\nabla^2 V$ does not change if the coordinates are rotated or translated. The Laplacian is the simplest linear second-order operator with this property.

There is an anisotropic version of $\nabla^2 u$, namely, $\text{div}(A \text{grad } u)$, where A is an $n \times n$ matrix with entries that could be constants or functions of the n independent variables. If A depends on u , a nonlinear operator is obtained. Another well-studied nonlinear variant is the p -Laplacian, defined by $\text{div}(|\text{grad } u|^{p-2} \text{grad } u)$ with $1 < p < \infty$.

A useful fourth-order operator is $\nabla^2 \nabla^2 = \nabla^4$. The *biharmonic equation*, $\nabla^4 u = 0$, arises in the theory of thin elastic plates, for example.

III.19 The Logistic Equation

Paul Glendinning

The *logistic equation* is a simple differential equation or difference equation with quadratic nonlinearity. It arises naturally in POPULATION MODELS [I.5 §3] (for

example) as a model of a process with population-limited growth, i.e., models that include the inhibitory effects of overcrowding.

The continuous-time version is a differential equation for a real variable x that represents the size of a population. It is

$$\frac{dx}{dt} = rx \left(1 - \frac{x}{K}\right), \quad r, K > 0,$$

although there are higher-dimensional analogues and extensions to partial differential equations. The application to population dynamics means that it is usual to assume that $x(0) = x_0 > 0$. The two parameters are the reproduction rate $r > 0$ (the difference between the birth rate and the death rate), and the carrying capacity K , which, as shown below, is the equilibrium population level.

The logistic equation is separable and solutions may be calculated explicitly using partial fractions (see ORDINARY DIFFERENTIAL EQUATIONS [IV.2 §2]). The solution is

$$x(t) = \frac{x_0 K}{x_0 + (K - x_0)e^{-rt}},$$

so all solutions with $x_0 > 0$ tend to the carrying capacity, K , as t tends to ∞ .

The right-hand side of the logistic equation can be interpreted as the first two terms of the Taylor series expansion of a function f with $f(0) = 0$, so the equation is a natural model in many other contexts.

The discrete-time version of the logistic equation is often called the *logistic map*. It is

$$x_{n+1} = \mu x_n (1 - x_n), \quad \mu > 0.$$

This difference equation is one of the paradigmatic examples of systems with chaotic attractors. One early interpretation is again from population biology: the equation may describe the successive population levels of an organism that has discrete generations, so x_n is the normalized number of insects (for example) in the n th generation, and this depends on the population size of the previous generation.

The logistic map illustrates the different dynamics that can exist in general unimodal, or one-hump, maps. If $0 < \mu \leq 4$ then all solutions that start in $[0, 1]$ stay in that interval, so there is (at least) one bounded attractor of the system. The way this attractor varies with μ can be very complicated.

If $\mu \in (0, 1)$ then the origin is a stable fixed point (if $x_0 = 0$ then $x_n = 0$ for all $n \in \mathbb{N}$), and for all initial conditions $x_0 \in [0, 1]$, $x_n \rightarrow 0$ as $n \rightarrow \infty$. If $\mu \in (1, 3)$ then there is a stable nontrivial fixed point ($\mu - 1$)/ μ

that attracts all initial conditions in $(0, 1)$. At $\mu = 3$ this fixed point undergoes a PERIOD-DOUBLING BIFURCATION [IV.21]. The effect of this bifurcation is to create a stable period-two orbit as μ increases through 3 and the fixed point becomes unstable. As μ increases further there is a sequence of period-doubling bifurcations at parameter values μ_n at which orbits of period 2^n lose stability, and a stable periodic orbit of period 2^{n+1} is created.

These bifurcation values accumulate geometrically at a special value μ_∞ , above which there are infinitely many periodic orbits in the system and the system is CHAOTIC [II.3], although the chaotic set may not be attracting. In this chaotic region of parameters there are “windows” (i.e., intervals of the parameter) for which the attracting behavior is again periodic. These orbits then lose stability, undergoing their own period-doubling sequences and having a similar bifurcation structure to the original map, but over a smaller parameter interval.

There are many interesting results about the dynamics in the chaotic region. For example, the set of parameters for which the map has a chaotic attractor has positive measure; and between any two parameters with chaotic attractors there are parameters with stable periodic behavior.

The order in which periodic orbits are created satisfies Sharkovskii’s theorem (valid for any continuous map of the interval). Sharkovskii’s theorem defines an order on the natural numbers that reflects the order in which different periods appear in families of maps. The Sharkovskii order, \prec , is a complete order on the positive integers, so for any positive integers p and q with $p \neq q$, either $p \prec q$ or $q \prec p$. The order is defined by the list below. To interpret this list, imagine you have two positive integers and think about where each one appears in the list (they must both appear somewhere!). If p appears before q , then $p \prec q$. The list is

$$\begin{aligned} 1 &\prec 2 \prec 2^2 \prec 2^3 \prec \dots \\ &\dots \\ &\dots \prec 2^{n+1} \times 9 \prec 2^{n+1} \times 7 \prec 2^{n+1} \times 5 \prec 2^{n+1} \times 3 \\ &\dots \prec 2^n \times 9 \prec 2^n \times 7 \prec 2^n \times 5 \prec 2^n \times 3 \\ &\dots \\ &\dots \prec 9 \prec 7 \prec 5 \prec 3, \end{aligned}$$

i.e., powers of two ascending, then for each n , 2^n times the odds descending, with n descending to zero. Sharkovskii’s theorem states that, if a continuous map

of the interval has an orbit of period p , then it also has orbits of period q for all $q < p$ in this order.

The logistic equation has different orbits of the same period that can be described by labeling the periodic points $x_1 < x_2 < \dots < x_p$ with $f(x_i) = x_{\pi(i)}$ for some permutation π of $\{1, \dots, p\}$. Sharkovskii's theorem does not distinguish between orbits with the same period and different permutation type. It turns out that the period and associated permutation type define a complete order on the periodic orbits arising in the logistic equation.

III.20 The Lorenz Equations

Paul Glendinning

The Lorenz equations provided one of the earliest examples of a nonlinear differential equation with chaotic behavior. They were derived in the early 1960s when the growing use and power of computers raised the exciting prospect of greatly improved weather forecasts, and particularly more reliable long-range forecasts. This generated work on improving the numerical techniques applied to meteorological models, and it also led to the study of simplified models and their properties. Saltzman used a crude truncation of the Fourier expansion of solutions to convert the partial differential equations describing convection in a horizontal layer into a finite set of coupled ordinary differential equations that are significantly easier to solve numerically. Saltzman concentrated on a fifty-two-mode truncation, but in an article published the next year (1963), Ed Lorenz took the model to its oversimplified extreme, retaining just three of the Galerkin modes.

Lorenz's model is normally written as a set of coupled differential equations in three variables, now known as the Lorenz equations:

$$\begin{aligned}\dot{x} &= \sigma(y - x), \\ \dot{y} &= rx - y - xz, \\ \dot{z} &= -bz + xy,\end{aligned}$$

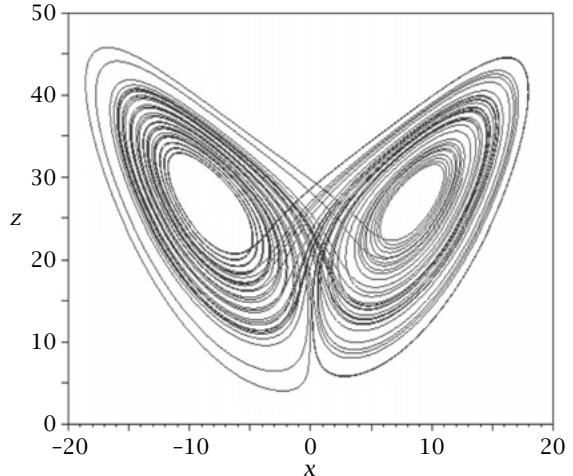

Figure 1 The Lorenz attractor projected onto the (x, z) coordinates.

where the dot denotes differentiation with respect to the independent variable t , and where σ is a normalized Prandtl number, r a normalized Rayleigh number, and b the aspect ratio of the convecting cell. The parameters used by Lorenz were

$$\sigma = 10, \quad r = 28, \quad b = \frac{8}{3}.$$

The insight derived through the investigation of these equations has motivated a greater understanding of the mathematics of CHAOS [II.3] and has had a major impact on the way weather forecasts are created and reported. A sample trajectory of the Lorenz equations at the parameter values given above is shown in figure 1. The solution clearly settles down to a bounded attracting set (the *Lorenz attractor*), but it appears not to be periodic. Moreover, solutions that start close together eventually diverge and behave completely differently, a property now called *sensitive dependence on initial conditions*, which is one of the hallmarks of chaos. (A little care is needed here. Sensitive dependence on initial conditions as usually defined in the twentieth century is *not* a good definition of chaos; some exponential divergence in time is necessary in more modern definitions (see CHAOS AND ERGODICITY [II.3].) The story goes that Lorenz discovered this phenomenon by a fortuitous mistyping of an initial condition when checking a modification of his computer code. Lorenz's genius was to recognize this as a significant property of the solutions.

The Lorenz attractor motivated several developments in bifurcation theory and chaos. In the late 1970s

mathematicians developed a simple geometric model of the flow that could be reduced to the analysis of a one-dimensional map with a discontinuity that could be proved to be chaotic. At the same time, researchers started to describe the development of the attractor as a function of the parameter r , showing that the solutions in the strange attractor are created as an initially unstable set by a GLOBAL BIFURCATION [IV.21]. Sparrow brought all these results together, giving a description of the bifurcations of the Lorenz attractor as r is changed, using a mixture of numerical simulations, mathematical proofs, and conjectured links between the two.

Sparrow's work provides strong evidence for the following description of the changes in the attractors of the Lorenz equations as r increases. The origin, which is a globally attracting stationary point if $0 < r < 1$, loses stability as r increases through 1 via a pitchfork bifurcation that creates a stable symmetric pair of stationary points corresponding to convective rolls (see BIFURCATION THEORY [IV.21 §2] for a description of different types of bifurcation). At $r = r_H \approx 24.74$ there is a pair of subcritical Hopf bifurcations. The effect of this bifurcation is that the stationary points lose stability as r increases through r_H , and a pair of unstable periodic orbits are created in $r < r_H$. Where did these orbits come from? Yorke and coworkers had shown in 1979 that the answer lies in a homoclinic bifurcation at $r \approx 13.926$. This creates an unstable chaotic set containing infinitely many unstable periodic orbits, many of which are destroyed in bifurcations before the chaotic set becomes attracting by a mechanism involving the two simple periodic orbits that are the orbits involved in the Hopf bifurcation at $r \approx 24.06$. There is therefore a brief interval of r values for which a complicated attractor coexists with the stable stationary points, and if r is a little greater than r_H , the only attractor is the chaotic set. This is initially similar to the geometric model, but it develops contracting regions ("hooks") as r increases further, which allows for the possibility of the creation of stable periodic orbits. At very large r the only attractor is a simple symmetric periodic orbit, so a sequence of bifurcations destroying the orbits of the chaotic set needs to occur.

Despite a host of theoretical results on the geometric models and on the bifurcations in systems such as the Lorenz equations, a proof that the Lorenz equations at the standard parameter values really do have a strange attractor remained open until 2002, when Tucker used a combination of rigorous numerically

computed bounds and mathematical analysis to show that the attractor has the chaotic properties required (see DYNAMICAL SYSTEMS [IV.20 §4.5] for more details).

While the mathematical issues were being resolved, questions about the physical relevance of the Lorenz equations continued to cause controversy. As more and more of the ignored modes of Saltzman's truncated model are added back into the equations, the chaotic region exists for larger and larger values of r and is no longer present in the full partial differential equations. More imaginative physical situations, such as convection in a rotating hoop, have been devised, and for these the Lorenz equations are a good model.

Even though it is not an accurate model of convection in a fluid layer, the physical insight Lorenz brought to the problem of weather forecasting was hugely influential. As a result of the recognition that sensitive dependence on initial conditions can be a problem, forecasters now routinely run computer simulations of their models with a variety of initial conditions so that when it is appropriate they can comment on the probability of rain rather than issue a simple statement that it will or will not rain. The understanding of how chaos can be accommodated in nonlinear prediction has also influenced the way in which sophisticated models of the climate and other nonlinear phenomena are interpreted.

III.21 Mathieu Functions

Julio C. Gutiérrez-Vega

Mathieu functions are solutions of the *ordinary Mathieu equation*

$$\frac{d^2y}{d\theta^2} + (a - 2q \cos 2\theta)y = 0, \quad (1)$$

where q is a free parameter and a is the eigenvalue of the equation. Mathieu's equation was first studied by

Émile Mathieu in 1868 in the context of the vibrational modes of an elliptic membrane.

For arbitrary parameters (a, q) , (1) is a linear second-order differential equation with two independent solutions. In general, these solutions are not periodic functions and their behavior depends on the initial conditions $y(0)$ and $y'(0)$. Of particular interest are the periodic solutions with period π or 2π . In this case, according to Sturm-Liouville theory, there exists a countably infinite set of characteristic eigenvalues $a_m(q)$ that yield even periodic solutions of (1), and another set of characteristic eigenvalues $b_m(q)$ that yield odd periodic solutions of (1). The eigenfunctions associated with these sets of eigenvalues are known as the even and odd *Mathieu functions*:

$$\gamma_m = \begin{cases} \text{ce}_m(\theta; q), & m = 0, 1, 2, \dots, \\ \text{se}_m(\theta; q), & m = 1, 2, 3, \dots, \end{cases}$$

where m is the order. The notation ce and se comes from *cosine-elliptic* and *sine-elliptic*, and it is now a widely accepted notation for the periodic Mathieu functions.

Mathieu functions occur in two main categories of physical problems. First, they appear in applications involving the separation of the wave equation in elliptic coordinates, e.g., the vibrating modes in elliptic membranes, the propagating modes in elliptic pipes, or the oscillations of water in a lake of elliptic shape. Second, they occur in phenomena that involve periodic motion, e.g., the trajectory of an electron in a periodic array of atoms, the mechanics of the quantum pendulum, or the oscillations of floating vessels.

The behavior of Mathieu functions is rather complicated, and their analysis is difficult using standard methods, mainly due to their nontrivial dependence on the parameters (a, q) . In figure 1 we plot the functions $\text{ce}_m(\theta; q)$ and $\text{se}_m(\theta; q)$ for several values of m over the plane (θ, q) . Note that Mathieu's equation becomes the harmonic equation when $q \rightarrow 0$. Evidently, ce_m and se_m converge to the trigonometric functions $\cos(m\theta)$ and $\sin(m\theta)$ as q tends to zero.

The parity, periodicity, and normalization of the periodic Mathieu functions are exactly the same as for their trigonometric counterparts. That is, ce_m is even and se_m is odd, and they have period π when m is even or period 2π when m is odd. The Mathieu functions have m real zeros in the open interval $\theta \in (0, \pi)$, and the zeros cluster around $\pi/2$ as q increases. Because the Mathieu equation is of Sturm-Liouville type, the Mathieu functions form a complete family of orthogonal

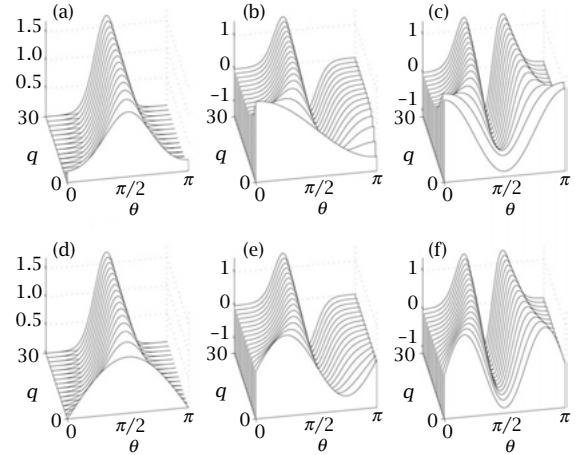

Figure 1 The behavior of Mathieu functions over the plane (θ, q) . The range of the plots has been limited to $[0, \pi]$, since their behavior over the entire range can be deduced from the parity and symmetry relations. (a) $\text{ce}_0(\theta; q)$. (b) $\text{ce}_1(\theta; q)$. (c) $\text{ce}_2(\theta; q)$. (d) $\text{se}_1(\theta; q)$. (e) $\text{se}_2(\theta; q)$. (f) $\text{se}_3(\theta; q)$.

functions whose normalization conditions are

$$\int_0^{2\pi} \text{ce}_m \text{ce}_n d\theta = \int_0^{2\pi} \text{se}_m \text{se}_n d\theta = \pi \delta_{m,n}. \quad (2)$$

If a function $f(\theta)$ is periodic with period π or 2π , then it can be expanded as a series of orthogonal Mathieu functions.

III.22 Maxwell's Equations

Mark R. Dennis

In the early 1860s James Clerk Maxwell wrote down a set of equations summarizing the spatial and temporal behavior of electric and magnetic fields; these equations are the foundation of the physical theory of *electromagnetism*. In modern notation they are usually written as first-order vector differential equations depending on time t and three-dimensional position \mathbf{r} . With ∇ denoting the gradient operator and a dot above a quantity denoting its time derivative, Maxwell's

equations are usually written

$$\nabla \cdot \mathbf{B} = 0, \quad (1)$$

$$\nabla \times \mathbf{E} + \dot{\mathbf{B}} = 0, \quad (2)$$

$$\nabla \cdot \mathbf{D} = \rho, \quad (3)$$

$$\nabla \times \mathbf{H} - \dot{\mathbf{D}} = \mathbf{J}. \quad (4)$$

The various electromagnetic fields are called the *electric field* \mathbf{E} , the *electric displacement* \mathbf{D} , the *magnetic induction* \mathbf{B} , and the *magnetic field* \mathbf{H} . \mathbf{E} and \mathbf{B} are usually viewed as more fundamental, and \mathbf{D} and \mathbf{H} can often be expressed as functions of them. Equations (3) and (4) are inhomogeneous and depend on sources determined by the scalar electric *charge density* ρ and vector *current density* \mathbf{J} . Equations (1)–(4) may also be expressed in integral form, in terms of surface and volume integrals. Conventionally, they are referred to as Gauss's law (3), Gauss's law for magnetism (1) (also sometimes referred to as "no magnetic monopoles"), Faraday's law (2), and the Maxwell–Ampère law (4).

All electromagnetic phenomena are described by Maxwell's equations, including the behavior of electricity and electronic circuits, motors and dynamos, light and optics, wireless communication, microwaves, etc. The phenomena they describe are ubiquitous in the modern world, and much of the machinery of applied mathematics, such as partial differential equations, Green functions, DELTA FUNCTIONS [III.7], and vector calculus were introduced in part to describe electromagnetic situations. Maxwell's equations take on various special forms depending on the system being considered. For instance, when the fields are static (i.e., when time derivatives are zero), the electric field around charges resembles the gravitational field around masses determined by Newton's law.

In *free space*, all sources are zero, and $\mathbf{D} = \epsilon_0 \mathbf{E}$, $\mathbf{H} = \mu_0^{-1} \mathbf{B}$, with constants the *permittivity of free space* $\epsilon_0 = 8.85 \times 10^{-12} \text{ F m}^{-1}$ and the *permeability of free space* $\mu_0 = 4\pi \times 10^{-7} \text{ N A}^{-2}$, given in conventional SI units, originally determined experimentally using electrical currents, charges, and magnets. Written like this, Maxwell's equations are symmetric in form between \mathbf{E} and \mathbf{B} (with the exception of a minus sign), and can be combined to give the d'Alembert equation for \mathbf{E} and \mathbf{B} , propagating at speed $c = (\epsilon_0 \mu_0)^{-1/2} = 2.998 \times 10^8 \text{ m s}^{-1}$. Maxwell himself originally noticed this fact, realizing that c was close to the experimentally measured speed of light and therefore that light itself is an electromagnetic wave. *Plane-wave solutions* of Maxwell's equations in free space are $\mathbf{E}_0 \cos(\mathbf{k} \cdot \mathbf{r} - \omega t)$

$\mathbf{B}_0 = \cos(\mathbf{k} \cdot \mathbf{r} - \omega t)$, where $\mathbf{E}_0, \mathbf{B}_0$ are constant *polarization vectors* that form a right-handed orthogonal triple $(\mathbf{E}_0, \mathbf{B}_0, \mathbf{k})$ with the wave vector \mathbf{k} , and $c = \omega/|\mathbf{k}|$, with ω the angular frequency. Free-space solutions of Maxwell's equations are studied systematically in the field of OPTICS AND PHOTONICS [V.14].

Many naturally occurring materials without free charges (*dielectric materials*) are *linear*: \mathbf{D} and \mathbf{H} are linear functions of \mathbf{E} and \mathbf{B} , but with different permittivities and permeabilities (possibly in different directions). The relative speed of electromagnetic wave propagation with respect to c in these materials is called the *refractive index*. Laws of refraction, reflection, and transmission can all in principle be derived by applying Maxwell's equations to the interface region between materials. Other materials can have more complicated dependence between the various field quantities and sources. Some of the simplest nonlinear phenomena occur in materials where \mathbf{D} depends quadratically on \mathbf{E} .

The homogeneity of (1) and (2) suggests that \mathbf{E} and \mathbf{B} may themselves be expressed as derivatives of the *scalar potential* V and the *vector potential* \mathbf{A} , via

$$\mathbf{B} = \nabla \times \mathbf{A}, \quad \mathbf{E} = -\nabla V - \dot{\mathbf{A}}. \quad (5)$$

In terms of these potentials, (1) and (2) are automatically satisfied, and (3) and (4) become second-order differential equations in V and \mathbf{A} . As only their derivatives are defined by the electromagnetic fields, the absolute values of V and \mathbf{A} are somewhat arbitrary, and choices of potential field may be changed by a *gauge transformation* that preserves the derivative relations in (5), $\mathbf{A} \rightarrow \mathbf{A}' = \mathbf{A} + \nabla \chi$, $V \rightarrow V' = V - \dot{\chi}$, for some sufficiently differentiable scalar field χ . It is often convenient to simplify (1) and (2) by reexpressing them in terms of the potentials and then choosing a restriction on the gauge transformations to be considered (known as *fixing the gauge*), by requiring the potential fields to satisfy some extra equation compatible with (5), such as $\nabla \cdot \mathbf{A} = 0$ (the Coulomb gauge) or $\nabla \cdot \mathbf{A} + c^{-2} \dot{V} = 0$ (the Lorenz gauge).

Maxwell's equations describe how electric and magnetic fields depend spatially and temporally on electric charges and their motion. They do not, however, describe directly how the motion of charges depends on fields; the force \mathbf{F} on a particle of electric charge q at position \mathbf{r} due to electromagnetic fields is given by the *Lorentz force law*

$$\mathbf{F} = q(\mathbf{E} + \dot{\mathbf{r}} \times \mathbf{B}). \quad (6)$$

The combined theory of electromagnetic fields, charged matter, and their mutual dependence is called *electrodynamics*.

A particularly interesting aspect of Maxwell's equations from the physical point of view is that they appear to apply equally well at many different length scales, from the astronomical (used to understand electromagnetic radiation in the cosmos) down to the microscopic (and even interactions at the scale of subatomic particles). Inside materials, at the atomic level, electrons and nuclei are separated by free space, and only the fundamental fields \mathbf{E} and \mathbf{B} play a role. In situations where length scales are longer, the electric displacement \mathbf{D} and magnetic field \mathbf{H} arise through HOMOGENIZATION [IV.6 §13.3] of length scales. Maxwell's equations can also be made compatible with the laws of QUANTUM MECHANICS [IV.23], both in treatments with the field as classical and in treatments in which the electromagnetic fields themselves are quantized, with their energy quanta $\hbar\omega$ referred to as *photons*, where \hbar is Planck's constant. The combined quantum theory of charged matter and electromagnetic fields is *quantum electrodynamics*. Gauge transformations take on an important role and a new physical interpretation in quantum theory.

Unlike Newton's equations in CLASSICAL MECHANICS [IV.19], Maxwell's equations are not invariant with respect to Galilean coordinate transformations. Historically, this provided Einstein with the main motivation for the theory of special relativity, as providing the appropriate set of transformations keeping Maxwell's equations covariant. Maxwell's equations in free space can thus be expressed in 4-vector notation (which is explained in TENSORS AND MANIFOLDS [II.33]), in which the electromagnetic field is specified by an antisymmetric rank-2 tensor, the *Faraday tensor*:

$$F^{ab} = \begin{pmatrix} 0 & -E_x/c & -E_y/c & -E_z/c \\ E_x/c & 0 & -B_z & B_y \\ E_y/c & B_z & 0 & -B_x \\ E_z/c & -B_y & B_x & 0 \end{pmatrix}.$$

Reexpressed in tensor form, Maxwell's equations are

$$\partial_a F_{bc} + \partial_b F_{ca} + \partial_c F_{ab} = 0,$$

$$\partial_a F^{ab} = \mu_0 J^b,$$

with the first equation corresponding to (1) and (2), and the second to (3) and (4), with the current 4-vector $J^b = (c\rho, J_x, J_y, J_z)$. These equations transform covariantly under Lorentz transformations. The Lorentz law

(6) can also be relativistically generalized to the equation for a force 4-vector $f^a = qF^{ab}u_b$, acting on a particle with velocity 4-vector u^b . These equations can be further generalized to fields in curved space-time, in which they play a role in GENERAL RELATIVITY AND COSMOLOGY [IV.40].

III.23 The Navier-Stokes Equations

H. K. Moffatt

The Navier-Stokes equations are the partial differential equations that govern the flow of a fluid (a liquid or a gas) that is regarded as a continuum; that is to say, a medium whose density field $\rho(\mathbf{x}, t)$ and (vector) velocity field $\mathbf{u}(\mathbf{x}, t)$ may be considered to be smooth functions of position $\mathbf{x} = (x, y, z)$ and time t . These equations express in mathematical form the physical principles of conservation of mass and balance of momentum for each small element (or *parcel*) of fluid in the course of its motion.

1 The Mass-Conservation Equation

This equation relates $\rho(\mathbf{x}, t)$ and $\mathbf{u}(\mathbf{x}, t)$ in a very simple way:

$$\frac{D\rho}{Dt} \equiv \frac{\partial\rho}{\partial t} + \mathbf{u} \cdot \nabla\rho = -\rho\nabla \cdot \mathbf{u}.$$

Here, the symbol ∇ represents the vector differential operator $(\partial/\partial x, \partial/\partial y, \partial/\partial z)$. The operator $D/Dt \equiv \partial/\partial t + \mathbf{u} \cdot \nabla$ is the *Lagrangian* derivative (or “derivative following the fluid”); this consists of two parts, the local time derivative $\partial/\partial t$ and the *convective* derivative $\mathbf{u} \cdot \nabla$. The equation indicates that the density of a fluid element decreases or increases according to whether the local divergence $\nabla \cdot \mathbf{u}$ is positive or negative, respectively.

An important subclass of flows is described as *incompressible*. For these, the density of any element of fluid is constant: $D\rho/Dt = 0$, and so, from the above, $\nabla \cdot \mathbf{u} = 0$. Attention is focused on incompressible flows in the following section.

2 The Momentum Equation

This equation represents the fundamental Newtonian balance

$$\text{mass} \times \text{acceleration} = \text{force}$$

for each fluid element. Of course, density is just mass per unit volume, and the (Lagrangian) acceleration of a fluid element is $D\mathbf{u}/Dt \equiv (\partial/\partial t + \mathbf{u} \cdot \nabla)\mathbf{u}$. The left-hand side of the following *momentum equation* should therefore come as no surprise:

$$\rho \left(\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} \right) = -\nabla p + \mu \nabla^2 \mathbf{u} + \mathbf{f}.$$

The right-hand side contains three terms that represent the forces that may act on a fluid element. The term $-\nabla p$ represents (minus) the gradient of the local fluid pressure $p(\mathbf{x}, t)$; the second term, $\mu \nabla^2 \mathbf{u}$, represents the net force associated with *viscosity* $\mu (> 0)$ (i.e., internal friction); and the third term, $\mathbf{f}(\mathbf{x}, t)$, represents any *external* force per unit mass acting on the fluid. The most common force of this kind is that associated with gravity, \mathbf{g} , i.e., $\mathbf{f} = \rho \mathbf{g}$. This is by no means the only possibility; for example, in an electrically conducting fluid in which a current density \mathbf{j} flows across a magnetic field \mathbf{B} , the force per unit mass is the Lorentz force given by the vector product $\mathbf{f} = \mathbf{j} \times \mathbf{B}$.

It might appear from the above that a further equation is needed to determine the pressure distribution $p(\mathbf{x}, t)$. However, this equation is already implied by the above; it may be obtained by taking the divergence of the momentum equation to give a Poisson equation for p . In the simplest case of incompressible flow of constant density ρ_0 , this Poisson equation takes the form

$$\nabla^2 p = -\rho_0 \nabla \cdot (\mathbf{u} \cdot \nabla) \mathbf{u} = -\rho_0 \frac{\partial u_i}{\partial x_j} \frac{\partial u_j}{\partial x_i},$$

using suffix notation and the summation convention (and, from incompressibility, $\partial u_i / \partial x_i = 0$).

In the inviscid limit ($\mu = 0$), the above equations were derived in 1758 by Euler, and they are known as the (incompressible) EULER EQUATIONS [III.11]. The viscous equations (with $\mu > 0$) are named after Claude-Louis Navier, who obtained them in 1822 assuming a particular “atomic” model to take account of internal friction, and George Gabriel Stokes, who in 1845 developed the more general continuum treatment that is still normally used today. A full derivation of these Navier-Stokes equations may be found in Batchelor’s *An Introduction to Fluid Dynamics*.

III.24 The Painlevé Equations

Peter A. Clarkson

The six nonlinear second-order ordinary differential equations that follow are called the Painlevé equations:

$$\begin{aligned} w'' &= 6w^2 + z, \\ w'' &= 2w^3 + zw + \alpha, \\ w'' &= \frac{(w')^2}{w} - \frac{w'}{z} + \frac{\alpha w^2 + \beta}{z} + \gamma w^3 + \frac{\delta}{w}, \\ w'' &= \frac{(w')^2}{2w} + \frac{3}{2}w^3 + 4zw^2 + 2(z^2 - \alpha)w + \frac{\beta}{w}, \\ w'' &= \left(\frac{1}{2w} + \frac{1}{w-1} \right)(w')^2 - \frac{w'}{z} \\ &\quad + \frac{(w-1)^2}{z^2} \left(\alpha w + \frac{\beta}{w} \right) + \frac{\gamma w}{z} + \frac{\delta w(w+1)}{w-1}, \\ w'' &= \frac{1}{2} \left(\frac{1}{w} + \frac{1}{w-1} + \frac{1}{w-z} \right)(w')^2 \\ &\quad - \left(\frac{1}{z} + \frac{1}{z-1} + \frac{1}{w-z} \right)w' \\ &\quad + \frac{w(w-1)(w-z)}{z^2(z-1)^2} \\ &\quad \times \left\{ \alpha + \frac{\beta z}{w^2} + \frac{\gamma(z-1)}{(w-1)^2} + \frac{\delta z(z-1)}{(w-z)^2} \right\}, \end{aligned}$$

where $w = w(z)$; a prime denotes differentiation with respect to z ; and α, β, γ , and δ are arbitrary constants. The equations are commonly referred to as P_I-P_{VI} in the literature, a convention that we will adhere to here.

These equations were discovered about a hundred years ago by Painlevé, Gambier, and their colleagues while studying second-order ordinary differential equations of the form

$$w'' = F(z; w, w'), \quad (1)$$

where F is rational in w' and w and locally analytic in z . In general, the singularities of the solutions are movable in the sense that their location depends on the constants of integration associated with the initial or boundary conditions. An equation is said to have the *Painlevé property* if all its solutions are free from movable branch points, i.e., the locations of multivalued singularities of any of its solutions are independent of the particular solution chosen and so are dependent only on the equation; the solutions may have movable poles or movable isolated essential singularities.

Painlevé et al. showed that there are 50 canonical equations of the form (1) that have this property, up to a Möbius (bilinear rational) transformation. Of these 50 equations, 44 can be reduced to linear equations, solved in terms of elliptic functions, or are reducible to one of six new nonlinear ordinary differential equations that define new transcendental functions.

Although first discovered as a result of mathematical study, the Painlevé equations have arisen in a variety of applications including statistical mechanics (correlation functions of the XY model and the Ising model), random-matrix theory, topological field theory, plasma physics, nonlinear waves (resonant oscillations in shallow water, convective flows with viscous dissipation, Görtler vortices in boundary layers, and Hele-Shaw problems), quantum gravity, quantum field theory, general relativity, nonlinear and fiber optics, polyelectrolytes, Bose-Einstein condensation, and stimulated Raman scattering. The Painlevé equations also arise as symmetry reductions of the soliton equations, such as the Korteweg-de Vries and nonlinear Schrödinger equations, which are solvable by inverse scattering.

The Painlevé equations may be thought of as nonlinear analogs of the classical special functions. They have a large number of interesting properties, some of which we summarize below.

(1) For arbitrary values of the parameters α , β , γ , and δ , the general solutions of P_1-P_6 are *transcendental*, i.e., they cannot be expressed in terms of closed-form elementary functions.

(2) All Painlevé equations can be expressed as the compatibility condition of a linear system: the *isomonodromy problem* or *Lax pair*. Suppose that

$$\frac{\partial \Psi}{\partial \lambda} = A(z; \lambda) \Psi, \quad \frac{\partial \Psi}{\partial z} = B(z; \lambda) \Psi$$

is a linear system in which Ψ is a vector, A and B are matrices, and λ is independent of z . Then the equation

$$\frac{\partial^2 \Psi}{\partial z \partial \lambda} = \frac{\partial^2 \Psi}{\partial \lambda \partial z}$$

is satisfied provided that

$$\frac{\partial A}{\partial z} - \frac{\partial B}{\partial \lambda} + AB - BA = 0,$$

which is the *compatibility condition*.

(3) Each of the Painlevé equations can be written as a *Hamiltonian system*,

$$q' = \frac{\partial \mathcal{H}_J}{\partial p}, \quad p' = -\frac{\partial \mathcal{H}_J}{\partial q},$$

for suitable (nonautonomous) Hamiltonian functions $\mathcal{H}_J(q, p, z)$, $J = I, II, \dots, VI$. Furthermore, the function $\sigma = \mathcal{H}_I(q, p, z)$ satisfies a second-order, second-degree equation. For example, the Hamiltonian for P_I is

$$\mathcal{H}_I(q, p, z) = \frac{1}{2}p^2 - 2q^3 - zq,$$

and so

$$q' = p, \quad p' = 6q^2 + z,$$

and the function $\sigma = \mathcal{H}_I(q, p, z)$ satisfies

$$(\sigma'')^2 + 4(\sigma')^3 + 2z\sigma' - 2\sigma = 0.$$

(4) Equations $P_{II}-P_{VI}$ possess *Bäcklund transformations*, which relate one solution to another solution of the same equation, with different values of the parameters, or to another equation. For example, if $w = w(z; \alpha)$ is a solution of P_{II} , then so are

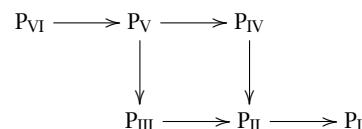

$$w(z; \alpha \pm 1) = -w - \frac{2\alpha \pm 1}{2w^2 \pm 2w' + z},$$

provided that $\alpha \neq \mp \frac{1}{2}$.

(5) For certain values of the parameters, $P_{II}-P_{VI}$ possess rational solutions, algebraic solutions, and solutions expressible in terms of classical special functions (Airy functions for P_{II} , Bessel functions for P_{III} , parabolic cylinder functions for P_{IV} , confluent hypergeometric functions for P_V , and hypergeometric functions for P_V). These solutions, which are known as “classical solutions,” can often be expressed in the form of determinants. For example, P_{II} has rational solutions if $\alpha = n \in \mathbb{Z}$ and solutions in terms of Airy functions if $\alpha = n + \frac{1}{2}$, with $n \in \mathbb{Z}$.

(6) The asymptotic behavior of their solutions—together with the associated *connection formulas* that relate the asymptotic behaviors of the solutions as $|z| \rightarrow \infty$ in different regions of the complex plane—play an important role in the application of the Painlevé equations.

(7) The Painlevé equations possess a coalescence cascade, in that P_1-P_V can be obtained from P_{VI} by the cascade

For example, if we make the transformation

$$w(z; \alpha) = \varepsilon u(\zeta) + \varepsilon^{-5}, \\ z = \varepsilon^2 \zeta - 6\varepsilon^{-10}, \quad \alpha = 4\varepsilon^{-15}$$

in P_{II} , then

$$\frac{d^2u}{d\zeta^2} = 6u^2 + \zeta + \varepsilon^6(2u^3 + \zeta u).$$

So in the limit as $\varepsilon \rightarrow 0$, $u(\zeta)$ satisfies P_I .

III.25 The Riccati Equation

Alan J. Laub

1 History

The name Riccati equation is given to a wide variety of algebraic and differential (or difference) equations characterized by the quadratic appearance of the unknown X . Such equations are named after the Italian mathematician Count Jacopo Francesco Riccati (1676–1754). The variable X was a scalar in the original writings of Riccati, but in modern applications X is often a matrix, and that is the focus here.

2 The Algebraic Riccati Equation

The simplest form of the algebraic Riccati equation (ARE) arises in the so-called continuous-time linear-quadratic theory of control. Suppose we have a linear differential equation (with initial conditions)

$$\frac{d}{dt}x(t) = Ax(t) + Bu(t),$$

where $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$ ($n \geq m$) and the pair of matrices (A, B) is *controllable*, that is, $\text{rank}(A - \lambda I, B) = n$ for all $\lambda \in \Lambda(A)$, where $\Lambda(A)$ denotes the spectrum of A . Suppose, further, that only a subset of the state variables x can be measured, namely the *outputs* $y = Cx$,

where $C \in \mathbb{R}^{q \times n}$ ($q \leq n$), and that the pair of matrices (C, A) is *observable*, that is, $\text{rank}(A - \lambda I, C) = n$ for all $\lambda \in \Lambda(A)$. The *control* $u(t)$ is to be chosen to minimize the quadratic functional

$$\int_0^\infty (y^T Q y + u^T R u) dt,$$

where Q and R are given weighting matrices that are symmetric positive-semidefinite and symmetric positive-definite, respectively. It turns out that the optimal $u(t)$ is given by $u(t) = -R^{-1}B^T X x(t)$, where the symmetric positive-definite matrix X solves the ARE

$$A^T X + X A - X B R^{-1} B^T X + C^T Q C = 0. \quad (1)$$

The closed-loop matrix $A - BR^{-1}B^T X$ (formed by substituting the feedback control $u(t)$ above into the differential equation) is asymptotically stable; that is, its eigenvalues lie in the open left half-plane.

The assumptions made in the linear-quadratic problem are sufficient to guarantee that the $2n \times 2n$ system matrix associated with the problem, namely

$$H = \begin{bmatrix} A & -BR^{-1}B^T \\ -C^T Q C & -A^T \end{bmatrix},$$

has no pure imaginary eigenvalues. There is a long history of the association between the system matrix H , its invariant subspaces, and solutions X of the ARE.

It is easily shown that the matrix H is Hamiltonian, that is, $J A$ is symmetric where $J = \begin{bmatrix} 0 & I_n \\ -I_n & 0 \end{bmatrix}$. The Hamiltonian structure has the consequence that if λ is an eigenvalue of H then so is $-\lambda$ with the same multiplicity. Thus, by our linear-quadratic assumptions, H has precisely n eigenvalues in the open left half-plane and n eigenvalues in the open right half-plane. Hence we can find an orthogonal matrix $U \in \mathbb{R}^{2n \times 2n}$ with $n \times n$ blocks U_{ij} (with U_{11} nonsingular) that transforms H to upper quasi-triangular REAL SCHUR FORM [IV.10 §5.5]

$$U^T H U = \begin{bmatrix} S_{11} & S_{12} \\ 0 & S_{22} \end{bmatrix},$$

where $\Lambda(S_{11})$ is contained in the open left half-plane. Setting $X = U_{21} U_{11}^{-1}$, it can then be verified (after a modest amount of matrix algebra) that X solves (1) and is symmetric positive-definite and that the closed-loop eigenvalues are asymptotically stable, since $\Lambda(A - BR^{-1}B^T X) = \Lambda(S_{11})$. Note that the n columns of $\begin{bmatrix} U_{11} \\ U_{21} \end{bmatrix}$ are the Schur vectors of H that form a basis for the stable invariant subspace (corresponding to the stable left half-plane eigenvalues of S_{11}). Other orderings of the eigenvalues give rise to other solutions (even non-symmetric ones) of the ARE. The ARE can have infinitely many solutions (think of the Riccati equation $X^2 = I$).

There are also results in terms of the SINGULAR VALUE DECOMPOSITION [II.32] of U_{11} that explicitly exhibit the symmetry of the solution X .

The foregoing describes the case for the simplest linear-quadratic problem. Many of the assumptions can be weakened considerably. For example, controllability can be weakened to stabilizability, while observability can be weakened to detectability. In this case, X is still symmetric and stabilizing but may only be positive-semidefinite.

The connection between the $2n \times 2n$ Hamiltonian matrix H and the ARE has been known for well over a hundred years. The use of Schur vectors, as opposed to eigenvectors, as a basis for the stable invariant subspace is crucial for reliable numerical solution. This (and related topics) has been a fertile subject of research. Perhaps surprisingly, the Schur method was not published until the late 1970s, but since then methods based on Schur vectors have found numerous other applications in systems theory, control, and beyond.

In the discrete-time problem, the differential equation is replaced by the difference equation (with initial conditions)

$$x_{k+1} = Ax_k + Bu_k,$$

where $A \in \mathbb{R}^{n \times n}$ and $B \in \mathbb{R}^{n \times m}$. As before, $y_k = Cx_k$, but we will work with $C = I$ for convenience. The integral performance constraint is replaced by an appropriate summation, and (one form of) the resulting discrete-time ARE is given by

$$A^T X A - X - A^T X B (R + B^T X B)^{-1} B^T X A + Q = 0,$$

where the closed-loop matrix $A - B(R + B^T X B)^{-1} B^T X A$ is asymptotically stable (which now means that its eigenvalues lie inside the unit circle in the complex plane). Provided A is nonsingular, the role of the $2n \times 2n$ Hamiltonian matrix H is taken here by the $2n \times 2n$ matrix

$$S = \begin{bmatrix} A + BR^{-1}B^TA^{-T}Q & -BR^{-1}B^TA^{-T} \\ -A^{-T}Q & A^{-T} \end{bmatrix},$$

which is symplectic; that is, $S^T JS = J$. The symplectic matrix S has a $\lambda \leftrightarrow 1/\lambda$ symmetry to its eigenvalues, and appropriate assumptions guarantee that there are no eigenvalues on the unit circle. If A is singular, it turns out to be much better to work with the $2n \times 2n$ symplectic pencil

$$\begin{bmatrix} A & 0 \\ -Q & I \end{bmatrix} - \lambda \begin{bmatrix} I & BR^{-1}B^T \\ 0 & A^T \end{bmatrix},$$

and this gives rise to a large number of new methods based on the Schur vectors of the corresponding generalized eigenproblem. This time the role of the invariant subspace is taken by a generalization for matrix pencils called the deflating subspace, but the essence of the method remains the same.

3 Extensions of the ARE

There are many generalizations of the linear-quadratic problem and the Riccati equation, such as

- extended (i.e., $(2n + m) \times (2n + m)$) pencils, in which even the R matrix may be singular;
- versions with a cross-performance term in the integral (or a sum in the discrete-time case);
- versions for which the system constraint (the differential equation or the difference equation) is given in so-called descriptor form with a matrix E (which may or may not be singular) multiplying the left-hand side;
- versions associated with the so-called H_∞ problem that are Riccati equations but with different sets of assumptions on the coefficient matrices; and
- AREs with specific structure on the matrices that then gives rise to other features of the solution (such as componentwise nonnegativity).

Many other solution techniques have been developed, including

- structured methods that try to preserve the underlying Hamiltonian or symplectic nature of the matrices;
- methods based on the MATRIX SIGN FUNCTION [II.14] that exploit the connection with an appropriate invariant subspace;
- methods that are iterative in nature, such as NEWTON'S METHOD [II.28], which involves solving a sequence of much-easier-to-solve LYAPUNOV [III.28] (or Sylvester) equations at each step; and
- doubling methods, which constitute another large class of iterative methods.

4 The Riccati Differential Equation

The ARE can be thought of as a stationary point of the associated Riccati differential equation. For the algebraic equation above, its differential equation takes the form (with initial conditions)

$$\frac{d}{dt} X(t) = F(X(t)),$$

where $F(X(t))$ has the form of the left-hand side of the ARE (1) and where each of the coefficient matrices may also vary with time. Symmetry is not necessary in the sense that so-called nonsymmetric equations of the form

$$\frac{d}{dt}X(t) = A_1 + A_2X(t) + X(t)A_3 - X(t)A_4X(t)$$

can be studied, where $X(t) \in \mathbb{R}^{m \times n}$ and the coefficient matrices A_i are general. In all cases, the defining property of equations of Riccati type is the characteristic appearance of the unknown matrix in quadratic form. Of course, there are also algebraic versions of these nonsymmetric equations.

III.26 Schrödinger's Equation

In its full generality, Schrödinger's equation describes the quantum mechanical evolution under time t of a vector (often called a *ket*) $|\Psi\rangle$ in a HILBERT SPACE [I.2 §19.4], according to a self-adjoint operator \hat{H} called the *Hamiltonian operator*,

$$i\hbar \frac{\partial}{\partial t} |\Psi\rangle = \hat{H} |\Psi\rangle, \quad (1)$$

where i is the imaginary unit and \hbar is a constant, known as Planck's constant or the quantum of action. In SI units, $\hbar \approx 1.05 \times 10^{-34}$ J s.

$|\Psi\rangle$ represents the time-dependent total state of the quantum system, and \hat{H} determines the energy of the system. If \hat{H} is independent of t and $|\Psi\rangle = e^{-iEt/\hbar} |E\rangle$ for $|E\rangle$ an eigenvector of \hat{H} with energy eigenvalue E , then (1) can be written in time-independent form, $\hat{H}|E\rangle = E|E\rangle$.

When the quantum system consists of a single particle of mass m (disregarding effects of quantum spin and electromagnetic interactions), the Hilbert space may be chosen to be the space of square-integrable complex-valued functions of t and position \mathbf{r} in Euclidean configuration space, and the quantum state is

described by a *wave function* $\Psi(\mathbf{r}, t)$. If the particle is subject to a potential $V(\mathbf{r}, t)$, then Schrödinger's equation takes the form of the partial differential equation

$$i\hbar \frac{\partial}{\partial t} \Psi(\mathbf{r}, t) = -\frac{1}{2m} \nabla^2 \Psi(\mathbf{r}, t) + V(\mathbf{r}, t) \Psi(\mathbf{r}, t),$$

where ∇^2 denotes the LAPLACE OPERATOR [III.18]. In the *nonlinear Schrödinger equation*, the potential is proportional to the modulus squared of the wave function: $V = \kappa |\Psi|^2$ for some positive or negative constant κ .

Study of the evolution of Schrödinger's equation is the subject of QUANTUM MECHANICS [IV.23], and it emerges naturally from Hamilton's approach to CLASSICAL MECHANICS [IV.19].

III.27 The Shallow-Water Equations

P. A. Martin

As one might expect, the shallow-water equations are appropriate when considering the motion of a liquid occupying a layer. Major applications concern ocean waves, so we use appropriate terminology. We therefore identify the bottom of the layer with the sea floor at $z = -b(x, y)$, where $b(x, y)$ is given and positive, and x, y, z are Cartesian coordinates with z pointing upward. The top of the layer is the moving free surface, $z = \eta(x, y, t)$, where t is time. The total depth of the water is $h(x, y, t) = b(x, y) + \eta(x, y, t)$. The water is assumed to be incompressible (with constant density ρ) and inviscid (viscous effects are ignored). Thus, the governing partial differential equations (PDEs) in the water are the EULER EQUATIONS [III.11],

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u} \cdot \nabla) \mathbf{u} + \frac{1}{\rho} \nabla p = -g \hat{\mathbf{z}}, \quad (1)$$

and the continuity equation, $\nabla \cdot \mathbf{u} = 0$, where $\mathbf{u} = (u, v, w)$ is the fluid velocity, p is the pressure, g is the acceleration due to gravity, and $\hat{\mathbf{z}}$ is a unit vector in the z -direction. In addition, there are boundary conditions at the free surface and at the bottom. They are

$$p = 0 \quad \text{and} \quad \frac{\partial \eta}{\partial t} + u \frac{\partial \eta}{\partial x} + v \frac{\partial \eta}{\partial y} = w \quad \text{at } z = \eta$$

and

$$u \frac{\partial b}{\partial x} + v \frac{\partial b}{\partial y} + w = 0 \quad \text{at } z = -b.$$

Integrating $\nabla \cdot \mathbf{u} = 0$ with respect to z gives

$$\frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x} \int_{-b}^{\eta} u \, dz + \frac{\partial}{\partial y} \int_{-b}^{\eta} v \, dz = 0, \quad (2)$$

where the boundary conditions at $z = \eta$ and $z = -b$ have been used.

So far, we have not made any approximations. Next, we assume that the waves generated are much longer than the water depth: this is what is implied by the “shallow-water” terminology. One consequence is that we can neglect the vertical acceleration terms (involving \mathbf{u}) in the z -component of (1), giving $p(x, y, z, t) = \rho g\{\eta(x, y, t) - z\}$ after integration with respect to z .

Finally, we assume further that the fluid velocity is horizontal and that it does not vary with depth: $\mathbf{u} = (u(x, y, t), v(x, y, t), 0)$. Then, using the horizontal components of (1) together with (2), we obtain the *shallow-water equations*:

$$\begin{aligned}\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} + g \frac{\partial \eta}{\partial x} &= 0, \\ \frac{\partial v}{\partial t} + u \frac{\partial v}{\partial x} + v \frac{\partial v}{\partial y} + g \frac{\partial \eta}{\partial y} &= 0, \\ \frac{\partial \eta}{\partial t} + \frac{\partial}{\partial x}(hu) + \frac{\partial}{\partial y}(hv) &= 0.\end{aligned}$$

This is a nonlinear hyperbolic system of PDEs. It can be rewritten in other ways; see, for example, how it is presented in the article on TSUNAMI MODELING [V.19 §2].

If the motions are small, a linearized version of the shallow-water equations can be derived. The result is a two-dimensional WAVE EQUATION [III.31] for $\eta(x, y, t)$:

$$\frac{\partial^2 \eta}{\partial t^2} = \frac{\partial}{\partial x} \left(g b \frac{\partial \eta}{\partial x} \right) + \frac{\partial}{\partial y} \left(g b \frac{\partial \eta}{\partial y} \right).$$

The basic nonlinear shallow-water equations can be augmented to include other effects. For example, if we want to model global phenomena, we should take account of the rotation of the Earth.

III.28 The Sylvester and Lyapunov Equations

Nicholas J. Higham

The *Sylvester equation* (named after James Joseph Sylvester, who introduced it in 1884) is the linear matrix equation

$$AX + XB = C,$$

where $A \in \mathbb{C}^{m \times m}$, $B \in \mathbb{C}^{n \times n}$, and $C \in \mathbb{C}^{m \times n}$ are given and $X \in \mathbb{C}^{m \times n}$ is to be determined. It has a unique solution provided that A and $-B$ have no eigenvalues in common. One interesting property is that if the integral

$\int_0^\infty e^{At} C e^{Bt} dt$ exists, then minus that integral is a solution of the Sylvester equation. Another is that the block upper triangular matrix $\begin{bmatrix} A & C \\ 0 & -B \end{bmatrix}$ can be reduced by a similarity transformation to block-diagonal form $\begin{bmatrix} A & 0 \\ 0 & -B \end{bmatrix}$ if and only if the Sylvester equation has a solution.

The Sylvester equation can be generalized by including coefficient matrices on both sides of X and increasing the number of terms:

$$\sum_{i=1}^k A_i X B_i = C, \quad A_i \in \mathbb{C}^{m \times m}, B_i \in \mathbb{C}^{n \times n}.$$

When $m = n$, numerical methods are available that solve the system with $k = 2$ terms in $O(n^3)$ operations, but for $k > 2$ the best available methods require $O(n^6)$ operations. In applications in which the coefficient matrices are large, sparse, and possibly highly structured, much recent research has focused on computing inexpensive approximations to the solution using iterative methods, with good low-rank approximations being possible in some cases.

The *Lyapunov equation* is the special case of the Sylvester equation with $B = A^* \in \mathbb{C}^{n \times n}$:

$$AX + XA^* = C.$$

It is common in control and systems theory. Usually, C is Hermitian, in which case the solution X is Hermitian when the equation has a unique solution, which is the case when $\lambda_i + \bar{\lambda}_j \neq 0$ for all eigenvalues λ_i and λ_j of A .

A classic theorem says that for any given Hermitian positive-definite C the Lyapunov equation has a unique Hermitian negative-definite solution if and only if all the eigenvalues of A lie in the open left half-plane. The latter condition is equivalent to the asymptotic stability of the linear system of differential equations $\dot{x}(t) = Ax(t)$, and the Lyapunov equation is correspondingly also known as the *continuous-time Lyapunov equation*.

The *discrete-time Lyapunov equation* (also known as the *Stein equation*) is

$$X - A^* X A = C.$$

Given any Hermitian positive-definite matrix C , there is a unique Hermitian positive-definite solution X if and only if all the eigenvalues of A lie within the unit circle, and the latter condition is equivalent to the asymptotic stability of the discrete system $x_{k+1} = Ax_k$.

The Sylvester and Lyapunov equations both arise when Newton’s method is used to solve ALGEBRAIC RICCATI EQUATIONS [III.25].

III.29 The Thin-Film Equation

Andrew J. Bernoff

The thin-film equation (TFE),

$$\frac{\partial h}{\partial t} = -\frac{\partial}{\partial x} \left(Q(h) \frac{\partial^3 h}{\partial x^3} \right),$$

is a nonlinear fourth-order partial differential equation describing the flow of thin viscous films with strong surface tension. It has received a great deal of attention over the last two decades, both as a tractable model of thin fluid films and as a paradigm of challenges in the study of partial differential equations. Here, $h(x, t)$ represents the nonnegative height of the film's free surface (as a function of position x and time t (see figure 1)), and $Q(h)$ is a mobility function that is degenerate ($Q(0) = 0$) and increasing ($Q'(h) > 0$ for $h > 0$). The degeneracy allows compactly supported solutions (with $h = 0$ except on some compact subset of the real line), and the increasing mobility, which is necessary for the problem to be well-posed, leads to solutions that are infinitely smooth within their support. The most common choice for the mobility is $Q(h) = h^n$ for some $n > 0$.

1 Physical Origins

The TFE is an example of a *lubrication theory*, whereby a problem is considered in the asymptotic limit where horizontal variation occurs on a scale much longer than the film thickness. Lubrication theory applied to a thin viscous film on a no-slip substrate yields the TFE with $Q(h) = h^3$; the introduction of slip on the boundary yields $Q(h) = \beta h^2 + h^3$ for some $\beta > 0$.

2 Mathematical Structure

A mathematical theory for the existence of compactly supported weak solutions emerged in the 1990s. The TFE conserves mass,

$$M \equiv \int h \, dx \Rightarrow \frac{dM}{dt} = 0,$$

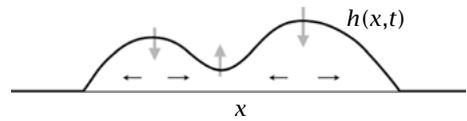

Figure 1 A typical compactly supported configuration for a thin film of height $h(x, t)$. Variations in surface tension forces (proportional to h_{xx} and indicated by the vertical gray arrow) create a pressure gradient that drives fluid motion (horizontal black arrows).

and dissipates surface energy (a lubrication approximation of the free surface's arc length),

$$E \equiv \frac{1}{2} \int (h_x)^2 \, dx \Rightarrow \frac{dE}{dt} = - \int Q(h) (h_{xxx})^2 \, dx \leq 0,$$

where integrals are over the support of $h(x, t)$.

It is believed that for $n \geq 3$ the support of the solution cannot increase; this means that the *contact line* (where the solution vanishes) cannot move for a no-slip boundary, which reflects the well-known contact line paradox in fluid mechanics (where we observe contact lines physically moving whenever a fluid wets a solid surface, but mathematically it is known that a contact line cannot move for the Navier-Stokes equation with a no-slip boundary condition). However, for $0 < n < 3$ one can find moving contact line solutions, which allow one to model spreading drops. Physically, this reflects the fact that the addition of slip to the boundary condition allows contact line motion, a modeling strategy that also resolves the contact line paradox for the full fluid equations.

The question of whether a film can rupture, leaving a dry spot (where $h = 0$), is only partially resolved; numerical results suggest that films may rupture for $n < \frac{3}{2}$ and will not rupture for greater n , but rigorous analytical results for this problem are lacking.

For $0 < n < 3$ one can find self-similar spreading drop solutions that are analogous to the Barenblatt solution of the porous media equation.

3 Higher Dimensions and Generalizations

The TFE generalizes naturally to N dimensions; the film height $h(\mathbf{x}, t)$, $\mathbf{x} \in \mathbb{R}^N$, satisfies

$$\frac{\partial h}{\partial t} = -\nabla \cdot [Q(h) \nabla (\Delta h)],$$

and the existence theory for weak solutions, energy dissipation, contact line motion, axisymmetric spreading droplets, and film rupture remains largely unchanged from the one-dimensional TFE.

Variants of the TFE incorporating gravity, inertia, substrate topography, variable surface tension due to heat or surfactants (known as Marangoni effects), van der Waals forces, evaporation, and many other physical effects have been highly successful in modeling thin films; the common theme in these models is that the additional terms are lower order, and the fourth-order thin-film term ensures well-posedness.

III.30 The Tricomi Equation

Gui-Qiang G. Chen

The *Tricomi equation* is a second-order partial differential equation of mixed elliptic-hyperbolic type. It takes the following form for an unknown function $u(x, y)$:

$$u_{xx} + xu_{yy} = 0.$$

The Tricomi equation was first analyzed in 1923 by Francesco Giacomo Tricomi when he was studying the well-posedness of a boundary-value problem. The equation is hyperbolic in the half-plane $x < 0$, elliptic in the half-plane $x > 0$, and degenerates on the line $x = 0$. Its characteristic equation is

$$dy^2 + xdx^2 = 0,$$

whose solutions are

$$y \pm \frac{2}{3}(-x)^{3/2} = C$$

for any constant C ; the solutions are real for $x < 0$. The characteristics constitute two families of semicubical parabolas lying in the half-plane $x < 0$, with cusps on the line $x = 0$. This shows that the Tricomi equation is of hyperbolic degeneracy in the domain $x \leq 0$, for which the two characteristic families coincide, *perpendicularly* to the line $x = 0$.

For $\pm x > 0$, set $\tau = \frac{2}{3}(\pm x)^{3/2}$. The Tricomi equation then becomes the classical elliptic or hyperbolic *Euler-Poisson-Darboux equation*:

$$u_{\tau\tau} \pm u_{yy} + \frac{\beta}{\tau}u_\tau = 0.$$

The index $\beta = \frac{1}{3}$ determines the singularity of solutions near $\tau = 0$ (or, equivalently, near $x = 0$).

Many important problems in fluid mechanics and differential geometry can be reduced to corresponding problems for the Tricomi equation, particularly *transonic flow problems* and *isometric embedding problems*. The Tricomi equation is a prototype of the *generalized Tricomi equation*:

$$u_{xx} + K(x)u_{yy} = 0,$$

where $K(x)$ is a given function with $xK(x) > 0$ for $x \neq 0$. For a steady-state transonic flow in \mathbb{R}^2 , $u(x, y)$ is the stream function of the flow, x is a function of the velocity (which is positive at subsonic speeds and negative at supersonic speeds), and y is the angle of inclination of the velocity. The solutions $u(x, y)$ also serve as entropy generators for entropy pairs of the potential flow system for the velocity. For the isometric embedding problem of two-dimensional Riemannian manifolds into \mathbb{R}^3 , the function $K(x)$ has the same sign as the Gaussian curvature.

A closely related partial differential equation is the *Keldysh equation*:

$$xu_{xx} + u_{yy} = 0.$$

It is hyperbolic when $x < 0$, elliptic when $x > 0$, and degenerates on the line $x = 0$. Its characteristics are given by

$$y \pm \frac{1}{2}(-x)^{1/2} = C$$

for any constant C ; the characteristics are real for $x < 0$. The two characteristic families are (quadratic) parabolas lying in the half-plane $x < 0$; they coincide *tangentially* to the degenerate line $x = 0$. This shows that the Keldysh equation is of parabolic degeneracy. For $\pm x > 0$, the Keldysh equation becomes the elliptic or hyperbolic *Euler-Poisson-Darboux equation* with index $\beta = -\frac{1}{4}$, by setting $\tau = \frac{1}{2}(\pm x)^{1/2}$. Many important problems in continuum mechanics can also be reduced to corresponding problems for the Keldysh equation, particularly shock reflection-diffraction problems in gas dynamics.

III.31 The Wave Equation

The one-dimensional *wave equation* is a PARTIAL DIFFERENTIAL EQUATION [IV.3] for $u(x, t)$,

$$\frac{\partial^2 u}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}, \quad (1)$$

where c is a constant. It is classified as a linear second-order homogeneous hyperbolic equation. Unusually, its

general solution (*d'Alembert's solution*) is known:

$$u(x, t) = f(x - ct) + g(x + ct). \quad (2)$$

Here, f and g are arbitrary twice-differentiable functions of one variable.

Small motions of a stretched string are governed by (1). Suppose that, in equilibrium, the string is along the x -axis. Then $u(x, t)$ gives the lateral displacement at position x and time t . The solution $u(x, t) = f(x - ct)$ represents a wave traveling to the right (x increasing) as t increases: a photograph at $t = 0$ would show the string to have displacement $u(x, 0) = f(x)$; a second photograph at time $1/c$ would show the same displacement but moved to the right by one unit, $u(x, 1/c) = f(x - 1)$. Equation (2) shows that the general solution consists of two waves, one moving to the right and one to the left, both moving at speed c .

Part IV

Areas of Applied Mathematics

IV.1 Complex Analysis

P. A. Martin

1 Introduction

All calculus textbooks start with $f(x)$: f is a function of one (real) variable x . Topics covered include limits, continuity, differentiation, and integration, with the associated notation, such as $df/dx = f'(x)$ and $\int_a^b f(x) dx$. It is also usual to include a discussion of infinite sequences and series. The rigorous treatment of all these topics constitutes *real analysis*.

Complex analysis starts with the following question. What happens if we replace x by $z = x + iy$, where x and y are two independent real variables and $i = \sqrt{-1}$? Answering this question leads to rich new fields of mathematics; we shall be concerned with those parts that are used in applied mathematics.

Let us begin with basic terminology and concepts. We call $z = x + iy$ a *complex variable*. The *imaginary unit* i should be treated as a symbol that obeys all the usual laws of algebra together with $i^2 = -1$. We call $x = \operatorname{Re} z$ the *real part* of z and $y = \operatorname{Im} z$ the *imaginary part* of z . We can identify $z = x + iy$ with a point in the xy -plane (known as the *z -plane* or the *complex plane*).

The *complex conjugate* of z is $\bar{z} = x - iy$; complex conjugation is reflection in the x -axis. The *absolute value* (or *modulus* or *magnitude*) of z is $|z| = \sqrt{x^2 + y^2}$, the distance from z to the origin. Given $w = u + iv$, we define $z + w = (x + u) + i(y + v)$. Addition of complex quantities is therefore equivalent to addition of two-dimensional vectors. For multiplication, $zw = xu - yv + i(xv + yu)$. Putting $z = w$ shows that $\operatorname{Re} z^2 = x^2 - y^2 \neq x^2$ unless z is real ($y = 0$). Also, $z\bar{z} = |z|^2$ and $z/w = z\bar{w}/|w|^2$ when $w \neq 0$.

Introducing plane polar coordinates, r and θ , we have $z = r \cos \theta + ir \sin \theta = re^{i\theta}$ by Euler's formula. Thus, $r = |z|$. The angle θ is called an *argument* of z , denoted by $\arg z$ or $\operatorname{ph} z$ (for *phase*). Notice that $\arg z$

is not unique, as we can always add any integer multiple of 2π ; this nonuniqueness is sometimes useful and sometimes a nuisance.

If we let $r \rightarrow \infty$, the point z recedes to infinity. It is usual to state that there is a single “point at infinity,” denoted by $z = \infty$, that is reached by letting $r \rightarrow \infty$ in any direction, θ . Alternatively, we can state that the formula $z = 1/w$ takes the point $w = 0$ to the point $z = \infty$.

2 Functions

A function of a complex variable, $f(z)$, is a rule; given $z = x + iy$ in some set (the *domain* of f), the rule provides a unique complex number denoted by $f(z) = u + iv$, say, where $u = \operatorname{Re} f$ and $v = \operatorname{Im} f$ are real. We write $f(z) = u(x, y) + iv(x, y)$ to emphasize the dependence on x and y .

Simple examples of functions are $f(z) = z^2$ and $f(z) = \bar{z}$. Elementary functions are defined “naturally”; for example, $e^z = e^{x+iy} = e^x e^{iy}$ and $\cos z = \frac{1}{2}(e^{iz} + e^{-iz})$. For powers and logarithms, we have the formulas $z^\alpha = r^\alpha e^{i\alpha\theta}$ (α is real) and $\log z = \log(r e^{i\theta}) = \log r + i\theta$. Strictly, these do not define functions because of the nonuniqueness of θ ; changing θ by 2π does not change z but it does change the values of z^α (unless α is an integer) and $\log z$. One response to this phenomenon is to say that $\log z$, for example, is a multivalued “function”; increasing θ by 2π takes us onto another *branch* or *Riemann sheet* of $\log z$. However, in practice, it is usually better to introduce a *branch cut*, which, for $\log z$, is any line from $z = 0$ to $z = \infty$. This cut is regarded as an artificial barrier; we must not cross it. Its presence prevents us from increasing θ by 2π . For example, we could restrict θ to satisfy $-\pi < \theta < \pi$ and put the cut on the negative x -axis. Once we have restricted θ to lie in some interval of length 2π , $\log z$ and z^α become single-valued; they are now functions. We shall have more to say about branches in section 4.

There are many other ways to define functions. For example, $f(z) = \sum_{n=0}^{\infty} c_n z^n$ is a function provided the

power series converges at z ; characteristically, power series converge in disks, $|z| < R$, for some $R > 0$ (R is the *radius of convergence*). The prototype power series is the *geometric series*; it converges inside the unit disk where its sum is known:

$$\sum_{n=0}^{\infty} z^n = \frac{1}{1-z}, \quad |z| < 1. \quad (1)$$

For another example, take

$$f(z) = \int_0^{\infty} g(t) e^{-zt} dt. \quad (2)$$

This defines the *Laplace transform* of g . Typically, such integrals converge for $\operatorname{Re} z > A$, where A is a constant that depends on g . Another function defined by an integral is Euler's gamma function:

$$\Gamma(z) = \int_0^{\infty} t^{z-1} e^{-t} dt, \quad \operatorname{Re} z > 0. \quad (3)$$

Much is known about the properties of Γ . For example, $\Gamma(n) = (n-1)!$ when n is any positive integer. There is more on this in section 13 below.

3 Analytic Functions

The notions of limit, continuity, and derivative are defined exactly as in real-variable calculus. In particular, the *derivative* of f at z is defined by

$$f'(z) = \frac{df}{dz} = \lim_{h \rightarrow 0} \frac{f(z+h) - f(z)}{h}, \quad (4)$$

provided the limit exists. Here, h is allowed to be complex; the point $z+h$ must be able to approach the point z in any direction, and the limit must be the same. As a consequence, if $f(z) = u(x, y) + i v(x, y)$ has a derivative, $f'(z)$, at z , then u and v satisfy the *Cauchy-Riemann equations*:

$$\frac{\partial u}{\partial x} = \frac{\partial v}{\partial y} \quad \text{and} \quad \frac{\partial u}{\partial y} = -\frac{\partial v}{\partial x}. \quad (5)$$

If these are not both satisfied, then $f'(z)$ does not exist. Two examples: $f(z) = \bar{z}$ is not differentiable for any z ; and any real-valued function $f(z) = u(x, y)$ is not differentiable unless u is a constant. If both Cauchy-Riemann equations (5) are satisfied and the partial derivatives in (5) are continuous functions, then f' exists.

Using (5), if f' exists, then

$$\begin{aligned} f'(z) &= \frac{\partial u}{\partial x} + i \frac{\partial v}{\partial x} = \frac{\partial v}{\partial y} - i \frac{\partial u}{\partial y} \\ &= \frac{\partial u}{\partial x} - i \frac{\partial u}{\partial y} = \frac{\partial v}{\partial y} + i \frac{\partial v}{\partial x}. \end{aligned}$$

The first equality follows by taking h to be real in (4) and the second by taking h to be purely imaginary. The four

formulas for f' show that we can calculate f' from $\operatorname{Re} f$ or $\operatorname{Im} f$, or by differentiating with respect to x or y .

Differentiability is a local property, defined at a point z . Usually, we are interested in functions that are differentiable at all points in their domains. Such functions are called *analytic* or *holomorphic*. Points at which a function is not differentiable are called *singularities*.

Derivatives of higher order (such as $f''(z)$) are defined in the natural way. One surprising fact is that a differentiable function can be differentiated any number of times; once differentiable implies infinitely differentiable (see (13) below for an indication of a proof). This result is certainly not true for real functions.

If we eliminate v from (5), we obtain

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = 0. \quad (6)$$

Thus, the real part of an analytic function, $u(x, y)$, satisfies LAPLACE'S EQUATION [III.18] (6). The imaginary part, $v(x, y)$, satisfies the same partial differential equation (PDE). This reveals a close connection between analytic functions and solutions of one particular PDE. As Laplace's equation arises in the modeling of many physical phenomena, this connection has been exploited extensively.

4 More on Branches

Let us return to \log , which we can define as a (single-valued) function by

$$\log z = \log r + i\theta, \quad r > 0, \quad -\pi < \theta < \pi, \quad (7)$$

with $z = re^{i\theta}$. There is a branch cut along the negative x -axis, with a branch point at $z = 0$ and a branch point at $z = \infty$. Thus, our domain of definition for $\log z$ is the cut plane, i.e., the whole complex plane with the cut removed. Then, $\log z$ is analytic; it is differentiable at all points in its domain of definition. Moreover, $(d/dz) \log z = z^{-1}$.

According to (7), $\log z$ is not defined on the negative x -axis. Some authors regard this as unacceptable, and so they replace the (open) interval $-\pi < \theta < \pi$ in (7) by $-\pi < \theta \leq \pi$ or $-\pi \leq \theta < \pi$. The first choice gives, for example, $\log(-1) = i\pi$ and the second gives $\log(-1) = -i\pi$. Either choice enlarges the domain of definition to the whole plane with $z = 0$ removed. However, we lose analyticity; $\log z$ is not differentiable on the line $\theta = \pi$ (first choice) because points on that line are not accessible in all directions (as they must be if one wants to compute limits, as in the definition of derivative) without leaving the domain of definition.

For some applications this may be acceptable, but, in practice, it is usual to simply move the cut. We can therefore replace $-\pi < \theta < \pi$ in (7) by another open interval, $\theta_0 < \theta < 2\pi + \theta_0$, implying a cut along the straight half-line $\theta = \theta_0$, $r \geq 0$. (In fact, the cut need not be straight; any line connecting the branch point at $z = 0$ to $z = \infty$ may be used.) Then $\log z$ is analytic in a new cut plane.

Once we define a function such as $\log z$ or $z^{1/2}$ with a specified range for θ , we can say that we have defined a *principal value* of that function. Certain choices (such as $-\pi < \theta < \pi$ or $-\pi < \theta \leq \pi$) are common, but the reader should not overlook the option of moving cuts when it is convenient to do so.

There is another consequence of insisting on having (single-valued) functions: some standard identities, such as $\log(z^2) = 2\log z$, may no longer hold. For example, with $z = -1 + i$ and the definition (7), we find $\log(z^2) = \log 2 - \frac{1}{2}i\pi$ but $2\log z = \log 2 + \frac{3}{2}i\pi$.

Summarizing, functions with branches are very common (for another example, see the article on THE LAMBERT W -FUNCTION [III.17]) but their presence often leads to complications, subtle difficulties, and calculational errors; care is always required.

5 Infinite Series

A power series about the point z_0 has the form

$$\sum_{n=0}^{\infty} c_n(z - z_0)^n, \quad (8)$$

where the coefficients c_n are complex numbers. The series (8) converges for $|z - z_0| < R$ and diverges for $|z - z_0| > R$, where the radius of convergence, R , may be finite or infinite. (It may happen that (8) converges at $z = z_0$ only, with sum c_0 .) When the series does converge, we denote its sum by $S(z)$. For an example, see the geometric series (1).

The sum $S(z)$ is analytic for $|z - z_0| < R$; power series define analytic functions.

Now we turn this around. We take an analytic function, $f(z)$, and we try to write it as a power series. Doing this is familiar from calculus, and the result is Taylor's theorem:

$$f(z) = \sum_{n=0}^{\infty} \frac{f^{(n)}(z_0)}{n!} (z - z_0)^n,$$

where $f^{(n)}$ is the n th derivative of f . The series is known as the *Taylor expansion* of $f(z)$ about z_0 . It converges for $|z - z_0| < R$, where R is the distance from

z_0 to the nearest singularity of $f(z)$. A Taylor expansion about the origin ($z_0 = 0$) is known as a *Maclaurin expansion*. All these expansions are the same as those occurring in the calculus of functions of one real variable. For example, (1) gives the Maclaurin expansion of $1/(1 - z)$. Another familiar Maclaurin expansion is $e^z = \sum_{n=0}^{\infty} z^n/n!$, which is convergent for all z .

A generalization of Taylor's theorem, Laurent's theorem, will be given in section 8.

Not all infinite series are power series. A famous series is the RIEMANN ZETA FUNCTION [IV.7 §4], which is defined by

$$\zeta(z) = \sum_{n=1}^{\infty} \frac{1}{n^z} \quad \text{for } \operatorname{Re} z > 1, \quad (9)$$

which is intimately connected with the distribution of the prime numbers.

It is possible to develop the theory of analytic functions by starting with power series; this approach, which goes back to Weierstrass, has a constructive flavor. We started with the notion of differentiability; this approach, which goes back to Riemann and Cauchy, is closer to real-variable calculus. The two approaches are equivalent; power series define analytic functions and analytic functions have power-series expansions.

6 Contour Integrals

In the calculus of functions of two real variables x and y , double integrals over regions of the xy -plane and line integrals along curves in the xy -plane are defined. In complex analysis, we are mainly concerned with integrals along curves in the z -plane. They are defined similarly to line integrals. Thus, suppose that points on a curve C are located by a parametrization,

$$C: z(t) = x(t) + iy(t), \quad a \leq t \leq b,$$

where a and b are constants and $x(t)$ and $y(t)$ are real functions of the real variable t . As t increases from a to b , $z(t)$ moves from $z(a)$ to $z(b)$; the parametrization induces a direction or *orientation* on C . The curve C is *smooth* if $x'(t)$ and $y'(t)$ exist and are continuous. Then, if $f(z)$ is defined for all points z on a smooth curve C ,

$$\int_C f(z) dz = \int_a^b f(z(t)) z'(t) dt, \quad (10)$$

where $z'(t) = x'(t) + iy'(t)$. In (10), the right-hand side defines the expression on the left-hand side as an integration with respect to the parameter t . More generally, suppose that C is a *contour*, defined as a continuous curve made from smooth pieces joined at corners.

Then, to define $\int_C f(z) dz$, we parametrize each smooth piece separately, and then sum the contributions from each piece, ensuring that the parametrizations are such that z moves continuously along C .

If C_0 is the same curve as C but traversed in the opposite direction (from $z(b)$ to $z(a)$), then $\int_{C_0} f(z) dz = -\int_C f(z) dz$; changing the direction changes the sign.

7 Cauchy's Theorem

A contour C is *closed* if $z(a) = z(b)$, and it is *simple* if it has no self-intersections. Cauchy's theorem can be stated as follows. Suppose that $f(z)$ is analytic inside a simple closed contour C and continuous on C . Then

$$\int_C f(z) dz = 0. \quad (11)$$

It is worth emphasizing the hypotheses. First, we do not need to know anything about $f(z)$ outside C ; Cauchy assumed stronger conditions, but these were later weakened by Goursat. Second, C is a contour, so corners are allowed. Third, by requiring that " f is analytic inside C ," we mean that $f(z)$ must be differentiable at all points z inside C ; singularities (including branch points) are not allowed (although they may be present outside C).

There are many consequences of Cauchy's theorem. One is known as *deforming the contour*. Suppose that C_1 and C_2 are simple closed contours, both traversed in the same direction, with C_1 enclosed by C_2 . Suppose that $f(z)$ is analytic in the region between C_1 and C_2 and that it is continuous on C_1 and C_2 . (Note that f may have singularities inside the smaller contour C_1 or outside the larger contour C_2 .) Then, $\int_{C_1} f(z) dz = \int_{C_2} f(z) dz$; one contour can be deformed into another without changing the value of the integral, provided the integrand is analytic between the contours. The same result is true when C_1 and C_2 are two contours with the same endpoints, provided f is analytic between C_1 and C_2 . These results are useful because they may allow us to deform a complicated contour into a simpler contour (such as a circle or a straight line).

Another consequence of Cauchy's theorem is the *Cauchy integral formula*. Under the same conditions, we have

$$f(z_0) = \frac{1}{2\pi i} \int_C \frac{f(z)}{z - z_0} dz, \quad (12)$$

where z_0 is an arbitrary point inside C , and C is traversed counterclockwise. This shows that we can recover the values of an analytic function inside C from its values on C .

More generally, and again under the same conditions, we have

$$f^{(n)}(z_0) = \frac{n!}{2\pi i} \int_C \frac{f(z)}{(z - z_0)^{n+1}} dz. \quad (13)$$

Formally, this can be seen as the n th derivative of the Cauchy integral formula (12), but it is deeper; it can be used to prove the existence of $f^{(n)}$, for $n = 2, 3, \dots$, assuming that f' exists. This is done using an inductive argument. We have (compare with (4))

$$f^{(n+1)}(z_0) = \lim_{h \rightarrow 0} \frac{f^{(n)}(z_0 + h) - f^{(n)}(z_0)}{h},$$

provided the limit exists. Now, on the right-hand side, use (13) twice; the limit can then be taken.

Formula (13) with $n = 1$ can be used to prove *Liouville's theorem*. Suppose that $f(z)$ is analytic everywhere in the z -plane (that is, there are no singularities); such a function is called *entire*. Suppose further that $|f(z)| < M$ for some constant M and for all z ; we say that f is *bounded*. Liouville's theorem states that a bounded entire function is necessarily constant. In other words, (nonconstant) entire functions must be large somewhere in the complex plane. For example,

$$\begin{aligned} |\cos z|^2 &= \cos z \overline{\cos z} = \frac{1}{4} (e^{iz} + e^{-iz})(e^{i\bar{z}} + e^{-i\bar{z}}) \\ &= \frac{1}{4} (e^{2ix} + e^{-2ix} + e^{2iy} + e^{-2iy}) \\ &= \frac{1}{2} (\cos 2x + \cosh 2y) = \cos^2 x + \cosh^2 y - 1 \end{aligned}$$

using $z + \bar{z} = 2x$ and $z - \bar{z} = 2iy$. Thus, $|\cos z|$ grows rapidly as we move away from the real axis (where $y = 0$ and $\cosh 0 = 1$).

8 Laurent's Theorem

Suppose that $f(z)$ is analytic inside an annulus, $a < |z - z_0| < b$, centered at z_0 . We say nothing about $f(z)$ when z is in the "hole" of radius a ($|z - z_0| < a$) or when z is outside the annulus ($|z - z_0| > b$). We then have the Laurent expansion

$$f(z) = \sum_{n=-\infty}^{\infty} c_n (z - z_0)^n \quad (14)$$

for all z in the annulus, where the coefficients are given by contour integrals,

$$c_n = \frac{1}{2\pi i} \int_C \frac{f(z)}{(z - z_0)^{n+1}} dz, \quad (15)$$

in which C is a simple closed contour in the annulus that encircles the hole (once) in the counterclockwise direction. Note that the sum in (14) is over all n . It is often convenient to split the sum, giving, for all z in the

annulus,

$$f(z) = \sum_{n=0}^{\infty} a_n(z - z_0)^n + \sum_{n=1}^{\infty} \frac{b_n}{(z - z_0)^n}, \quad (16)$$

where $a_n = c_n$ for $n = 0, 1, 2, \dots$ and $b_n = c_{-n}$ for $n = 1, 2, \dots$. In particular,

$$b_1 = \frac{1}{2\pi i} \int_C f(z) dz. \quad (17)$$

Suppose that $f(z)$ is also analytic in the hole, so that $f(z)$ is analytic in the disk $|z - z_0| < b$. Then $b_n = 0$ ($n = 1, 2, \dots$) by Cauchy's theorem and $a_n = f^{(n)}(z_0)/n!$ by (13); Taylor's theorem is recovered. Note that, in general, when f does have singularities in the hole, we cannot use (13) to evaluate the contour integrals defining a_n .

9 Singularities

A singularity is a point at which a function is not differentiable. There are several kinds of singularities. A point z_0 is called an *isolated singularity* if there is an annulus $0 < |z - z_0| < b$ (a “punctured disk”) in which there are no other singularities. In this annulus, we have a Laurent expansion, (16). The first part (the sum over a_n) is a power series, and so it defines an analytic function on the whole disk. The singular behavior resides in the second sum (over b_n); it is called the *principal part*, $P(z)$. In practice, $P(z)$ often has a finite number of terms,

$$P(z) = \frac{b_1}{z - z_0} + \frac{b_2}{(z - z_0)^2} + \cdots + \frac{b_m}{(z - z_0)^m}, \quad (18)$$

with $b_n = 0$ for all $n > m$ and $b_m \neq 0$. In this situation, we say that f has a *pole of order m* at z_0 . A pole of order 1 is called a *simple pole* and a pole of order 2 is called a *double pole*. For example, all the following have simple poles at $z = 0$:

$$\frac{1}{z}, \quad \frac{1+z}{z}, \quad \frac{e^z}{z}, \quad \frac{\sin z}{z^2}, \quad \frac{\pi}{\sin \pi z}; \quad (19)$$

the last in this list also has simple poles at $z = \pm 1, \pm 2, \dots$. All the following have double poles at $z = 0$:

$$\frac{1}{z^2}, \quad \frac{1+z}{z^2}, \quad \frac{1}{z \sin z}, \quad \frac{\cos z}{z^2}, \quad \frac{1}{\sin^2 \pi z}. \quad (20)$$

If the principal part of the Laurent expansion contains an infinite number of nonzero terms, z_0 is called an *isolated essential singularity*. For example, $e^{1/z}$ has such a singularity at $z = 0$.

The coefficient b_1 (given by (17)) will play a special role later; it is called the *residue* of f at the isolated singularity, z_0 , and it is denoted by $\text{Res}[f; z_0]$.

There are also nonisolated singularities. The most common of these occur at branch points. For example, $f(z) = z^{1/2}$ has a branch-point singularity at $z = 0$. Note that any disk centered at $z = 0$ will include a piece of the branch cut emanating from the branch point; f is discontinuous across the cut, so it is certainly not differentiable there, implying that $z = 0$ is not an isolated singularity.

10 Cauchy's Residue Theorem

If we want to evaluate $I = \int_C f(z) dz$, the basic method is to parametrize each smooth piece of C and then use the definition (10). In principle, this works for any f and for any C . However, in practice, C is often closed and f is analytic apart from some singularities. In these happy situations, we can calculate I efficiently by using Cauchy's residue theorem. Thus, suppose that $f(z)$ is analytic inside the simple closed contour C (and continuous on C) apart from isolated singularities at z_j , $j = 1, 2, \dots, n$. (Note that f may have other singularities, including branch points, outside C , but these are of no interest here.) Then

$$\int_C f(z) dz = 2\pi i \sum_{j=1}^n \text{Res}[f; z_j], \quad (21)$$

where C is traversed counterclockwise. This important result is remembered as “ $2\pi i$ times the sum of the residues at the isolated singularities inside the contour.” If there are no singularities inside, we recover Cauchy's theorem (11).

To prove the theorem, we start with the case $n = 1$. There is a Laurent expansion about the sole singularity z_1 , convergent in a punctured disk $0 < |z - z_1| < b$. We deform C into a smaller contour (enclosing z_1) that is inside the disk. Then we use (17). In the general case, we deform C and “pinch off,” giving a sum of n contour integrals, each one containing one singularity.

To understand the pinching-off process, suppose that $n = 2$ and deform C into a dumbbell-shaped contour, with two circles joined by two parallel straight lines, L_1 and L_2 , traversed in opposite directions. The contributions from L_1 and L_2 cancel in the limit as the lines go together, leaving the contributions from disjoint closed contours around each singularity. This process is readily extended to any (finite) number of isolated singularities.

In order to exploit the residue theorem, we need efficient methods for computing residues. Recall that $\text{Res}[f; z_0]$ is the coefficient b_1 in the Laurent expansion

about z_0 (see (18)). For simple poles, b_1 is the only non-trivial coefficient in the principal part; thus, at a simple pole z_0 ,

$$\text{Res}[f; z_0] = \lim_{z \rightarrow z_0} \{(z - z_0)f(z)\}. \quad (22)$$

Often, simple poles are characterized by writing $f(z) = p(z)/q(z)$ with $q(z_0) = 0$, $p(z_0) \neq 0$, and $q'(z_0) \neq 0$. Then

$$\text{Res}[f; z_0] = p(z_0)/q'(z_0). \quad (23)$$

For a pole of order m , we can use

$$\text{Res}[f; z_0] = \frac{1}{m!} \lim_{z \rightarrow z_0} \frac{d^{m-1}}{dz^{m-1}} \{(z - z_0)^m f(z)\}.$$

However, it is sometimes quicker to construct the Laurent expansion directly and then to pick off b_1 , the coefficient of $1/(z - z_0)$. Thus, almost by inspection, all the simple-pole examples in (19) have $\text{Res}[f; 0] = 1$. The five double-pole examples in (20) have $\text{Res}[f; 0] = 0, 1, 0, 0$, and 0, respectively.

11 Evaluation of Integrals

Cauchy's residue theorem gives a powerful method for evaluating integrals. We give a few examples.

Let C be a circle of radius a centered at the origin and traversed counterclockwise. The function e^z/z has a simple pole at $z = 0$ with residue = 1. Hence

$$\int_C \frac{e^z}{z} dz = 2\pi i. \quad (24)$$

This result could have been obtained from the Cauchy integral formula (12) with $f(z) = e^z$ and $z_0 = 0$. Note also that the value of the integral does not depend on a ; this is not surprising because we know that we can deform C into a concentric circular contour (for example) without changing the value of the integral.

Now, starting from the result (24), suppose we parametrize C and then use (10); a suitable parametrization is $z(t) = ae^{it}$, $-\pi \leq t \leq \pi$. As $z'(t) =iae^{it} = iz(t)$, we obtain

$$\int_{-\pi}^{\pi} \exp(iae^{it}) dt = 2\pi.$$

By Euler's formula, $e^{it} = \cos \theta + i \sin \theta$, the integrand is $e^{a \cos t} \cos(a \sin t) + ie^{a \cos t} \sin(a \sin t)$. The second term is an odd function of t and so it integrates to zero, leaving

$$\int_0^{\pi} e^{a \cos t} \cos(a \sin t) dt = \pi. \quad (25)$$

Thus, from the known value of a fairly simple contour integral, (24), we obtained the value of a complicated real integral. Notice that the formula (25) was derived by assuming that the parameter a is real and positive.

In fact, it is valid for arbitrary complex a ; this is an example of analytic continuation (see section 13).

We now consider doing the opposite: evaluating integrals by converting them into contour integrals, followed by use of the residue theorem.

For trigonometric integrals such as

$$I_1 = \int_0^{2\pi} \frac{d\theta}{5 + 4 \cos \theta},$$

the substitution $z = e^{i\theta}$ will convert I_1 into a contour integral around the unit circle, $|z| = 1$. Using $d\theta/dz = 1/(iz)$ and $\cos \theta = \frac{1}{2}(z + z^{-1})$, we obtain

$$I_1 = \frac{1}{2i} \int_{|z|=1} \frac{dz}{(z+2)(z+\frac{1}{2})}.$$

The integrand is analytic apart from simple poles at $z = -2$ and $z = -\frac{1}{2}$. The latter is inside the contour; its residue is $\frac{2}{3}$ (use (22)). Cauchy's residue theorem (21) therefore gives $I_1 = \frac{2}{3}\pi$.

The method just described requires that the range of integration for θ have length 2π and that the resulting integrand have only isolated singularities (not branch points) inside $|z| = 1$.

For a second example, consider

$$I_2 = \int_{-\infty}^{\infty} f(x) dx \quad \text{with } f(x) = \frac{1}{x^4 + 1}.$$

In order to use the residue theorem, we need a closed contour C , so we try $\int_C f(z) dz$ with C consisting of a piece of the real axis from $z = -R$ to $z = R$ and a semicircle C_R in the upper half-plane of radius R and centered at $z = 0$. Then

$$\int_{-R}^R f(x) dx + \int_{C_R} f(z) dz = 2\pi i \times \begin{cases} \text{residues} \\ \text{at poles} \\ \text{inside } C. \end{cases} \quad (26)$$

After calculation of the residues, we let $R \rightarrow \infty$, so that the first integral $\rightarrow I_2$. We will see in a moment that the second integral $\rightarrow 0$ as $R \rightarrow \infty$.

Now, $z^4 + 1 = 0$ at $z = z_n = \exp(i(2n+1)\pi/4)$, $n = 0, 1, 2, 3$. These are simple poles of $f(z)$ with residue $1/(4z_n^3)$ (use (23) with $p = 1$, $q = z^4 + 1$). The poles z_0 and z_1 are in the upper half-plane. Hence the right-hand side of (26) is $\pi/\sqrt{2}$, and this is I_2 .

For $z \in C_R$ we parametrize using $z(t) = Re^{it}$, $0 \leq t \leq \pi$. We see that $f(z)$ decays as R^{-4} , whereas the length of C_R , πR , increases; overall, $\int_{C_R} f dz$ decays as R^{-3} . This rough argument can be made precise.

If we replace $f(z)$ by $e^{ikz}f(z)$, we can evaluate Fourier transforms such as

$$I_3 = \int_{-\infty}^{\infty} e^{ikx} f(x) dx \quad \text{with } f(x) = \frac{1}{x^2 + 1},$$

where k is a real parameter. However, some care is needed; as $e^{ikz} = e^{ikx}e^{-ky}$, we have exponential decay as $y \rightarrow \infty$ when $k > 0$ but exponential growth when $k < 0$. Therefore, we use C_R when $k > 0$, but we close using a semicircle in the lower half-plane when $k < 0$. We find that $I_3 = \pi e^{-|k|}$.

Laplace transforms (2) can be inverted using

$$g(t) = \frac{1}{2\pi i} \int_{c-i\infty}^{c+i\infty} f(z) e^{zt} dz.$$

The contour (called the *Bromwich contour*) is parallel to the y -axis in the z -plane. The constant c is chosen so that all the singularities of $f(z)$ are to the left of the contour. If $f(z)$ has poles only, the integral can be evaluated by closing the contour using a large semi-circle on the left.

There are many other applications of contour-integral methods to the evaluation of integrals. They can also be used to find the sums of infinite series. Integrands containing branch points can also be considered. In all cases, one may need some ingenuity in selecting an appropriate closed contour and/or the function $f(z)$.

12 Conformal Mapping

Suppose that $f(z)$ is analytic for $z \in D$. We can regard f as a mapping, taking points $z = x + iy$ to points $w = f(z) = u + iv$; denote the set of such points in the uv -plane for all points $z \in D$ by R . Given f and D , we can determine R . More interestingly, given the regions D and R , can we find an analytic function f that maps D onto R ? The *Riemann mapping theorem* asserts that any simply connected region D can be mapped to the unit disk $|w| < 1$. (A region bounded by a simple closed curve is simply connected if it does not contain any holes.) The analytic function f effecting the mapping is called a **CONFORMAL MAPPING** [II.5]; two small lines meeting at a point $z_0 \in D$ will be mapped into two small lines meeting at a point $w_0 = f(z_0) \in R$, and the angles between the two pairs of lines will be equal. The conformality property holds for all $z_0 \in D$ except for *critical points* (where $f'(z_0) = 0$ or ∞). Many conformal mappings are known (there are dictionaries of them), but constructing them for regions D with complicated shapes or holes remains a challenge. Once a conformal mapping is available, it can be used to solve boundary-value problems for Laplace's equation (6), for example.

13 Analytic Continuation

Return to the geometric series (1). Denote the infinite series on the left-hand side by $f(z)$, with domain D ($|z| < 1$). Denote the sum on the right-hand side by $g(z) = 1/(1-z)$, with domain D' ($z \neq 1$). We observe that $f(z)$ is analytic in D whereas $g(z)$ is analytic in the larger region D' . As $f(z) = g(z)$ for $z \in D$, we say that g is the *analytic continuation* of f into D' . In practice, we do not usually distinguish between f and g , we just say that $g(z)$ is analytic for $z \in D'$ and that it can be defined for $z \in D \subset D'$ using $f(z)$. This point of view is surprisingly powerful.

There are several aspects to this, and it raises several questions. To begin with, suppose we are given f and D and we want to find g outside D . There are analytical and numerical methods available for doing so. For example, we could use a chain of overlapping disks with a Taylor expansion about each center. The result will be locally unique (each step in the chain gives a unique result) but, if g has a branch point, we could step onto another branch and thus lose global uniqueness.

Often, we do not know D' ; typical analytic continuations will have singularities. For example, the gamma function, $\Gamma(z)$, is defined by the integral (3) for $\text{Re } z > 0$; in this half-plane, Γ is analytic. If we continue $\Gamma(z)$ into $\text{Re } z \leq 0$, we find that there are simple poles at $z = -N$, $N = 0, 1, 2, \dots$ (so that D' is the whole complex plane with the points $z = -N$ removed). Explicitly, we can use *Hankel's loop integral*:

$$\Gamma(z) = \frac{1}{2i \sin(\pi z)} \int_C t^{z-1} e^t dt.$$

This is a contour integral in the complex t -plane. There is a cut along the negative real- t axis. The branch of t^z is chosen so that $t^z = e^{z \log t}$ when t is real and positive. The contour starts at $\text{Re } t = -\infty$, below the cut, goes once around $t = 0$, and then returns to $\text{Re } t = -\infty$ above the cut.

There are also loop integrals for the Riemann zeta function, $\zeta(z)$, defined initially for $\text{Re } z > 1$ by the series (9). Thus, it turns out that $\zeta(z)$ can be analytically continued into the whole z -plane apart from a simple pole at $z = 1$.

14 Differential Equations

We usually think of a differential equation as being something to be solved for a real function of a real variable. However, it can be advantageous to "complexify" the problem. One good reason is that we may be able to construct solutions using a power-series expansion (8),

and we know that the convergence of such a series is governed by singularity locations. (More generally, we could use the “method of Frobenius.”) For example, one solution of *Airy’s equation*, $w''(z) = zw(z)$, is

$$w(z) = 1 + \frac{1}{3!} z^3 + \frac{1 \cdot 4}{6!} z^6 + \frac{1 \cdot 4 \cdot 7}{9!} z^9 + \dots,$$

which defines an entire function of z .

We may be able to write solutions as contour integrals, which then offers possibilities for further analysis. For example, solutions of Airy’s equation can be written (or sought) in the form

$$w(z) = \int_C e^{-zt+t^3/3} dt,$$

where C is a carefully chosen contour in the complex t -plane.

The study of linear differential equations is a well-established branch of complex analysis, especially in the context of the classical SPECIAL FUNCTIONS [IV.7] (e.g., Bessel functions and hypergeometric functions). Nonlinear differential equations and their associated special functions are also of interest. For example, there are the six PAINLEVÉ EQUATIONS [III.24], the simplest being $w''(z) = 6w^2 + z$; their solutions, known as *Painlevé transcedents*, have a variety of physical applications, but their properties are not well understood.

15 Cauchy Integrals

Let C be a simple closed smooth contour. Denote the interior of C by D_+ and the exterior by D_- . Define a function $F(z)$ by the *Cauchy integral*

$$F(z) = \frac{1}{2\pi i} \int_C \frac{g(\tau)}{\tau - z} d\tau, \quad z \notin C, \quad (27)$$

where $g(t)$ is defined for $t \in C$. For example, if $g(t) = 1$, $t \in C$, then

$$\frac{1}{2\pi i} \int_C \frac{d\tau}{\tau - z} = \begin{cases} 1, & z \in D_+, \\ 0, & z \in D_-. \end{cases} \quad (28)$$

The integral in (27) is similar to that which appears in Cauchy’s integral formula (12), except we are not given any information about $g(t)$ when $t \notin C$. Nevertheless, under mild conditions on g , $F(z)$ is analytic for $z \in D_+ \cup D_-$, and $F(z) \rightarrow 0$ as $z \rightarrow \infty$. What are the values of F on C ? The example (28) suggests that we should expect $F(z)$ to be discontinuous as z crosses C . Therefore, we consider the limits of $F(z)$ as z approaches C (if they exist), and write

$$F_{\pm}(t) = \lim_{z \rightarrow t} F(z) \quad \text{with } z \in D_{\pm} \text{ and } t \in C. \quad (29)$$

For the example (28), $F_+(t) = 1$ and $F_-(t) = 0$.

Notice that we cannot simply put $z = t \in C$ on the right-hand side of (27); the resulting integral diverges. However, if g is differentiable at t (in fact, Hölder continuity is sufficient), we can define the *Cauchy principal-value integral*

$$\int_C \frac{g(\tau)}{\tau - t} d\tau = \lim_{\varepsilon \rightarrow 0} \int_{C_\varepsilon} \frac{g(\tau)}{\tau - t} d\tau, \quad t \in C,$$

where C_ε is obtained from C as follows: draw a little circle of radius ε , centered at $t \in C$, and then remove the piece of C inside the circle.

Using this definition, define

$$F(t) = \frac{1}{2\pi i} \int_C \frac{g(\tau)}{\tau - t} d\tau, \quad t \in C.$$

This function is related to $F_{\pm}(t)$, defined by (29), by the *Sokhotski-Plemelj formula*:

$$F_{\pm}(t) = \pm \frac{1}{2} g(t) + F(t), \quad t \in C. \quad (30)$$

This describes the “jump behavior” of the Cauchy integral $F(z)$ as z crosses C . In particular,

$$F_+(t) - F_-(t) = g(t), \quad t \in C. \quad (31)$$

One elegant consequence of (30) is that the solution, w , of the *singular integral equation*

$$\frac{1}{\pi i} \int_C \frac{w(\tau)}{\tau - t} d\tau = g(t), \quad t \in C,$$

is given by the formula

$$w(t) = \frac{1}{\pi i} \int_C \frac{g(\tau)}{\tau - t} d\tau, \quad t \in C.$$

16 The Riemann-Hilbert Problem

Let D_{\pm} and C be as in section 15. Suppose that two functions, $G(t)$ and $g(t)$, are given for $t \in C$. Then, the basic *Riemann-Hilbert problem* is to find two functions $\Phi_+(z)$ and $\Phi_-(z)$, with Φ_{\pm} analytic in D_{\pm} , that satisfy

$$\Phi_+(t) = G(t)\Phi_-(t) + g(t), \quad t \in C, \quad (32)$$

where $\Phi_+(t)$ and $\Phi_-(t)$ are defined as in (29); conditions on $\Phi_-(z)$ as $z \rightarrow \infty$ are usually imposed too. (There is a variant where C is not closed; in this case, the behavior near the endpoints of C plays a major role.)

When $G \equiv 1$, we can solve (32) using a Cauchy integral and (31). When $G \neq 1$, we start with the following homogeneous problem ($g \equiv 0$).

Find functions K_+ and K_- , with K_{\pm} analytic in D_{\pm} , that satisfy

$$K_+(t) = G(t)K_-(t), \quad t \in C. \quad (33)$$

Suppose we can find such functions and that they do not vanish. Then, eliminating G from (32) gives

$$\frac{\Phi_+(t)}{K_+(t)} - \frac{\Phi_-(t)}{K_-(t)} = \frac{g(t)}{K_+(t)}, \quad t \in C,$$

which, again, we can solve using a Cauchy integral and (31).

The problem of finding K_{\pm} is more delicate. At first sight, we could take the logarithm of (33), giving $\log K_+ - \log K_- = \log G$. This looks similar to (31), but it usually happens that $\log G(t)$ is not continuous for all $t \in C$, which means that we cannot use (30). However, this difficulty can be overcome.

The problem of finding K_{\pm} such that (33) is satisfied is also the key step in the *Wiener-Hopf technique* (a method for solving linear PDEs with mixed boundary conditions and semi-infinite geometries). In that context, a typical problem would be: factor a given function $L(z)$ as $L(z) = L_+(z)L_-(z)$, where $L_+(z)$ is analytic in an upper half-plane, $\text{Im } z > a$, $L_-(z)$ is analytic in a lower half-plane, $\text{Im } z < b$, and $a < b$ so that the two half-planes overlap. There are also related problems where L is a 2×2 or 3×3 matrix; it is not currently known how to solve such *matrix Wiener-Hopf problems* except in some special cases.

17 Closing Remarks

Complex analysis is a rich, deep, and broad subject with a history going back to Cauchy in the 1820s. Inevitably, we have omitted some important topics, such as approximation theory in the complex plane and analytic number theory. There are numerous fine textbooks, a few of which are listed below. However, do not get the impression that complex analysis is a dead subject; it is not. In this article we have tried to cover the basics, with some indications of where problems and opportunities remain.

IV.2 Ordinary Differential Equations

James D. Meiss

1 Introduction

Differential equations are near-universal models in applied mathematics. They encapsulate the idea that change occurs incrementally but at rates that may depend upon the state of the system. A system of *ordinary differential equations* (ODEs) prescribes the rate of change of a set of functions, $\mathbf{y}(t) = (y_1(t), y_2(t), \dots, y_k(t))$, that depend upon a single variable t , which may be real or complex. The functions y_j are the *dependent variables* of the system, and t is the *independent variable*. (If there is more than one independent variable, then the system becomes a *PARTIAL DIFFERENTIAL EQUATION* [IV.3] (PDE).) Perhaps the most famous ODE is Newton's second law of motion,

$$m\ddot{\mathbf{y}} = \mathbf{F}(\mathbf{y}, \dot{\mathbf{y}}, t),$$

which relates the acceleration of the center of mass $\mathbf{y} \in \mathbb{R}^3$ of a body of mass m to an externally applied force \mathbf{F} . This force commonly depends upon the position of the body, \mathbf{y} ; its velocity, $\dot{\mathbf{y}}$ (e.g., electromagnetic or damping forces); and perhaps upon time, t (e.g., time-varying external control). The force may also depend upon positions of other bodies; a prominent example is the *n-BODY PROBLEM* [VI.16] of gravitation. We will follow the convention of denoting the first derivative by $\dot{\mathbf{y}}$ or \mathbf{y}' , the second by $\ddot{\mathbf{y}}$ or \mathbf{y}'' , and, in general, the k th by $\mathbf{y}^{(k)}$.

Newton's law is a system of second-order ODEs. More generally, an ODE system is of n th order if it involves the first n derivatives of a k -dimensional vector \mathbf{y} ; formally, therefore, it is a relation of the form

$$G(\mathbf{y}, \mathbf{y}^{(1)}, \mathbf{y}^{(2)}, \dots, \mathbf{y}^{(n)}; t) = 0. \quad (1)$$

An example is Clairaut's differential equation for a scalar function $y(t)$:

$$-y + t\dot{y} + g(\dot{y}) = 0. \quad (2)$$

This is a first-order ODE since it involves only the first derivative of y . Equations like this are *implicit*,

since they can be viewed as implicitly defining the highest derivative as a function of y and its lower derivatives. Clairaut's equation depends explicitly on the independent variable; such ODEs are said to be *nonautonomous*.

Clairaut showed in 1734 that (2) has a particularly simple family of solutions: $y(t) = ct + g(c)$ for any $c \in \mathbb{R}$. While it might not be completely obvious how to find this solution, it is easy to verify that it does solve (2) by simple substitution since, on the proposed solution $\dot{y} = c$, we have $-y + t\dot{y} + g(\dot{y}) = -(ct + g(c)) + tc + g(c) \equiv 0$. More generally, a *solution* of the ODE (1) on an interval (a, b) is a function $y(t)$ that makes (1) identically zero for all $t \in (a, b)$. More specifically, a solution may be required to solve an *initial-value problem* (IVP) or a boundary-value problem (see section 5). For the first-order case, the former means finding a function with a given value, $y(t_0) = y_0$, at a given "initial" time t_0 . For example, the family of solutions to (2) satisfies the initial condition $y(0) = y_0$ so long as there is a c such that $y_0 = g(c)$, i.e., y_0 is in the range of g . A family $y(t; c)$ that satisfies an IVP for a domain of initial values is known as a *general solution*.

Apart from these families of solutions, implicit ODEs can also have *singular* solutions. For example, (2) also has the solution defined parametrically by $(t(s), y(s)) = (-g'(s), g(s) - sg'(s))$. Again, it is easy to verify that this is a solution to (2) by substitution (and implicit differentiation), but it is perhaps not obvious how to find it. Lagrange showed that some singular solutions of an implicit ODE can be found as envelopes of the general solutions, but the general theory was developed later by Cayley and Darboux.

The classical theory of ODEs, originating with Newton in his *Method of Fluxions* in 1671, has as its goal the construction of the general and singular solutions of an ODE in terms of elementary functions. However, in most cases, ODEs do not have such explicit solutions. Indeed most of the well-known SPECIAL FUNCTIONS [IV.7] of mathematics are defined as solutions of differential equations. For example, the BESSEL FUNCTION [III.2] $J_n(x)$ is defined to be the unique solution of the second-order, explicit, nonautonomous, scalar IVP

$$\left. \begin{aligned} x^2 y'' + xy' + (x^2 - n^2)y &= 0, \\ y(0) &= \delta_{n,0}, \quad y'(0) = \frac{1}{2}\delta_{n,1}, \end{aligned} \right\} \quad (3)$$

where $\delta_{i,j}$, the Kronecker delta, is nonzero only when $i = j$ and $\delta_{i,i} = 1$. This equation arises from a number of PDEs through separation of variables. Many

of the properties of J_n (e.g., its power-series expansion, asymptotic behavior, etc.) are obtained by direct manipulation of this ODE.

In most applications, the ODE (1) can be written in the explicit form

$$\frac{d^n}{dt^n} y = H(y, \dot{y}, \ddot{y}, \dots, \dot{y}^{(n-1)}; t). \quad (4)$$

Such systems can always be converted into a system of first-order ODEs. For example, if we let $x = (y, \dot{y}, \dots, \dot{y}^{(n-1)}, t)$ denote a list of $d = nk + 1$ variables, it is then easy to see that (4) can be rewritten as the autonomous first-order system

$$\dot{x} = f(x) \quad (5)$$

for a suitable f . Every coupled set of k , n th-order, explicit ODEs can be written in the form (5).¹ The ODE (5) is a common form in applications, e.g., in population models of ecology or in Hamiltonian dynamics. In general, $x \in M$, where M is a d -dimensional manifold called the *phase space*. For example, the phase space of the planar pendulum is a cylinder with $x = (\theta, p_\theta)$, where θ and p_θ are the angle and angular momentum, respectively.

In general, the function f in (5) gives a velocity vector (an element of the tangent space TM) for each point in the manifold M ; thus $f: M \rightarrow TM$. Such a function is a *vector field*. A solution $\varphi: (a, b) \rightarrow M$ of (5) is a differentiable curve $x(t) = \varphi(t)$ in M with velocity $f(\varphi(t))$; it is everywhere tangent to f . Given such a curve it is trivial to check to see if it solves (5); by contrast, the construction of solutions is a highly nontrivial task. A *general solution* of (5) has the form $x(t) = \varphi(t; c)$. Here, $c \in \mathbb{R}^d$ is a set of parameters such that, for each $t_0 \in (a, b)$ and each initial condition $x_0 \in M$, the equation $\varphi(t_0; c) = x_0$ can be solved for c .

A *general solution* of (5) is a solution $x(t) = \varphi(t; c)$ that depends upon d parameters, c , such that for any IVP, $x(t_0) = x_0 \in M$ with $t_0 \in (a, b)$, there is a $c \in \mathbb{R}^d$ such that $\varphi(t_0; c) = x_0$. The search for explicit, general solutions of (5) is, in most cases, quixotic.

2 First-Order Differential Equations

Many techniques were developed through the first half of the eighteenth century for obtaining analytical solutions of first-order ODEs. The equations were often motivated by mechanical problems such as the

1. Though (5) is autonomous, the study of nonautonomous equations per se is not without merit. For example, stability of periodic orbits is most fruitfully studied as a nonautonomous linear problem.

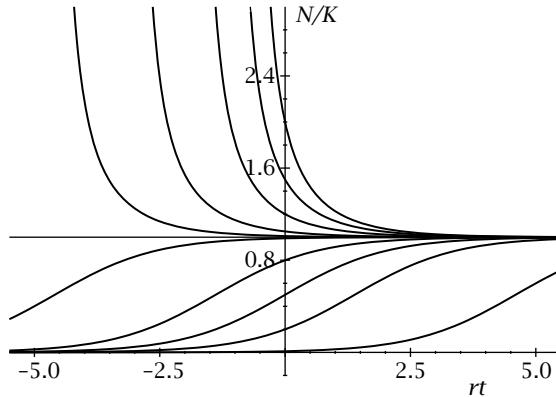

Figure 1 Solutions of the logistic ODE (7). The equilibria $N = 0$ and $N = K$ are the horizontal lines.

isochrone (find a pendulum whose period is independent of amplitude), which was solved by James Bernoulli in 1690, and da Vinci's catenary (find the shape of a suspended cable), which was solved by John Bernoulli in 1691.

During this period a number of methods were devised that can be applied to general categories of systems. In 1691 Leibniz formulated the method of separation of variables: the formal solution of the ODE $dy/dx = g(x)h(y)$ has the implicit form

$$\int \frac{dy}{h(y)} = \int g(x) dx. \quad (6)$$

Any autonomous first-order ODE is separable. For example, for the LOGISTIC POPULATION MODEL [III.19]

$$\dot{N} = rN(1 - N/K), \quad (7)$$

the integrals can be performed and the result solved for N to obtain

$$N(t) = \frac{N_0 K}{N_0 + (K - N_0)e^{-rt}}. \quad (8)$$

Representative solutions are sketched in figure 1. Note that, whenever $N_0 > 0$, this solution tends, as $t \rightarrow \infty$, to K , the “carrying capacity” of the environment. This value and $N = 0$ are the two *equilibria* of (7), since the vector field vanishes at these points.

The differential equation $N(x, y)y' + M(x, y) = 0$ can be formally rewritten as the vanishing of a differential one-form, $M(x, y)dx + N(x, y)dy = 0$. In 1739 Clairaut solved such equations when this one-form is exact, that is (for \mathbb{R}^2), when $\partial M/\partial y = \partial N/\partial x$. In 1734 Euler had already developed the more general method of integrating factors: if one can devise a function $F(x, y)$ such that the form $F(Mdx + Ndy)$ equals

the total differential

$$dH \equiv \frac{\partial H}{\partial x} dx + \frac{\partial H}{\partial y} dy$$

of a function $H(x, y)$, then the solutions to $dH = 0$ lie on contours of $H(x, y)$. As an example, the integral curves of a Hamiltonian system with one degree of freedom,

$$\dot{x} = -\frac{\partial H}{\partial y}(x, y), \quad \dot{y} = \frac{\partial H}{\partial x}(x, y), \quad (9)$$

are those curves that are everywhere tangent to the velocity; equivalently, they are orthogonal to the gradient vector $\nabla H \equiv (\partial H/\partial x, \partial H/\partial y)$. Denoting the infinitesimal tangent vector by (dx, dy) , this requirement becomes the exact one-form $(dx, dy) \cdot \nabla H = 0$. Its solutions lie on contours $H(x, y) = E$ with constant “energy.” This method gives the phase curves or *trajectories* of the planar system but does not provide the time-dependent functions $x(t)$ and $y(t)$. However, using the constancy of H , the ODE for x , say, becomes $\dot{x} = \partial_y H(x, y(x; E))$, a separable first-order equation whose solution can be obtained *up to the quadrature* (6).

The technique of substitution was also used to solve many special cases (just as for integrating factors, there is no general prescription for finding an appropriate substitution). For example, James Bernoulli's nonautonomous, first-order ODE

$$y' = P(x)y + Q(x)y^n$$

is linearized by the change of variables $z = y^{1-n}$. Similarly, Leibniz showed that the degree-zero, homogeneous equation $y' = G(y/x)$ becomes separable with the substitution $y(x) = xv(x)$.

Discussion of these and other methods can be found in various classic texts, such as Ince (1956).

3 Linear ODEs

In 1743 Euler showed how to solve the n th-order linear constant-coefficient equation

$$\sum_{j=0}^n a_j \frac{d^j y}{dt^j} = 0 \quad (10)$$

by using the exponential ansatz, $y = e^{rt}$, to reduce the ODE to the n th-degree *characteristic equation* $p(r) = \sum_{j=0}^n a_j r^j = 0$. Each root, r_k , of p provides a solution $y(t) = e^{r_k t}$. Linearity implies that a superposition of these solutions, $y(t) = \sum_{k=0}^n c_k e^{r_k t}$, is also a solution for any constant coefficients c_k . When $p(r)$ has a root r^* of multiplicity $m > 1$, Euler's reduction-of-order

method suggests the further ansatz $y(t) = e^{r^* t} u(t)$. This provides new solutions when u satisfies $u^{(m)} = 0$, which has as its general solution a degree- $(m - 1)$ polynomial in t . The general solution therefore becomes a superposition of n linearly independent functions of the form $t^\ell e^{r_k t}$. Even when the ODE is real, the roots $r_k = \alpha_k + i\beta_k$ may be complex. In this case, the conjugate root can be used to construct real solutions of the form $t^\ell e^{\alpha_k t} \cos(\beta_k t)$ and $t^\ell e^{\alpha_k t} \sin(\beta_k t)$ for $\ell = 0, \dots, m - 1$. A superposition of these real solutions has n arbitrary real constants c_k , and since the functions are independent, there is a choice of these constants that solves the IVP $y^{(k)}(t_0) = b_k$, $k = 0, \dots, n - 1$, for arbitrarily specified values b_k .

More generally, when (5) is linear, it reduces to

$$\dot{x} = Ax \quad (11)$$

for a constant, $n \times n$ matrix A . Formally, the general solution of this system can be written as the matrix exponential: $x(t) = e^{tA}x(0)$. As for more general FUNCTIONS OF MATRICES [II.14], we can view this as defining the symbol e^{tA} as the solution of the ODE. More explicitly, this exponential is defined by the same convergent MacLaurin series as e^{at} for scalar a . If A is semisimple (i.e., if it has a complete eigenvector basis), then A is diagonalized by the matrix P whose columns are eigenvectors: $A = P\Lambda P^{-1}$, where $\Lambda = \text{diag}(\lambda_1, \dots, \lambda_n)$ is the diagonal matrix of eigenvalues. In this case,

$$e^{tA} = P \text{diag}(e^{\lambda_1 t}, \dots, e^{\lambda_n t})P^{-1}.$$

More generally, e^{tA} also contains powers of t , generalizing the simpler, scalar situation.

The nonhomogeneous linear system

$$\dot{x} = Ax + g(t)$$

with forcing function $g \in \mathbb{R}^n$ can be solved by Lagrange's method of variation of parameters. The idea is to replace the parameters $x(0)$ in the homogeneous solution by functions $u(t)$. Substitution of $x(t) = e^{tA}u(t)$ into the ODE permits the unknown functions to be isolated and yields the integral form

$$x(t) = e^{tA}x(0) + \int_0^t e^{(t-s)A}g(s)ds.$$

Solution of linear, nonautonomous ODEs, $\dot{x} = A(t)x$, is much more difficult. The source of the difficulty is that $A(t)$ does not generally commute with $A(s)$ when $t \neq s$. Indeed, $e^A e^B \neq e^{A+B}$ unless the matrices do commute (the Baker–Campbell–Hausdorff theorem from Lie theory gives a series expansion for the product). The special case of a time-periodic family of matrices $A(t) = A(t + T)$ can be solved. Floquet showed

that the general solution for this case takes the form $x(t) = P(t)e^{tB}x(0)$, where B is a real, constant matrix and $P(t)$ is a periodic matrix with period $2T$. One much-studied example of this form is MATHIEU'S EQUATION [III.21].

More generally, finding a transformation to a set of coordinates in which the effective matrix is constant is called the *reducibility problem*; even for a quasiperiodic dependence on time, this is nontrivial.

4 Singular Points

Consider the linear ODE (10), now allowing the coefficients $a_j(t)$ to be analytic functions of $t \in \mathbb{C}$ so that it is nonautonomous. Cauchy showed that, if the coefficients are analytic in a neighborhood of t_0 and if $a_n(t_0) \neq 0$, this ODE has n independent analytic solutions. The coefficients of the power series of y can be determined from a recursion relation upon substitution of a series for y into the ODE.

A point at which some of the ratios $a_j(t)/a_n(t)$ are singular is a (fixed) *singular point* of the ODE, and the solution need not be analytic at t_0 . There are two distinct cases. A singular point is *regular* if $a_{n-j}(t)/a_n(t)$ has at most a j th-order pole for each $j = 1, \dots, n$. In this case, there is an $r \in \mathbb{C}$ such that there is at least one solution of the form $y(t) = (t - t_0)^r \phi(t)$ with ϕ analytic at t_0 . Additional solutions may also have logarithmic singularities. An ODE for which all singular points are regular is called *Fuchsian*.

Most of the SPECIAL FUNCTIONS [IV.7] of mathematical physics are defined as solutions of second-order linear ODEs with regular singular points. Many are special cases of the hypergeometric equation

$$z(1-z)w'' + (y - (\alpha + \beta + 1)z)w' - \alpha\beta w = 0 \quad (12)$$

for a complex-valued function $w(z)$. This ODE has regular singular points at $z = 0, 1$, and ∞ (the latter obtained upon transforming the independent variable to $u = 1/z$). For the singular point at 0, following Frobenius, we make the ansatz that the solution has the form of a series:

$$w(z) = z^r \sum_{j=0}^{\infty} c_j z^j.$$

Substitution into (12) yields $c_0 p(r)z^{r-1} + \mathcal{O}(z^r) = 0$, and if this is to vanish with $c_0 \neq 0$, then r must satisfy the *indicial equation* $p(r) = r^2 + (y - 1)r = 0$, with roots $r_1 = 0$ and $r_2 = 1 - y$. A recursion relation for the c_j , $j > 0$, is obtained from the terms of order z^{r+j-1} .

For $r_1 = 0$, this yields the GAUSS HYPERGEOMETRIC FUNCTION [IV.7 §5]

$$F(\alpha, \beta, \gamma; z) = \frac{\Gamma(\gamma)}{\Gamma(\alpha)\Gamma(\beta)} \sum_{j=0}^{\infty} \frac{\Gamma(\alpha+j)\Gamma(\beta+j)}{j!\Gamma(\gamma+j)} z^j,$$

where the gamma function Γ generalizes the factorial. When $\gamma \notin \mathbb{Z}$, the second solution turns out to be $x^{1-\gamma} F(\alpha-\gamma+1, \beta-\gamma+1, 2-\gamma; x)$, which is not analytic at $z = 0$.

When the indicial equation has roots that differ by an integer, a second solution can be found by the method of reduction of order. For example, for the second-order case, suppose $r_1 - r_2 \in \mathbb{N}$ and let $w_1(z) = e^{r_1 t} \phi_1(t)$ be the solution for r_1 . Substitution of the ansatz $w(z) = w_1(z) \int v(z) dz$ shows that v satisfies a first-order ODE with a regular singular point at 0 whose indicial equation has the negative integer root $r_2 - r_1 - 1$. If the power series for v has $\mathcal{O}(z^{-1})$ terms, then $w(z)$ has logarithmic singularities; ultimately, the second solution has the form $w(z) = z^{r_2} \phi_2(z) + c w_1(z) \ln z$, where ϕ_2 is analytic at 0 and c might be zero. Thus, for example, the second hypergeometric solution for integral γ , where the roots of the indicial equation differ by an integer, has logarithmic singularities.

Near an *irregular* singular point, the solution may have essential singularities. For example, the first-order ODE $z^2 w' = w$ has an irregular singular point at 0; its solution, $w(z) = ce^{-1/z}$, has an essential singularity there. Similarly, Bessel's equation (3) has an irregular singular point at ∞ .

Singular points of nonlinear ODEs can be fixed (i.e., determined by singularities of the vector field) or movable. In the latter case, the position of the singularity depends upon initial conditions. The study of equations whose only movable singularities are poles leads to the theory of PAINLEVÉ TRANSCENDENTS [III.24].

5 Boundary-Value Problems

So far we have considered IVPs for systems of the form (5), that is, when the imposed values occur at one point, $t = t_0$. Another common formulation is that of a boundary-value problem (BVP), where properties of the solution are specified at two distinct points. Such problems commonly occur for ODEs that arise by separation of variables from PDEs. They also occur in control theory, where constraints may be applied at different times.

A classical BVP is the Sturm-Liouville equation:

$$\left. \begin{aligned} -(p(x)y')' + q(x)y &= \lambda r(x)y, \\ \alpha_1 y(a) + \alpha_2 y'(a) &= 0, \\ \beta_1 y(b) + \beta_2 y'(b) &= 0. \end{aligned} \right\} \quad (13)$$

Here, λ is a parameter, e.g., the separation constant for the PDE case, $p \in C^1[a, b]$, $q, r \in C^0[a, b]$, p and the weight function r are assumed to be positive, and $\alpha_1 \alpha_2, \beta_1 \beta_2 \neq 0$. For example, Bessel's equation (3) takes this form, with $p(x) = -q(x) = x$ and $r(x) = 1/x$, if appropriate boundary conditions are imposed.

The Sturm-Liouville problem has (unique) solutions $y_n(x) \in C^2[a, b]$ only for a discrete set λ_n , $n \in \mathbb{N}$, of values of the separation constant. Moreover, these “eigenfunctions” and their corresponding “eigenvalues” have a number of remarkable properties.

Ordering: $\lambda_1 < \lambda_2 < \dots < \lambda_n < \dots$

Oscillation: $y_n(x)$ has $n - 1$ simple zeros in (a, b) .

Growth: $\lambda_n \rightarrow \infty$ as $n \rightarrow \infty$.

Orthogonality: $\int_a^b r(x) y_n(x) y_m(x) dx = \delta_{m,n}$.

Completeness: the set y_n is a basis for the space $L^2(a, b)$.

Perhaps the simplest such problem is $y'' = -\lambda y$ with $y(0) = y(1) = 0$. Here, the eigenvalues are $\lambda_n = (n\pi)^2$ and the eigenfunctions are $y_n = \sin(n\pi x)$. The completeness of these functions in $L^2(0, 1)$ is the expression of the convergence of the Fourier sine series. A more interesting problem is the quantum harmonic oscillator, which, when nondimensionalized, is governed by the Schrödinger equation

$$-\psi'' + x^2 \psi = \lambda \psi. \quad (14)$$

Here, λ is related to the energy $E = \frac{1}{2}\lambda\hbar\omega$ for classical frequency ω . This is a Sturm-Liouville problem for $\psi \in L^2(-\infty, \infty)$. The solutions are most easily obtained by the substitution $\psi(x) = e^{-x^2/2} y(x)$ that transforms (14) to the Hermite equation $y'' - 2xy' + (\lambda - 1)y = 0$. This ODE has degree- $(n - 1)$ polynomial solutions when $\lambda_n = 2n - 1$, $n \in \mathbb{N}$; otherwise, the wave function ψ is not square integrable. The first five orthonormal eigenstates of (14) are shown in figure 2.

6 Equilibria and Stability

Apart from the solution of linear PDEs, linear systems of ODEs find their primary application in the study of the stability of equilibria of the nonlinear system (5). A point x^* is an equilibrium if $f(x^*) = 0$. If $f \in C^1$, then

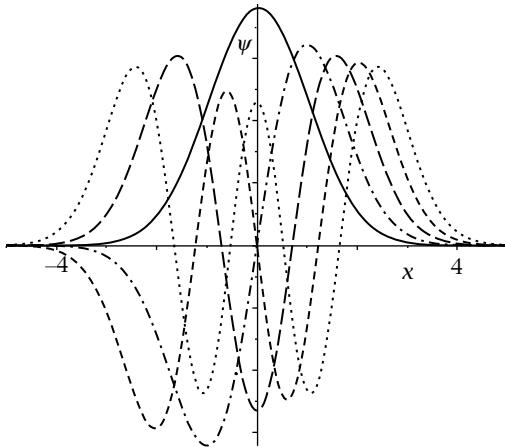

Figure 2 The first five eigenstates of the Sturm-Liouville problem (14).

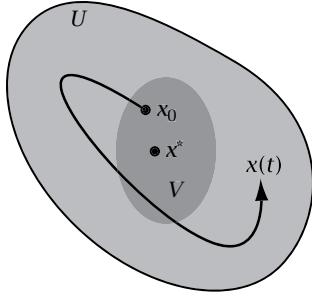

Figure 3 A Lyapunov-stable equilibrium x^* .

the dynamics of a nearby point $x(t) = x^* + \delta x(t)$ may be approximated by $\delta \dot{x} = Df(x^*)\delta x$, where $(Df)_{ij} = \partial f_i / \partial x_j$ is the Jacobian matrix of the vector field.

An equilibrium is *Lyapunov stable* if, for every neighborhood U , there is a neighborhood $V \subset U$ such that if $x(0) \in V$ then $x(t) \in U$ for all $t > 0$ (see figure 3). For the case in which $A = Df(x^*)$ is a hyperbolic matrix (its spectrum does not intersect the imaginary axis), the stability of x^* can be decided by the eigenvalues of A . Indeed, the Hartman-Grobman theorem states that in this case there is a neighborhood U of x^* such that there is a coordinate change (a homeomorphism) that takes the dynamics of (5) in U to that of (11). In this case we say that the two dynamical systems are topologically conjugate on U .

An equilibrium is stable if all of the eigenvalues of A are in the left half of the complex plane, $\text{Re}(\lambda) < 0$. Indeed, in this case it is *asymptotically* stable: there is a neighborhood U such that every solution that starts in

U remains in U and converges to x^* as $t \rightarrow \infty$. In this case, x^* is a stable *node*. When there are eigenvalues with both positive and negative real parts, then x^* is a *saddle*. The case of complex eigenvalues deserves special mention, since the solution of the linear system then involves trigonometric functions and there are solutions in \mathbb{R}^d that are infinite spirals. This is not necessarily the case when nonlinear terms are added, however: the homeomorphism that conjugates the system in U may unwrap the spirals.

As an example consider the damped Duffing oscillator²

$$\dot{x} = y, \quad \dot{y} = -\mu y + x(1 - x^2), \quad (15)$$

with the phase portrait shown in figure 4 when $\mu = \frac{1}{2}$. There are three equilibria: $(0, 0)$ and $(\pm 1, 0)$. The Jacobian at the origin is

$$Df(0, 0) = \begin{pmatrix} 0 & 1 \\ 1 & -\frac{1}{2} \end{pmatrix},$$

with eigenvalues $\lambda_{1,2} = -\frac{1}{4}(1 \pm \sqrt{17})$. Since these are real and of opposite signs, the origin is a saddle. By contrast, the Jacobian of the other fixed points is

$$Df(\pm 1, 0) = \begin{pmatrix} 0 & 1 \\ -2 & -\frac{1}{2} \end{pmatrix},$$

with the complex eigenvalues $\lambda_{1,2} = -\frac{1}{4}(1 \pm i\sqrt{31})$. Since the real parts are negative, these points are both attracting foci. They are still foci in the nonlinear system, as illustrated in figure 4, since trajectories that approach them cross the line $y = 0$ infinitely many times. Apart from the saddle and its *stable manifold* (the dotted curve in the figure), every other trajectory is asymptotic to one of the foci; these are *attractors* whose basins of attraction are separated by the stable manifold of the saddle.

The stability of a nonhyperbolic equilibrium (when A has eigenvalues on the imaginary axis) is delicate and depends in detail on the nonlinear terms, i.e., the $\mathcal{O}(\delta x^2)$ terms in the expansion of f about x^* . For example, the system

$$\dot{x} = -y + ax(x^2 + y^2), \quad \dot{y} = x + ay(x^2 + y^2) \quad (16)$$

has only one equilibrium, $(0, 0)$. The Jacobian at the origin has eigenvalues $\lambda = \pm i$; its dynamics are that of a *center*. Nevertheless, the dynamics of (16) near $(0, 0)$ depend upon the value of a . This can be easily seen by transforming to polar coordinates using $(x, y) =$

2. George Duffing studied the periodically forced version of (15) in 1918.

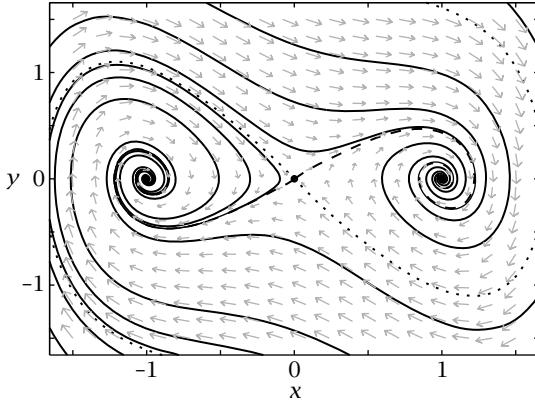

Figure 4 The phase portrait of (15) for $\mu = \frac{1}{2}$. Arrows depict the vector field, and dots depict the three equilibria. The unstable (dashed) and stable (dotted) manifolds of the saddle are shown.

$(r \cos \theta, r \sin \theta)$:

$$\begin{aligned}\dot{r} &= \frac{1}{r}(x\dot{x} + y\dot{y}) = ar^3, \\ \dot{\theta} &= \frac{1}{r^2}(x\dot{y} - y\dot{x}) = 1.\end{aligned}$$

Thus if $a < 0$, the origin is a global attractor: every trajectory limits to the origin as $t \rightarrow \infty$. If $a > 0$, the origin is a repeller. The study of nonhyperbolic equilibria is the first step in BIFURCATION THEORY [IV.21].

7 Existence and Uniqueness

Before one attempts to find solutions to an ODE, it is important to know whether solutions exist, and if they exist whether there is more than one solution to a given IVP. There are two types of problems that can occur.

The first is that the velocity f may be unbounded on M ; in this case, a solution might exist but only over a finite interval of time. For example, the system $\dot{x} = x^2$ for $x \in \mathbb{R}$ has the general solution $x(t) = x_0/(1-tx_0)$. Note that $|x| \rightarrow \infty$ as $t \rightarrow 1/x_0$, even though f is a “nice” function: it is smooth, and moreover, it is analytic. The problem is, however, that as $|x|$ increases, the velocity increases even more rapidly, leading to infinite speed in finite time. The existence theorem deals with this problem by being local; it guarantees existence only on a compact interval.

The second problem is that f may not be smooth enough to guarantee a unique solution. One might expect that it is sufficient that f be continuous. However, the simple system $\dot{x} = \sqrt{|x|}$ for $x \in \mathbb{R}$ has

infinitely many solutions that satisfy the initial condition $x(0) = 0$. The obvious solution is $x(t) \equiv 0$, but $x(t) = \frac{1}{4} \operatorname{sgn}(t)t^2$ is also a solution. Moreover, any function $x(t)$ that is zero up to an arbitrary time $t_0 > 0$ and then connects to the parabola $\frac{1}{4}(t - t_0)^2$ also solves the IVP. Elimination of this problem requires assuming that f is *more* than continuous; it must be at least Lipschitz. A function $f: M \rightarrow \mathbb{R}^d$ is *Lipschitz* on $M \subset \mathbb{R}^m$ if there is a constant K such that for all $x, y \in M$, $\|f(x) - f(y)\| \leq K\|x - y\|$.

With this concept, we can state a theorem of existence and uniqueness. Let $B_r(x)$ denote the closed ball of radius r about x .

Theorem 1 (Picard-Lindelöf). Suppose that for $x_0 \in \mathbb{R}^d$ there exists $b > 0$ such that $f: B_b(x_0) \rightarrow \mathbb{R}^d$ is Lipschitz. Then the IVP (5) with $x(t_0) = x_0$ has a unique solution $x: [t_0 - a, t_0 + a] \rightarrow B_b(x_0)$ with $a = b/V$, where $V = \max_{x \in B_b(x_0)} \|f(x)\|$.

This theorem can be proved iteratively (e.g., by Picard iteration), but the most elegant proof uses the contraction mapping theorem.

8 Flows

When the vector field of (5) satisfies the conditions of the Picard-Lindelöf theorem, the solution is necessarily a C^1 function of time. It is also a Lipschitz function of the initial condition. Suppose now that $f \in C^1(\mathbb{R}^d, \mathbb{R}^d)$ and is locally Lipschitz. Though the theorem guarantees the existence only on a (perhaps small) interval $t \in [t_0 - a, t_0 + a]$, this solution can be uniquely extended to a maximal open interval $J = (\alpha, \beta)$ such that the solution is unbounded as t approaches α or β when they are finite. As noted in section 7, unbounded solutions may arise even for “nice” vector fields; however, if f is bounded or globally Lipschitz, then $J = \mathbb{R}$.

If $\varphi_t(x_0)$ denotes the maximally extended solution, then $\varphi: J \times \mathbb{R}^d \rightarrow \mathbb{R}^d$ satisfies a number of conditions:

- $\varphi \in C^1$,
- $\varphi_0(x) = x$, and
- $\varphi_t \circ \varphi_s = \varphi_{t+s}$ whenever t, s , and $t+s \in J$.

The last condition encapsulates the idea of autonomy: flowing from the point $\varphi_s(x)$ for a time t is the same as flowing for time $t+s$ from x ; the origin of time is a matter of convention.

For example, (8), the solution of the logistic ODE, gives such a function if it is rewritten as $\varphi_t(N_0) = N(t)$.

In this case (for r and K positive), $J = \mathbb{R}$ if $0 \leq N_0 \leq K$, and $J = (\alpha, \infty)$ with

$$\alpha = \frac{1}{r} \ln \left(1 - \frac{K}{N_0} \right) < 0$$

if $N_0 > K$. Indeed, it is apparent from figure 1 that solutions with initial conditions above the carrying capacity K grow rapidly for decreasing t ; the theory implies that $\varphi_t(N_0) \rightarrow \infty$ as $t \downarrow \alpha$.

More generally, any function satisfying these conditions is called a *flow*. The flow is *complete* if $J = \mathbb{R}$, and it is a *semiflow* if α is finite but β is still ∞ . It is not hard to see that every flow is the solution of a differential equation (5) for some C^0 vector field. Flows form one fundamental part of the theory of DYNAMICAL SYSTEMS [IV.20].

9 Phase-Plane Analysis

A system of two differential equations

$$\begin{cases} \dot{x} = P(x, y), \\ \dot{y} = Q(x, y) \end{cases} \quad (17)$$

can be qualitatively analyzed by considering a few simple properties of P and Q . The goals of such an analysis include determining the asymptotic behavior for $t \rightarrow \pm\infty$ and the stability of any equilibria or periodic orbits.

The *nullclines* are the sets

$$\begin{aligned} N_h &= \{x, y: Q(x, y) = 0\}, \\ N_v &= \{x, y: P(x, y) = 0\}. \end{aligned}$$

Typically these are curves on which the instantaneous motion is horizontal or vertical, respectively. The set of equilibria is precisely the intersection of the nullclines, $E = N_h \cap N_v$. The web of nullclines divides the phase plane into sectors in which the velocity vector lies in one of the four quadrants.

For example, the Lotka–Volterra system

$$\begin{cases} \dot{x} = bx(1 - x - 2y), \\ \dot{y} = cy(1 - 2x - y) \end{cases} \quad (18)$$

can be thought of as a model of competition between two species with normalized populations $x \geq 0$ and $y \geq 0$. The species have per capita birth rates b and c , respectively, when their populations are small, but these decrease if either or both of x and y grows because of competition for the same resource. In the absence of competition, the environment has a carrying capacity of one population unit. The nullclines are pairs of lines $N_h = \{y = 0\} \cup \{y = 1 - 2x\}$ and

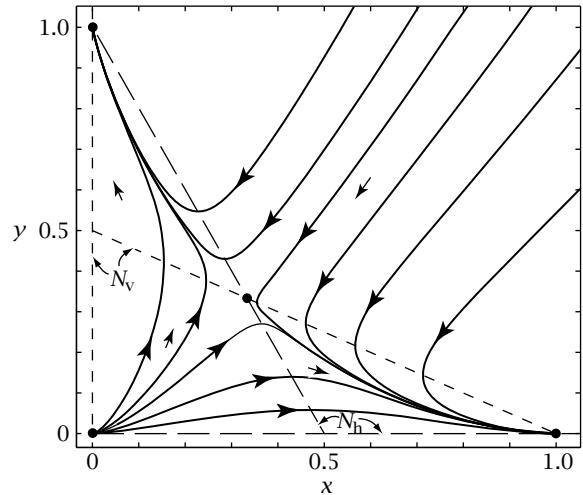

Figure 5 The phase portrait for (18) for $2c = 3b > 0$. Representative velocity vectors are shown in each sector defined by the nullclines, as are several numerically generated trajectories.

$N_v = \{x = 0\} \cup \{y = \frac{1}{2}(1 - x)\}$. Consequently, there are four equilibria: $(0, 0)$, $(1, 0)$, $(0, 1)$, and $(\frac{1}{3}, \frac{1}{3})$. The nullclines divide the biologically relevant domain into four regions within which the velocity lies in one of the four quadrants, as shown in figure 5. In particular, when both x and y are large (e.g., bigger than the carrying capacity), the velocity must be in the third quadrant since both $\dot{x} < 0$ and $\dot{y} < 0$. Since a component of the velocity can reverse only upon crossing a nullcline (and in this case does reverse), the remainder of the qualitative behavior is then determined.

From this simple observation one can conclude that the origin is a *source*, i.e., every nearby trajectory approaches the origin as $t \rightarrow -\infty$. By contrast, the two equilibria on the axes are *sinks* since all nearby trajectories approach them as $t \rightarrow +\infty$. The remaining equilibrium is a *saddle* since there are approaching and diverging solutions nearby. Moreover, every trajectory in the positive quadrant is bounded, and almost all trajectories asymptotically approach one of the two sinks. The only exceptions are a pair of trajectories that are on the stable manifold of the saddle. Details that are not determined by this analysis include the timescale over which this behavior occurs and the curvature of the solution curves, which depends upon the ratio b/c . This model demonstrates the ecological phenomenon of competitive exclusion; typically, only one species survives.

10 Limit Cycles

If the simplest solutions of ODE systems are equilibria, periodic orbits form the second class. A solution $\Gamma = \{x(t) : 0 \leq t < T\}$ of an autonomous ODE is periodic with (minimal) period T if Γ is a simple closed loop in the phase space. Indeed, uniqueness of solutions implies that, if $x(T) = x(0)$, then $x(nT) = x(0)$ for all $n \in \mathbb{Z}$.

A one-dimensional autonomous ODE (5) cannot have any periodic solutions. Indeed, every solution of such a system is a monotone function of t . Periodic trajectories are common in two dimensions. For example, each planar Hamiltonian system (9) has periodic trajectories on every closed nondegenerate ($\nabla H \neq 0$) contour $H(x, y) = E$. These periodic trajectories are not isolated. An isolated periodic orbit is called a limit cycle. More generally, a *limit cycle* is a periodic orbit that is the forward (ω) or backward (α) limit of another trajectory.

The van der Pol oscillator,

$$\dot{x} = y, \quad \dot{y} = -x + 2\mu y - x^2 y, \quad (19)$$

was introduced in 1922 as a model of a nonlinear circuit with a triode tube. Here, x represents the current through the circuit, and y represents the voltage drop across an inductor. The parameter μ corresponds to the “negative” resistance of the triode passing a small current. This system has a unique periodic solution when $\mu > 0$ (see figure 6). The creation of this limit cycle at $\mu = 0$ follows from the HOPF BIFURCATION [IV.21 §2] theorem. Its uniqueness is a consequence of a more general theorem due to Liénard.

Planar vector fields can therefore have equilibria and periodic orbits. Are there more complicated trajectories, e.g., quasiperiodic or chaotic orbits? The negation of this speculation is contained in the theorem proposed by Poincaré and proved later by Bendixson: the set of limit points of any bounded trajectory in the plane can contain only equilibria and periodic orbits. There is therefore *no chaos [II.3] in two dimensions!* From the point of view of finding periodic trajectories, this theorem implies the following.

Theorem 2 (Poincaré–Bendixson). Suppose that $A \subset \mathbb{R}^2$ is bounded and positively invariant and that φ is a complete semiflow in A . Then, if A contains no equilibria, it must contain a periodic orbit.

For example, consider the system

$$\dot{x} = y, \quad \dot{y} = -x + yh(r),$$

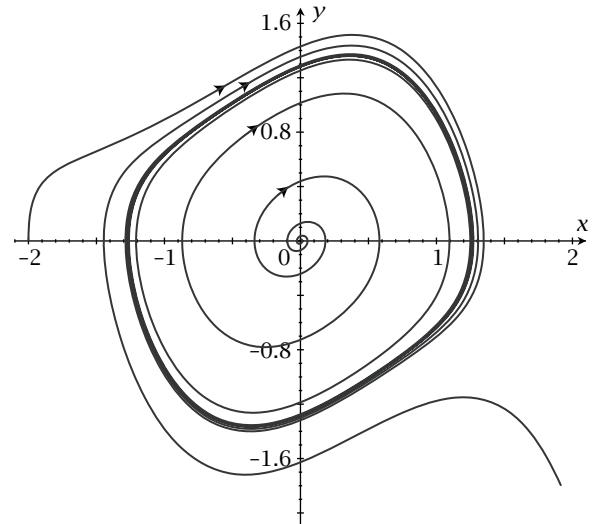

Figure 6 The phase portrait of the van der Pol oscillator (19) for $\mu = 0.2$.

where $r = \sqrt{x^2 + y^2}$, and let A be the annulus $\{(x, y) : a < r < b\}$. Thus A contains no equilibria for any $0 < a < b$. Converting to polar coordinates gives, for the radial equation,

$$\dot{r} = \frac{y^2}{r} h(r).$$

Now suppose that there exist $0 < a < b$ such that $h(b) < 0 < h(a)$. On the circle $r = a$ we then have $\dot{r} \geq 0$, implying that trajectories cannot leave A through its inner boundary. Similarly, trajectories cannot leave through $r = b$ because $\dot{r} \leq 0$ on this circle. By the Poincaré–Bendixson theorem, therefore, there is a periodic orbit in A .

11 Heteroclinic Orbits

Suppose that φ is a complete C^{r+1} flow that has a saddle equilibrium at x^* . The k -generalized eigenvectors of $Df(x^*)$ corresponding to the stable eigenvalues, $\text{Re}(\lambda_i) < 0$, define a k -dimensional tangent plane E^s at x^* . This linear plane can be extended to form a set of trajectories of the nonlinear flow whose forward evolution converges to x^* :

$$W^s(x^*) = \left\{ x \in M \setminus \{x^*\} : \lim_{t \rightarrow \infty} \varphi_t(x) = x^* \right\}.$$

The STABLE MANIFOLD THEOREM [IV.20] implies that this set is a k -dimensional, C^r , immersed manifold that is tangent to E^s at x^* . Similarly, a saddle has an

unstable manifold

$$W^u(x^*) = \left\{ x \in M \setminus \{x^*\} : \lim_{t \rightarrow -\infty} \varphi_t(x) = x^* \right\}$$

that is tangent to the $(n - k)$ -dimensional plane spanned by the unstable eigenvectors of x^* . It is important to note that this set is defined by its backward asymptotic behavior and not by the idea that it escapes from x^* . These concepts can also be generalized to hyperbolic invariant sets.

Poincaré realized that intersections of stable and unstable manifolds can give rise to complicated orbits. He called an orbit Γ *homoclinic* if $\Gamma \in W^u(x^*) \cap W^s(x^*)$. Similarly, an orbit is *heteroclinic* if $\Gamma \in W^u(a) \cap W^s(b)$ for distinct saddles a and b .

Planar Hamiltonian systems often have homoclinic or heteroclinic orbits. For example, the conservative Duffing oscillator, (15) with $\mu = 0$, has Hamiltonian $H(x, y) = \frac{1}{2}(y^2 - x^2 + \frac{1}{2}x^4)$. This function has a critical level set $H = 0$ that is a figure-eight intersecting the saddle equilibrium at $(0, 0)$. Since energy is conserved, trajectories remain on each level set; in particular, every trajectory on the figure-eight is biasymptotic to the origin (these are homoclinic trajectories). For this case, the stable and unstable manifolds coincide, and we say that there is a *homoclinic connection*. This set is also called a *separatrix* since it separates motion that encircles each center from that enclosing both centers. Such a homoclinic connection is fragile; for example, it is destroyed whenever $\mu \neq 0$ in (15). More generally, a homoclinic BIFURCATION [IV.21] corresponds to the creation/destruction of a homoclinic orbit from a periodic one.

If, however, the intersection of $W^u(a)$ with $W^s(b)$ is transverse, it cannot be destroyed by a small perturbation. A transversal intersection of two submanifolds is one for which the union of their tangent spaces at an intersection point spans TM :

$$T_x W^u(a) \oplus T_x W^s(b) = T_x M.$$

Note that for this to be the case, we must have $\dim(W^u) + \dim(W^s) \geq \dim(M)$. Every such intersection point lies on a heteroclinic orbit that is structurally stable. Poincaré realized that in certain cases the existence of such a transversal heteroclinic orbit implies infinite complexity. This idea was formalized by Steve Smale in his construction of the *Smale horseshoe*. The existence of a transversal heteroclinic orbit implies a chaotic invariant set.

12 Other Techniques and Concepts

Differential equations often have discrete or continuous SYMMETRIES [IV.22], and these are useful in constructing new solutions and reducing the order of the system. Given sufficiently many symmetries and invariants, a system of ODEs can be effectively solved, that is, it is integrable.

One often finds that no analytical method leads to explicit solutions of an ODE. In this case, NUMERICAL SOLUTION [IV.12] techniques are invaluable.

IV.3 Partial Differential Equations

Lawrence C. Evans

1 Overview

This article is an extremely rapid survey of the modern theory of partial differential equations (PDEs). Sources of PDEs are legion: mathematical physics, geometry, probability theory, continuum mechanics, optimization theory, etc. Indeed, *most of the fundamental laws of the physical sciences are partial differential equations* and most papers published in applied mathematics concern PDEs.

The following discussion is consequently very broad but also very shallow, and it will certainly be inadequate for any given PDE the reader may care about. The goal is rather to highlight some of the many key insights and unifying principles across the entire subject.

1.1 Confronting PDEs

Among the greatest accomplishments of the physical and other sciences are the discoveries of fundamental laws, which are usually PDEs. The great problems for mathematicians, both pure and applied, are then to understand the solutions of these equations,

using theoretical analysis, numerical simulations, perturbation theory, and whatever other tools they can find.

But this very success in physics—that some fairly simple-looking PDEs, for example the Euler equations for fluid mechanics (see (11) below), model complicated and diverse physical phenomena—causes all sorts of mathematical difficulties. Whatever general assertion we try to show mathematically must apply to all sorts of solutions with extremely disparate behavior.

It is therefore a really major undertaking to understand solutions of partial differential equations, and there are at least three primary mathematical approaches for doing so:

- discovering analytical formulas for solutions, either exact or approximate,
- devising accurate and fast numerical methods, and
- developing rigorous theory.

In other words, we can aspire to actually solve the PDE more or less explicitly, to compute solutions, or to indirectly deduce properties of the solutions (without relying upon formulas or numerics). This article surveys these viewpoints, with particular emphasis on the last.

Terminology

A *partial differential equation* is an equation involving an unknown function u of more than one variable and certain of its partial derivatives. The *order* of a PDE is the order of the highest-order partial derivative of the unknown appearing within it.

A *system* of PDEs comprises several equations involving an unknown vector-valued function \mathbf{u} and its partial derivatives.

A PDE is *linear* if it corresponds to a linear operator acting on the unknown and its partial derivatives; otherwise, the PDE is *nonlinear*.

Notation

Hereafter, u usually denotes the real-valued solution of a given PDE and is usually a function of points $x = (x_1, \dots, x_n) \in \mathbb{R}^n$, typically denoting a position in space, and sometimes also a function of $t \in \mathbb{R}$, denoting time. We write $u_{x_k} = \partial u / \partial x_k$ to denote the partial derivative of u with respect to x_k , and $u_t = \partial u / \partial t$, $u_{x_k x_l} = \partial^2 u / \partial x_k \partial x_l$, etc., for higher partial derivatives. The *gradient* of u in the variable x is

$$\nabla u = (u_{x_1}, \dots, u_{x_n}).$$

(In this article, ∇u always denotes the gradient in the variables x_1, \dots, x_n , even if u also depends on t .) We write the *divergence* of a vector field $\mathbf{F} = (F^1, \dots, F^n)$ as $\operatorname{div} \mathbf{F} = \sum_{i=1}^n F_{x_i}^i$.

The *Laplacian* of u is the divergence of its gradient:

$$\Delta u = \nabla^2 u = \sum_{k=1}^n u_{x_k x_k}. \quad (1)$$

Let us also write $\mathbf{u} = (u^1, \dots, u^m)$ to display the components of a vector-valued function. We always use boldface for vector-valued mappings.

The solid n -dimensional ball with center x and radius r is denoted by $B(x, r)$, and $\partial B(x, r)$ is its boundary, a sphere. More generally, ∂U means the boundary of a set $U \subset \mathbb{R}^n$; and we denote by

$$\int_{\partial U} f \, dS$$

the integral of a function f over the boundary, with respect to $(n - 1)$ -dimensional surface area.

1.2 Some Important PDEs

A list of some of the most commonly studied PDEs follows. To streamline and clarify the presentation, we have mostly set various physical parameters to unity in these equations.

First-Order PDEs

First-order PDEs appear in many physical theories—mostly in dynamics, continuum mechanics, and optics. For example, in the *scalar conservation law*

$$u_t + \operatorname{div} \mathbf{F}(u) = 0, \quad (2)$$

the unknown u is the density of some physically interesting quantity and the vector field $\mathbf{F}(u)$, its flux, depends nonlinearly on u .

Another important first-order PDE, the *Hamilton-Jacobi equation*

$$u_t + H(\nabla u, x) = 0, \quad (3)$$

appears in classical mechanics and in optimal control theory. In these contexts, H is called the *Hamiltonian*.

Second-Order PDEs

Second-order PDEs model a significantly wider variety of physical phenomena than do first-order equations. For example, among its many other interpretations, LAPLACE'S EQUATION [III.18]

$$\Delta u = 0 \quad (4)$$

records diffusion effects in equilibrium. Its time-dependent analogue is the HEAT EQUATION [III.8]

$$u_t - \Delta u = 0, \quad (5)$$

which is also known as the *diffusion equation*.

The WAVE EQUATION [III.31]

$$u_{tt} - c^2 \Delta u = 0 \quad (6)$$

superficially somewhat resembles the heat equation, but as the name suggests, it supports solutions with utterly different behavior.

SCHRÖDINGER'S EQUATION [III.26]

$$iu_t + \Delta u = 0, \quad (7)$$

for which solutions u are complex-valued, is the quantum mechanics analogue of the wave equation.

Systems of PDEs

In a SYSTEM OF CONSERVATION LAWS [II.6]

$$\mathbf{u}_t + \operatorname{div} \mathbf{F}(\mathbf{u}) = \mathbf{0}, \quad (8)$$

each component of $\mathbf{u} = (u^1, \dots, u^m)$ typically represents a mass, momentum, or energy density.

A *reaction-diffusion system* of PDEs has the form

$$\mathbf{u}_t - \Delta \mathbf{u} = \mathbf{f}(\mathbf{u}). \quad (9)$$

Here, the components of \mathbf{u} typically represent densities of, say, different chemicals, whose interactions are modeled by the nonlinear term \mathbf{f} .

The simplest form of MAXWELL'S EQUATIONS [III.22] reads

$$\left. \begin{aligned} \mathbf{E}_t &= \operatorname{curl} \mathbf{B}, \\ \mathbf{B}_t &= -\operatorname{curl} \mathbf{E}, \\ \operatorname{div} \mathbf{E} &= \operatorname{div} \mathbf{B} = 0, \end{aligned} \right\} \quad (10)$$

in which \mathbf{E} is the electric field and \mathbf{B} the magnetic field.

Fluid mechanics provides some of the most complicated and fascinating systems of PDEs in applied mathematics. The most important are EULER'S EQUATIONS [III.11] for incompressible, inviscid fluid flow,

$$\left. \begin{aligned} \mathbf{u}_t + \mathbf{u} \cdot \nabla \mathbf{u} &= -\nabla p, \\ \operatorname{div} \mathbf{u} &= 0, \end{aligned} \right\} \quad (11)$$

and the NAVIER-STOKES EQUATIONS [III.23] for incompressible, viscous flow,

$$\left. \begin{aligned} \mathbf{u}_t + \mathbf{u} \cdot \nabla \mathbf{u} - \Delta \mathbf{u} &= -\nabla p, \\ \operatorname{div} \mathbf{u} &= 0. \end{aligned} \right\} \quad (12)$$

In these systems \mathbf{u} denotes the fluid velocity and p the pressure.

Higher-Order PDEs

Equations of order greater than two are much less common. Generally speaking, such higher-order PDEs do not represent fundamental physical laws but are rather derived from such.

For instance, we can sometimes rewrite a system of two second-order equations as a single fourth-order PDE. In this way, the *biharmonic equation*

$$\Delta^2 u = 0 \quad (13)$$

comes up in linear elasticity theory.

The KORTEWEG-DE VRIES (KDV) EQUATION [III.16]

$$u_t + a u u_x + b u_{xxx} = 0, \quad (14)$$

a model of shallow-water waves, similarly appears when we combine a complicated system of lower-order equations appearing in appropriate asymptotic expansions.

1.3 Boundary and Initial Conditions

Partial differential equations very rarely appear alone; most problems require us to solve the PDEs subject to appropriate boundary and/or initial conditions. If, for instance, we are to study a solution $u = u(x)$, defined for points x lying in some region $U \subset \mathbb{R}^n$, we usually also prescribe something about how u behaves on the boundary ∂U . The most common prescriptions are *Dirichlet's boundary condition*

$$u = 0 \quad \text{on } \partial U \quad (15)$$

and *Neumann's boundary condition*

$$\frac{\partial u}{\partial \nu} = 0 \quad \text{on } \partial U, \quad (16)$$

where ν denotes the outward-pointing unit normal to the boundary and $\partial u / \partial \nu := \nabla u \cdot \nu$ is the *outer normal derivative*. If, say, u represents a temperature, then (15) specifies that the temperature is held constant on the boundary and (16) specifies that the heat flux through the boundary is zero.

Imposing initial conditions is usually appropriate for time-dependent PDEs, for which we require of the solution $u = u(x, t)$ that

$$u(\cdot, 0) = g, \quad (17)$$

where $g = g(x)$ is a given function, comprising the *initial data*. For PDEs that are second order in time, such as the wave equation (6), it is usually appropriate to also specify

$$u_t(\cdot, 0) = h. \quad (18)$$

2 Understanding PDEs

In this section we explore several general procedures for understanding PDEs and their solutions.

2.1 Exact Solutions

The most effective approach is, of course, just to solve the PDE outright, if we can. For instance, the boundary-value problem

$$\begin{aligned}\Delta u &= 0 \quad \text{in } B(0, 1), \\ u &= g \quad \text{on } \partial B(0, 1)\end{aligned}$$

is solved by *Poisson's formula*,

$$u(x) = \frac{1 - |x|^2}{n\alpha(n)} \int_{\partial B(0,1)} \frac{g(y)}{|x - y|^n} dS,$$

where $\alpha(n)$ denotes the volume of the unit ball in \mathbb{R}^n .

The solution of the initial-value problem for the wave equation in one space dimension,

$$\begin{aligned}u_{tt} - c^2 u_{xx} &= 0 \quad \text{in } \mathbb{R} \times (0, \infty), \\ u &= g, \quad u_t = h \quad \text{on } \mathbb{R} \times \{t = 0\},\end{aligned}$$

is provided by *d'Alembert's formula*:

$$u(x, t) = \frac{g(x + ct) + g(x - ct)}{2} + \frac{1}{2c} \int_{x-ct}^{x+ct} h(y) dy. \quad (19)$$

The wave equation can also be solved in higher dimensions, but the formulas become increasingly complicated. For example, *Kirchhoff's formula*,

$$\begin{aligned}u(x, t) &= \frac{1}{4\pi c^2 t} \int_{\partial B(x, ct)} h dS \\ &\quad + \frac{\partial}{\partial t} \left\{ \frac{1}{4\pi c^2 t} \int_{\partial B(x, ct)} g dS \right\}, \quad (20)\end{aligned}$$

satisfies this initial-value problem for the wave equation in three space dimensions:

$$\left. \begin{aligned}u_{tt} - c^2 \Delta u &= 0 \quad \text{in } \mathbb{R}^3 \times (0, \infty), \\ u &= g, \quad u_t = h \quad \text{on } \mathbb{R}^3 \times \{t = 0\}.\end{aligned} \right\} \quad (21)$$

The initial-value problem for the heat equation,

$$\left. \begin{aligned}u_t - \Delta u &= 0 \quad \text{in } \mathbb{R}^n \times (0, \infty), \\ u &= g \quad \text{on } \mathbb{R}^n \times \{t = 0\},\end{aligned} \right\} \quad (22)$$

has for all dimensions the explicit solution

$$u(x, t) = \frac{1}{(4\pi t)^{n/2}} \int_{\mathbb{R}^n} e^{-|x-y|^2/4t} g(y) dy. \quad (23)$$

Certain nonlinear PDEs, including the KdV equation (14), are also exactly solvable; discovering these so-called *integrable partial differential equations* is a very important undertaking.

It is however a fundamental truth that we cannot solve most PDEs, if by to "solve" we mean to come up with a more or less explicit formula for the answer.

2.2 Approximate Solutions and Perturbation Methods

It is consequently important to realize that *we can often deduce properties of solutions without actually solving the PDE*, either explicitly or numerically.

One such approach develops systematic perturbation schemes to build small "corrections" to a known solution. There is a vast repertoire of such techniques. Given a PDE depending on a small parameter ε , the idea is to posit some form for the corrections and to plug this guess into the differential equation, trying then to fine-tune the form of the perturbations to make the error as small as possible. These procedures do not usually amount to proofs but rather construct *self-consistent* guesses.

Multiple Scales

HOMOGENIZATION [II.17] problems entail PDEs whose solutions act quantitatively differently on different spatial or temporal scales, say of respective orders 1 and ε . Often, a goal is to derive simpler *effective PDEs* that yield good approximations. We guess the form of the effective equations by supposing an asymptotic expansion of the form

$$u^\varepsilon(x) \sim \sum_{k=0}^{\infty} \varepsilon^k u^k(x, x/\varepsilon)$$

and showing that the leading term u^0 is a function of x alone, solving some kind of simpler equation.

This example illustrates the insight that *simpler behavior often appears in asymptotic limits*.

Asymptotic Matching

Solutions of PDEs sometimes have quite different properties in different subregions. When this happens we can try to fashion an approximate solution by (a) constructing simpler approximate solutions in each subregion and then (b) appropriately *matching* these solutions across areas of overlap.

A common such application is to *boundary layers*. The *outer expansion* for the solution within some region often has a form like

$$u^\varepsilon(x) \sim \sum_{k=0}^{\infty} \varepsilon^k u^k(x). \quad (24)$$

Suppose we expect different behavior near the boundary, which we take for simplicity to be the plane $\{x_n = 0\}$. We can then introduce the *stretched variables* $y_n =$

x_n/ε^α , $y_i = x_i$ ($i = 1, \dots, n - 1$) and define $\bar{u}^\varepsilon(y) = u^\varepsilon(x)$. We then look for an *inner expansion*:

$$\bar{u}^\varepsilon(y) \sim \sum_{k=0}^{\infty} \varepsilon^k \bar{u}^k(y). \quad (25)$$

The idea now is to match terms in the outer expansion (24) in the limit $x_n \rightarrow 0$ with terms in the inner expansion (25) in the limit $y_n \rightarrow \infty$. Working this out determines, for instance, the value of α in the scaling.

2.3 Numerical Analysis of PDEs

Devising effective computer algorithms for PDEs is a vast enterprise—far beyond the scope of this article—and great ingenuity has gone into the design and implementation of such methods.

Among the most popular are the FINITE-DIFFERENCE [IV.13 §3] methods (which approximate functions by values at grid points), the *method of lines* (which discretizes all but the time variable), the FINITE-ELEMENT METHOD [II.12] and *spectral methods* (which represent functions using carefully designed basis functions), MULTIGRID METHODS [IV.13 §3] (which employ discretizations across different spatial scales), and the LEVEL SET METHOD [II.24] (which represents free boundaries as a level set of a function).

The design and analysis of such useful numerical methods, especially for nonlinear equations, depends on a good theoretical understanding of the underlying PDE.

2.4 Theory and the Importance of Estimates

The fully rigorous theory of PDEs focuses largely on the foundational issues of the existence, smoothness, and, where appropriate, uniqueness of solutions. Once these issues are resolved, at least provisionally, theorists turn their attention to understanding the behavior of solutions.

A key point is availability, or not, of strong analytic estimates. Many physically relevant PDEs predict that various quantities are conserved, but these identities are usually not strong enough to be useful, especially in three dimensions. For nonlinear PDEs the higher derivatives solve increasingly complicated, and thus intractable, equations. And so a major dynamic in modern theory is the interplay between (a) deriving “hard” analytic estimates for PDEs and (b) devising “soft” mathematical tools to exploit these estimates. In the remainder of this article we present for many important PDEs the key estimates upon which rigorous mathematical theory is built.

3 The Behavior of Solutions

Since PDEs model so vast a range of physical and other phenomena, their solutions display an even vaster range of behaviors. But some of these are more prevalent than others.

3.1 Waves

Many PDEs of interest in applied mathematics support at least some solutions displaying “wavelike” behavior.

The Wave Equation

The wave equation is, of course, an example, as is most easily seen in one space dimension from d'Alembert's formula (19). This dictates that the solution has the general form $u(x, t) = F(x + ct) + G(x - ct)$ and is consequently the sum of right- and left-moving waves with speed c . The wavelike behavior encoded within Kirchhoff's formula (20) in three space dimensions is somewhat less obvious.

Traveling Waves

A solution u of a PDE involving time t and the single space variable $x \in \mathbb{R}$ is a *traveling wave* if it has the form

$$u(x, t) = v(x - \sigma t) \quad (26)$$

for some speed σ . More generally, a solution u of a PDE in more space variables having the form

$$u(x, t) = v(\gamma \cdot x - \sigma t)$$

is a *plane wave*. An extremely useful first step for studying a PDE is to look for solutions with these special structures.

Dispersion

It is often informative to look for plane-wave solutions of the complex form

$$u(x, t) = e^{i(\gamma \cdot x - \sigma t)}, \quad (27)$$

where $\sigma \in \mathbb{C}$ and $\gamma \in \mathbb{R}^n$. We plug the guess (27) into some given linear PDE in order to discover the so-called *dispersion relationship* between γ and $\sigma = \sigma(\gamma)$ forced by the algebraic structure.

For example, inserting (27) into the *Klein-Gordon equation*,

$$u_{tt} - \Delta u + m^2 u = 0, \quad (28)$$

gives $\sigma = \pm(|\gamma|^2 + m^2)^{1/2}$. Hence the speed $\sigma/|\gamma|$ of propagation depends nonlinearly on the frequency of

the initial data $e^{iy \cdot x}$. So *waves of different frequencies propagate at different speeds*; this is dispersion.

Solitons

As a nonlinear example, putting (26) into the KdV equation (14) with $a = 6$ and $b = 1$ leads to the ordinary differential equation

$$-\sigma v' + 6v v' + v''' = 0,$$

a solution of which is the explicit profile

$$v(s) = \frac{1}{2} \sigma \operatorname{sech}^2\left(\frac{1}{2} \sqrt{\sigma} s\right)$$

for each speed σ . The corresponding traveling wave, $u(x, t) = v(x - \sigma t)$, is called a *soliton*.

3.2 Diffusion and Smoothing

We can read off a lot of interesting quantitative information about the solution u of the initial-value problem (22) for the heat equation from the explicit formula (23).

In particular, notice from (23) that, if the initial data function g is merely integrable, the solution u is infinitely differentiable in both the variables x and t at later times. So *the heat equation instantly smooths its initial data*; this observation makes sense as the PDE models diffusive effects.

3.3 Propagation Speeds

It is also easy to deduce from (23) that, if u solves the heat equation, then values of the initial data $g(y)$ at all points $y \in \mathbb{R}^n$ contribute to determining the solution at (x, t) for times $t > 0$. We can interpret this as an “infinite propagation speed” phenomenon.

By contrast, for many time-dependent PDEs we have instead “finite propagation speed.” This means that some parts of the initial data do not affect the solution at a given point in space until enough time has passed. This is so for first-order PDEs in general, for the wave equation, and remarkably also for some nonlinear diffusion PDEs, such as the *porous medium equation*

$$u_t - \Delta(u^\gamma) = 0 \quad (29)$$

with $\gamma > 1$. The particular explicit solution

$$u(x, t) = \frac{1}{t^\alpha} \left(b - \frac{\gamma-1}{2\gamma} \beta \frac{|x|^2}{t^{2\beta}} \right)_+^{1/(\gamma-1)} \quad (30)$$

for

$$\alpha = \frac{n}{n(\gamma-1)+2}, \quad \beta = \frac{1}{n(\gamma-1)+2},$$

and $x_+ = \max\{x, 0\}$ shows clearly that the region of positivity moves outward at finite speed.

3.4 Pattern Formation

The interplay between diffusion and nonlinear terms can create interesting effects. For example, let $\Phi(z) = \frac{1}{4}(z^2 - 1)^2$ denote a “two-well” potential, having minima at $z = \pm 1$. Look now at this scalar reaction-diffusion problem in which $\varepsilon > 0$ is a small parameter:

$$\begin{aligned} u_t^\varepsilon - \Delta u^\varepsilon &= \frac{1}{\varepsilon^2} \Phi'(u^\varepsilon) && \text{in } \mathbb{R}^2 \times (0, \infty), \\ u^\varepsilon &= g^\varepsilon && \text{on } \mathbb{R}^2 \times \{t = 0\}. \end{aligned}$$

For suitably designed, initial data functions g^ε , it turns out that

$$\lim_{\varepsilon \rightarrow 0} u^\varepsilon(x, t) = \pm 1;$$

so the solution asymptotically goes to one or the other of the two minima of Φ . We can informally think of these regions as being colored black and white.

For each time $t \geq 0$, denote by $\Gamma(t)$ the curve between the regions $\{u^\varepsilon(\cdot, t) \rightarrow 1\}$ and $\{u^\varepsilon(\cdot, t) \rightarrow -1\}$. Asymptotic matching methods reveal that *the normal velocity of $\Gamma(t)$ equals its curvature*. This is a *geometric law of motion* for the evolving black/white patterns emerging in the asymptotic limit as $\varepsilon \rightarrow 0$.

Much more complex pattern formation effects can be modeled by systems of reaction-diffusion PDEs of the general form (9); see the article on PATTERN FORMATION [IV.27] elsewhere in this volume.

3.5 Blow-up

Solutions of time-dependent PDEs may or may not exist for all future times, even if their initial conditions at time $t = 0$ are well behaved. Note, for example, that among solutions of the nonlinear heat equation

$$u_t - \Delta u = u^2, \quad (31)$$

subject to Neumann boundary conditions (16), are those solutions $u = u(t)$ that do not depend on x and consequently that solve the ordinary differential equation $u_t = u^2$. It is not hard to show that solutions of this equation go to infinity (“blow up”) at a finite positive time, if $u(0) > 0$.

For more general initial data, there is an interesting competition between the diffusive, and therefore stabilizing, term Δu and the destabilizing term u^2 .

3.6 Shocks

As we have just seen, a solution of a time-dependent PDE can fail to exist for large times since its maximum may explode to infinity in finite time. But there are other mechanisms whereby a solution may cease to exist; it is

possible, for example, that a solution remains bounded, but its gradient becomes singular in finite time.

This effect occurs for conservation laws (2). Consider, for example, the following initial-value problem for the BURGERS EQUATION [III.4]:

$$\left. \begin{aligned} u_t + \frac{1}{2}(u^2)_x &= 0 && \text{in } \mathbb{R} \times (0, \infty), \\ u &= g && \text{on } \mathbb{R} \times \{t = 0\}. \end{aligned} \right\} \quad (32)$$

Assume we have a smooth solution u and define the *characteristic curve* $x(t)$ to solve the ordinary differential equation

$$\begin{aligned} \dot{x}(t) &= u(x(t), t) && (t \geq 0), \\ x(0) &= x_0. \end{aligned}$$

Then

$$\begin{aligned} \frac{d}{dt}u(x(t), t) &= u_x(x(t), t)\dot{x}(t) + u_t(x(t), t) \\ &= u_x(x(t), t)u(x(t), t) + u_t(x(t), t) \\ &= 0, \end{aligned}$$

according to the PDE (32). Consequently, $u(x(t), t) \equiv g(x_0)$, and also the characteristic "curve" $x(t)$ is in fact a straight line.

So far, so good; and yet the foregoing often implies that *the PDE does not in fact possess a smooth solution*, existing for all times. To see this, notice that we can easily build initial data g for which the characteristic lines emanating from two distinct initial points cross at some later time, say at (x, t) . If we then use these two different characteristics to compute $u(x, t)$, we will get different answers. This seeming paradox is resolved once we understand that the Burgers equation with the initial data g simply does not have a smooth solution existing until the time t .

A major task for the rigorous analysis of the Burgers equation and related conservation laws is characterizing surfaces of discontinuity (called SHOCKS [II.30]) for appropriately defined generalized solutions.

3.7 Free Boundaries

Some very difficult problems require more than just finding the solution of some PDE: one must also find the region within which that PDE holds. Consider, for example, the *Stefan problem*, which asks us to determine the temperature within some body of water surrounded by ice. The temperature distribution solves the heat equation inside a region whose shape changes in time as the ice melts and/or the water freezes. The unknowns are therefore both the temperature profile and the so-called *free boundary* of the water.

There are in general two sorts of such free boundary problems that occur in PDE theory: those for which the free boundary is explicit, such as the Stefan problem, and those for which it is implicit. An example of the latter is the *obstacle problem*:

$$\min\{u, -\Delta u - f\} = 0.$$

The free boundary is

$$\Gamma = \partial\{u > 0\},$$

along which the solution satisfies the *overdetermined boundary conditions* $u = 0, \partial u / \partial \nu = 0$. Many important physical and engineering free boundary problems can be cast as obstacle problems.

Much more complicated free boundary problems occur in fluid mechanics, in which the unknown velocity \mathbf{u} satisfies differing sorts of PDE within the *sonic* and *subsonic* regions. We say that the equations *change type* across the free boundary.

4 Some Technical Methods

So vast is the field of PDEs that no small handful of procedures can possibly handle them all. Rather, mathematicians have discovered over the years, and continue to discover, all sorts of useful technical devices and tricks. This section provides a selection of some of the most important.

4.1 Transform Methods

A panoply of integral transforms is available to convert linear, constant-coefficient PDEs into algebraic equations. The most important is the FOURIER TRANSFORM [II.19]:

$$\hat{u}(\gamma) := \frac{1}{(2\pi)^{n/2}} \int_{\mathbb{R}^n} e^{-ix \cdot \gamma} u(x) dx.$$

Consider, as an example, the equation

$$-\Delta u + u = f \quad \text{in } \mathbb{R}^n. \quad (33)$$

We apply the Fourier transform and learn that $(1 + |\gamma|^2)\hat{u} = \hat{f}$. This algebraic equation lets us easily find \hat{u} , after which a somewhat tricky inversion yields the formula

$$u(x) = \frac{1}{(4\pi)^{n/2}} \int_0^\infty \int_{\mathbb{R}^n} \frac{e^{-s - (|x-y|^2/4s)}}{s^{n/2}} f(y) dy ds.$$

Strongly related are *Fourier series* methods, which represent solutions of certain PDEs on bounded domains as infinite sums entailing sines and cosines. Another favorite is the LAPLACE TRANSFORM [II.19], which for PDEs is mostly useful as a transform in the time variable.

4.2 Energy Methods and the Functional Analytic Framework

For many PDEs, various sorts of “energy estimates” are valid, where we use this term loosely to mean integral expressions involving squared quantities.

Integration by Parts

Important for what follows is the *integration by parts formula*:

$$\int_U u_{x_i} v \, dx = - \int_U u v_{x_i} \, dx + \int_{\partial U} u v \nu^i \, dS$$

for each $i = 1, \dots, n$. Here, ν denotes the outward-pointing unit normal to the boundary. This is a form of the DIVERGENCE THEOREM [I.2 §24] from multivariable calculus.

Energy Estimates

Assume that u solves Poisson’s equation:

$$-\Delta u = f \quad \text{in } \mathbb{R}^n. \quad (34)$$

Then, assuming that u goes to zero as $|x| \rightarrow \infty$ fast enough to justify the integration by parts, we compute that

$$\begin{aligned} \int_{\mathbb{R}^n} f^2 \, dx &= \int_{\mathbb{R}^n} \sum_{i,j=1}^n u_{x_i x_i} u_{x_j x_j} \, dx \\ &= - \int_{\mathbb{R}^n} \sum_{i,j=1}^n u_{x_i x_i x_j} u_{x_j} \, dx \\ &= \int_{\mathbb{R}^n} \sum_{i,j=1}^n (u_{x_i x_j})^2 \, dx. \end{aligned}$$

This identity implies something remarkable: if the Laplacian Δu (which is the sum of the pure second derivatives $u_{x_i x_i}$ for $i = 1, \dots, n$) is square integrable, then each individual second derivative $u_{x_i x_j}$ for $i, j = 1, \dots, n$ is square integrable, even those mixed second derivatives that do not even appear in (34).

This is an example of *regularity theory*, which aims to deduce the higher integrability and/or smoothness properties of solutions.

Time-Dependent Energy Estimates

As a next example suppose that $u = u(x, t)$ solves the wave equation (6), and define the *energy* at time t :

$$e(t) := \frac{1}{2} \int_{\mathbb{R}^n} (u_t^2 + c^2 |\nabla u|^2) \, dx.$$

Then, assuming that u goes to zero as $|x| \rightarrow \infty$ fast enough, we have

$$\begin{aligned} \dot{e}(t) &= \int_{\mathbb{R}^n} (u_t u_{tt} + c^2 \nabla u \cdot \nabla u_t) \, dx \\ &= \int_{\mathbb{R}^n} u_t (u_{tt} - c^2 \Delta u) \, dx = 0. \end{aligned}$$

This demonstrates *conservation of energy*.

For a *nonlinear wave equation* of the form

$$u_{tt} - \Delta u + f(u) = 0, \quad (35)$$

a similar calculation works for the modified energy

$$e(t) = \int_{\mathbb{R}^n} (\frac{1}{2} u_t^2 + \frac{1}{2} |\nabla u|^2 + F(u)) \, dx,$$

where $f = F'$.

4.3 Variational Problems

By far the most successful of the nonlinear theories is THE CALCULUS OF VARIATIONS [IV.6]; indeed, a fundamental question to ask of any given PDE is whether or not it is *variational*, meaning that it appears as follows.

Given the *Lagrangian density function* $L = L(v, z, x)$, we introduce the functional

$$I[u] := \int_U L(\nabla u, u, x) \, dx,$$

defined for functions $u: U \rightarrow \mathbb{R}$, subject to given boundary conditions that are not specified here. Suppose hereafter that u is a *minimizer* of $I[\cdot]$.

We will show that u automatically solves an appropriate PDE. To see this, put $i(\tau) := I[u + \tau v]$, where v vanishes near ∂U . Since i has a minimum at $\tau = 0$, we can use the chain rule to compute

$$0 = i'(0) = \int_U (\nabla_v L \cdot \nabla v + L_z v) \, dx;$$

and so

$$0 = \int_U (-\operatorname{div}(\nabla_v L) + L_z) v \, dx,$$

in which L is evaluated at $(\nabla u, u, x)$. Here we write $\nabla_v L = (L_{v_1}, \dots, L_{v_n})$.

This integral identity is valid for all functions v vanishing on ∂U , and from this the EULER-LAGRANGE EQUATION [III.12] follows:

$$-\operatorname{div}(\nabla_v L(\nabla u, u, x)) + L_z(\nabla u, u, x) = 0. \quad (36)$$

The Nonlinear Poisson Equation

For example, the Euler-Lagrange equation for

$$I[u] = \int_U \frac{1}{2} |\nabla u|^2 - F(u) \, dx$$

is the *nonlinear Poisson equation*

$$-\Delta u = f(u), \quad (37)$$

where $f = F'$.

Minimal Surfaces

The surface area of the graph of a function u is

$$I[u] = \int_U (1 + |\nabla u|^2)^{1/2} dx,$$

and the corresponding Euler-Lagrange equation is the *minimal surface equation*

$$\operatorname{div}\left(\frac{\nabla u}{(1 + |\nabla u|^2)^{1/2}}\right) = 0. \quad (38)$$

The expression on the left-hand side is (n times) the *mean curvature* of the surface; and consequently, a *minimal surface has zero mean curvature*.

4.4 Maximum Principles

The integral energy methods just discussed can be augmented for certain PDEs with pointwise maximum principle techniques. These are predicated upon the elementary observation that, if the function u attains its maximum at an interior point x_0 , then

$$u_{x_k}(x_0) = 0, \quad k = 1, \dots, n, \quad (39)$$

and

$$\sum_{k,l=1}^n u_{x_k x_l}(x_0) \xi_k \xi_l \leq 0, \quad \xi \in \mathbb{R}^n. \quad (40)$$

Linear Elliptic Equations

Such insights are essential for understanding the general *second-order linear elliptic equation*

$$Lu = 0, \quad (41)$$

where

$$Lu = - \sum_{i,j=1}^n a^{ij}(x) u_{x_i x_j} + \sum_{i=1}^n b^i(x) u_{x_i} + c(x) u.$$

We say L is *elliptic* provided the symmetric matrix $((a^{ij}(x)))$ is positive-definite. In usual applications u represents the density of some quantity. The second-order term $\sum_{i,j=1}^n a^{ij} u_{x_i x_j}$ records *diffusion*, the first-order term $\sum_{i=1}^n b^i u_{x_i}$ represents *transport*, and the zeroth-order term $c u$ describes the local *increase* or *depletion*.

We use the maximum principle to show, for instance, that if $c > 0$ then u cannot attain a positive maximum at an interior point. Indeed, if u took on a positive maximum at some point x_0 , then the first term of Lu at x_0 would be nonnegative (according to (40)), the next term would be zero (according to (39)), and the last would be positive. But this is a contradiction, since $Lu(x_0) = 0$.

Nonlinear Elliptic Equations

Maximum principle techniques also apply to many highly nonlinear equations, such as the *Hamilton-Jacobi-Bellman* equation:

$$\max_{k=1, \dots, m} \{L^k u\} = 0. \quad (42)$$

This is an important equation in *stochastic optimization theory*, in which each elliptic operator L^k is the infinitesimal generator of a different stochastic process. We leave it to the reader to use the maximum principle to show that a solution of (42) cannot attain an interior maximum or minimum.

Related, but much more sophisticated, maximum principle arguments can reveal many of the subtle properties of solutions to the linear elliptic equation (41) and the nonlinear equation (42).

4.5 Differential Inequalities

Since solutions of PDEs depend on many variables, another useful trick is to design appropriate integral expressions over all but one of these variables, in the hope that these expressions will satisfy interesting differential inequalities in the remaining variable.

Dissipation Estimates and Gradient Flows

For example, let $u = u(x, t)$ solve the *nonlinear gradient flow* equation

$$u_t - \operatorname{div}(\nabla L(\nabla u)) = 0 \quad (43)$$

in $\mathbb{R}^n \times (0, \infty)$. Put

$$e(t) := \frac{1}{2} \int_{\mathbb{R}^n} L(\nabla u) dx.$$

Then, assuming that u goes to zero rapidly as $|x| \rightarrow \infty$, we have

$$\begin{aligned} \dot{e}(t) &= \int_{\mathbb{R}^n} \nabla L(\nabla u) \cdot \nabla u_t dx \\ &= - \int_{\mathbb{R}^n} (\operatorname{div} \nabla L(\nabla u)) u_t dx \\ &= - \int_{\mathbb{R}^n} (u_t)^2 dx \leq 0. \end{aligned}$$

This is a dynamic *dissipation* inequality.

Entropy Estimates

Related to dissipation inequalities are *entropy* estimates for conservation laws. To illustrate these, assume that $u^\varepsilon = u^\varepsilon(x, t)$ solves the *viscous conservation law*

$$u_t^\varepsilon + F(u^\varepsilon)_x = \varepsilon u_{xx}^\varepsilon \quad (44)$$

for $\varepsilon > 0$. Suppose Φ is a convex function and put

$$e(t) := \int_{\mathbb{R}} \Phi(u^\varepsilon) dx.$$

Then

$$\begin{aligned} \dot{e}(t) &= \int_{\mathbb{R}} \Phi' u_t^\varepsilon dx = \int_{\mathbb{R}} \Phi' (-F_x + \varepsilon u_{xx}^\varepsilon) dx \\ &= - \int_{\mathbb{R}} (\Psi(u^\varepsilon)_x + \varepsilon \Phi''(u_x^\varepsilon)^2) dx \\ &= - \int_{\mathbb{R}} \varepsilon \Phi''(u_x^\varepsilon)^2 dx \leq 0, \end{aligned}$$

where Ψ satisfies $\Psi' = \Phi' F'$. What is important is that we have found not just one but rather a large collection of dissipation inequalities, corresponding to each pair of *entropy/entropy flux* functions (Φ, Ψ) .

Finding and utilizing entropy/entropy flux pairs for systems of conservation laws of the form (8) is a major challenge.

Monotonicity Formulas

For *monotonicity formulas* we try to find interesting expressions to integrate over balls $B(0, r)$, with center 0, say, and radius r . The hope is that these integral quantities will solve useful differential inequalities as functions of r .

As an example, consider the system

$$-\Delta \mathbf{u} = |D\mathbf{u}|^2 \mathbf{u}, \quad |\mathbf{u}|^2 = 1 \quad (45)$$

for the unknown $\mathbf{u} = (u^1, \dots, u^m)$, where we write $|D\mathbf{u}|^2 = \sum_{i=1}^n \sum_{j=1}^m (u_{x_i}^j)^2$. A solution \mathbf{u} is called a *harmonic map* into the unit sphere. It is a challenging exercise to derive from (45) the differential inequality

$$\begin{aligned} \frac{d}{dr} \left(\frac{1}{r^{n-2}} \int_{B(0,r)} |D\mathbf{u}|^2 dx \right) \\ = \frac{2}{r^n} \int_{\partial B(0,r)} \sum_{i,j,k} u_{x_i}^k x_i u_{x_j}^k x_j dS \geq 0, \end{aligned}$$

from which we deduce that

$$\frac{1}{r^{n-2}} \int_{B(0,r)} |D\mathbf{u}|^2 dx \leq \frac{1}{R^{n-2}} \int_{B(0,R)} |D\mathbf{u}|^2 dx$$

if $0 < r < R$. This inequality is often useful, as it lets us deduce fine information at small scales r from that at larger scales R .

5 Theory and Application

The foregoing listing of mathematical viewpoints and technical tricks provides at best a glimpse into the immensity of modern PDE theory, both pure and applied.

5.1 Well-Posed Problems

A common goal of most of these procedures is to understand a given PDE (plus appropriate boundary and/or initial conditions) as a *well-posed problem*, meaning that (a) the solution exists, (b) it is unique, and (c) it depends continuously on the given data for the problem. This is usually the beginning of wisdom, as well-posed problems provide the starting point for further theoretical inquiry, for numerical analysis, and for construction of approximate solutions.

5.2 Generalized Solutions

A *central theoretical problem* is therefore to fashion for any given PDE problem an appropriate notion of solution for which the problem is well-posed. For linear PDEs the concept of “distributional solutions” is usually the best, but for nonlinear problems there are many, including “viscosity solutions,” “entropy solutions,” “renormalized solutions,” etc.

For example, the unique *entropy solution* of the initial-value problem (2) for a scalar conservation law exists for all positive times, but it may support lines of discontinuities across so-called *shock waves*. Similarly, the unique *viscosity solution* of the initial-value problem for the Hamilton–Jacobi equation (3) generally supports surfaces of discontinuity for its gradient. The explicit solution (30) for the porous medium equation is, likewise, not smooth everywhere and so needs suitable interpretation as a valid generalized solution.

The research literature teems with many such notions, and some of the deepest insights in the field are uniqueness theorems for appropriate generalized solutions.

5.3 Learning More

As promised, this article is a wide-ranging survey that actually explains precious little in any detail.

To learn more, interested readers should definitely consult other articles in this volume as well as the following suggested reading. Markowich (2007) is a nice introduction to the subject, with lots of pictures, and Strauss (2008) is a very good undergraduate text, containing derivations of the various formulas cited here. The survey article by Klainerman (2008) is extensive and provides some different viewpoints. My graduate-level textbook (Evans 2010) carefully builds up much of the modern theory of PDEs, but it is aimed at mathematically advanced students.

IV.4 Integral Equations

Rainer Kress

1 Introduction

Some forty years ago when I was working on my thesis, I fell in love with integral equations, one of the most beautiful topics in both pure and applied analysis. This article is intended to stimulate the reader to share this love with me.

The term integral equation was first used by Paul du Bois-Reymond in 1888 for equations in which an unknown function occurs under an integral. Typical examples of such integral equations are

$$\int_0^1 K(x, y) \phi(y) dy = f(x) \quad (1)$$

and

$$\phi(x) + \int_0^1 K(x, y) \phi(y) dy = f(x). \quad (2)$$

In these equations the function ϕ is the unknown, and the *kernel* K and the right-hand side f are given functions. Solving one of these integral equations amounts to determining a function ϕ such that the equation is satisfied for all x with $0 \leq x \leq 1$. Equations (1) and (2) carry the name of Ivar Fredholm and are called *Fredholm integral equations of the first and second kind*, respectively. In the first equation the unknown function

only occurs under the integral, whereas in the second equation it also appears outside the integral. Later on we will show that this is more than just a formal difference between the two types of equations. A first impression of the difference can be obtained by considering the special case of a constant kernel $K(x, y) = c \neq 0$ for all $x, y \in [0, 1]$. On the one hand, it is easily seen that the equation of the second kind (2) has a unique solution given by

$$\phi(x) = f(x) - \frac{c}{1+c} \int_0^1 f(y) dy$$

provided $c \neq -1$. If $c = -1$ then (2) is solvable if and only if $\int_0^1 f(y) dy = 0$, and the general solution is given by $\phi = f + y$ with an arbitrary constant y . On the other hand, the equation of the first kind (1) is solvable if and only if f is a constant: $f(x) = y$ for all x , say. In this case every function ϕ with mean value y is a solution.

The integration domains in (1) and (2) are not restricted to the interval $[0, 1]$. In particular, the integration domain can be multidimensional, and for the integral equation of the first kind, the domain in which the equation is required to be satisfied need not coincide with the integration domain.

The first aim of this article is to guide the reader through part of the historical development of the theory and the applications of these equations. In particular, we discuss their close connection to partial differential equations and emphasize their fundamental role in the early years of the development of functional analysis as the appropriate abstract framework for studying integral (and differential) equations. Then, in the second part of the article, we will illustrate how integral equations play an important role in current mathematical research on *inverse* and *ill-posed problems* in areas such as medical imaging and nondestructive evaluation.

Two mathematical problems are said to be inverse to each other if the formulation of the first problem contains the solution of the second problem, and vice versa. According to this definition, at first glance it seems arbitrary to distinguish one of the two problems as an inverse problem. However, in general, one of the two problems is easier and more intensively studied, while the other is more difficult and less explored. The first problem is then denoted as the direct problem, and the second as the inverse problem.

A wealth of inverse problems arise in the mathematical modeling of noninvasive evaluation and imaging methods in science, medicine, and technology. For imaging devices such as conventional X-rays or X-ray

tomography, the direct problem consists of determining the images, i.e., two-dimensional projections of the known density distribution on planar photographic films in conventional X-ray devices and projections along all lines through the object measured via intensity losses in X-ray tomography (for the latter see also section 8). Conversely, the inverse problem demands that we reconstruct the density from the images. More generally, inverse problems answer questions about the cause of a given effect, whereas in the corresponding direct problem the cause is known and the effect is to be determined. A common feature of such inverse problems is their ill-posedness, or instability, i.e., small changes in the measured effect may result in large changes in the estimated cause.

Equations (1) and (2) are linear equations since the unknown function ϕ appears in a linear fashion. Though nonlinear integral equations also constitute an important part of the mathematical theory and the applications of integral equations, we do not consider them here.

2 Abel's Integral Equation

As an appetizer we consider Abel's integral equation. It was one of the first integral equations in mathematical history. A tautochrone is a planar curve for which the time taken by an object sliding without friction in uniform gravity to reach its lowest point is independent of its starting point. The problem of identifying this curve was solved by Christiaan Huygens in 1659, who, using geometrical tools, established that the tautochrone is a cycloid.

In 1823 Niels Henrik Abel attacked the more general problem of determining a planar curve such that the time of descent for a given starting height y coincides with the value $f(y)$ of a given function f . The tautochrone then reduces to the special case when f is a constant. Following Abel we describe the curve by $x = \psi(y)$ (with $\psi(0) = 0$) and, using the principle of conservation of energy, obtain

$$f(y) = \int_0^y \frac{\phi(\eta)}{\sqrt{y-\eta}} d\eta, \quad y > 0, \quad (3)$$

for the total time $f(y)$ required for the object to fall from $P = (\psi(y), y)$ to $P_0 = (0, 0)$, where

$$\phi := \sqrt{\frac{1 + (\psi')^2}{2g}}$$

and g denotes the acceleration due to gravity. Equation (3) is known as *Abel's integral equation*. Given the

shape ϕ , the falling time f is obtained by simply evaluating the integral on the right-hand side of (3). However, the solution of the generalized tautochrone problem requires the solution of the inverse problem; that is, given the function f , the solution ϕ of the integral equation (3) has to be found, which is certainly a more challenging task. This solution can be shown to be given by

$$\phi(y) = \frac{1}{\pi} \frac{d}{dy} \int_0^y \frac{f(\eta)}{\sqrt{y-\eta}} d\eta, \quad y > 0. \quad (4)$$

For the special case of a constant $f = \pi\sqrt{a/2g}$ with $a > 0$ one obtains from (4), after some calculations, that $[\psi'(y)]^2 = (a/y) - 1$, and it can be seen that the solution of this equation is given by the cycloid with parametric representation

$$(x(t), y(t)) = \frac{1}{2}a(t + \sin t, 1 - \cos t), \quad 0 \leq t \leq \pi.$$

3 The Early Years

We proceed by giving a brief account of the close connections between the early development of integral equations and potential theory. For the sake of simplicity we confine the presentation to the two-dimensional case as a model for the practically relevant three-dimensional case. In what follows, $x = (x_1, x_2)$ and $y = (y_1, y_2)$ stand for points or vectors in the Euclidean space \mathbb{R}^2 . Twice continuously differentiable solutions u of Laplace's equation

$$\frac{\partial^2 u}{\partial x_1^2} + \frac{\partial^2 u}{\partial x_2^2} = 0$$

are called HARMONIC FUNCTIONS [III.18 §1]. They model time-independent temperature distributions, potentials of electrostatic and magnetostatic fields, and velocity potentials of incompressible irrotational fluid flows.

For a simply connected bounded domain D in \mathbb{R}^2 with smooth boundary $\Gamma := \partial D$ the *Dirichlet problem* of potential theory consists of finding a harmonic function u in D that is continuous up to the boundary and assumes boundary values $u = f$ on Γ for a given continuous function f on Γ . A first approach to this problem, developed in the early nineteenth century, was to create a so-called single-layer potential by distributing point sources with a density ϕ on the boundary curve Γ , i.e., by looking for a solution in the form

$$u(x) = \int_{\Gamma} \phi(y) \ln |x - y| ds(y), \quad x \in D. \quad (5)$$

Here, $|\cdot|$ denotes the Euclidean norm, i.e., $|x - y|$ represents the distance between the two points x in D and

y on Γ . Since $\ln|x - y|$ satisfies Laplace's equation if $x \neq y$, the function u given by (5) is harmonic and in order to satisfy the boundary condition it suffices to choose the unknown function ϕ as a solution of the integral equation

$$\int_{\Gamma} \phi(y) \ln|x - y| ds(y) = f(x), \quad x \in \Gamma, \quad (6)$$

which is known as *Symm's integral equation*. However, the analysis available at that time did not allow a successful treatment of this integral equation of the first kind. Actually, only in the second half of the twentieth century was a satisfying analysis of (6) achieved. Therefore, it represented a major breakthrough when, in 1856, August Beer proposed to place dipoles on the boundary curve, i.e., to look for a solution in the form of a double-layer potential:

$$u(x) = \int_{\Gamma} \phi(y) \frac{\partial \ln|x - y|}{\partial v(y)} ds(y), \quad x \in D, \quad (7)$$

where v denotes the unit normal vector to the boundary curve Γ directed into the exterior of D . Now the so-called jump relations from potential theory require that

$$\phi(x) + \frac{1}{\pi} \int_{\Gamma} \phi(y) \frac{\partial \ln|x - y|}{\partial v(y)} ds(y) = \frac{1}{\pi} f(x) \quad (8)$$

is satisfied for $x \in \Gamma$ in order to fulfill the boundary condition. This is an integral equation of the second kind and as such, in principle, was accessible to the method of successive approximations. However, in order to achieve convergence for the case of convex domains, in 1877 Carl Neumann had to modify the successive approximations into what he called the method of arithmetic means and what we would call a relaxation method in modern terms.

For the general case, establishing the existence of a solution to (8) had to wait until the pioneering results of Fredholm that were published in final form in 1903 in the journal *Acta Mathematica* with the title "Sur une classe d'équations fonctionnelles." Fredholm considered equations of the form (2) with a general kernel K and assumed all the functions involved to be continuous and real-valued. His approach was to consider the integral equation as the limiting case of a system of linear algebraic equations by approximating the integral by Riemannian sums. Using Cramer's rule for this linear system, Fredholm passes to the limit by using Koch's theory of infinite determinants from 1896 and Hadamard's inequality for determinants from 1893. The idea of viewing integral equations as the limiting case of linear systems had already been proposed by Volterra in 1896, but it was Fredholm who followed it through successfully.

In addition to equation (2), Fredholm's results also contain the adjoint integral equation that is obtained by interchanging the variables in the kernel function. They can be summarized in the following theorem, which is known as the Fredholm alternative. Note that all four of equations (9)–(12) in Theorem 1 are required to be satisfied for all $0 \leq x \leq 1$.

Theorem 1. Either the homogeneous integral equations

$$\phi(x) + \int_0^1 K(x, y) \phi(y) dy = 0 \quad (9)$$

and

$$\psi(x) + \int_0^1 K(y, x) \psi(y) dy = 0 \quad (10)$$

only have the trivial solutions $\phi = 0$ and $\psi = 0$, and the inhomogeneous integral equations

$$\phi(x) + \int_0^1 K(x, y) \phi(y) dy = f(x) \quad (11)$$

and

$$\psi(x) + \int_0^1 K(y, x) \psi(y) dy = g(x) \quad (12)$$

have unique continuous solutions ϕ and ψ for each continuous right-hand side f and g , respectively, or the homogeneous equations (9) and (10) have the same finite number of linearly independent solutions and the inhomogeneous integral equations are solvable if and only if the right-hand sides satisfy $\int_0^1 f(x) \psi(x) dx = 0$ for all solutions ψ to the homogeneous adjoint equation (10) and $\int_0^1 \phi(x) g(x) dx = 0$ for all solutions ϕ to the homogeneous equation (9).

We explicitly note that this theorem implies that for the first of the two alternatives each one of the four properties implies the three others. Hence, in particular, uniqueness for the homogeneous equation (9) implies existence of a solution to the inhomogeneous equation (11) for each right-hand side. This is notable, since it is almost always much simpler to prove uniqueness for a linear problem than to prove existence.

Fredholm's existence results also clarify the existence of a solution to the boundary integral equation (8) for the Dirichlet problem for the Laplace equation. By inserting a parametrization of the boundary curve Γ we can transform (8) into the form (2) with a continuous kernel for which the homogeneous equation only allows the trivial solution.

Over the last century this boundary integral equation approach via potentials of the form (5) and (7)

has been successfully extended to almost all boundary and initial-boundary-value problems for second-order partial differential equations with constant coefficients, such as the time-dependent heat equation, the time-dependent and the time-harmonic wave equations, and Maxwell's equations, among many others. In addition to settling existence of solutions, boundary integral equations provide an excellent tool for obtaining approximate solutions of the boundary and initial-boundary-value problems by solving the integral equations numerically (see section 5). These so-called boundary element methods compete well with finite-element methods. It is an important part of current research on integral equations to develop, implement, and theoretically justify new efficient algorithms for boundary integral equations for very complex geometries in three dimensions that arise in real applications.

4 Impact on Functional Analysis

Fredholm's results on the integral equation (2) initiated the development of modern functional analysis in the 1920s. The almost literal agreement of the Fredholm alternative for linear integral equations as formulated in Theorem 1 with the corresponding alternative for linear systems soon gave rise to research into a broader and more abstract form of the Fredholm alternative. This in turn also allowed extensions of the integral equation theory under weaker regularity requirements on the kernel and solution functions. In addition, many years later it was found that more insight was achieved into the structure of Fredholm integral equations by abandoning the initially very fruitful analogy between integral equations and linear systems altogether.

Frigyes Riesz was the first to find an answer to the search for a general formulation of the Fredholm alternative. In his work from 1916 he interpreted the integral equation as a special case of an equation of the second kind,

$$\phi + A\phi = f,$$

with a compact linear operator $A: X \rightarrow X$ mapping a normed space X into itself. The notion of a normed space that is common in today's mathematics was not yet available in 1916.

Riesz set his work up in the function space of continuous real-valued functions on the interval $[0, 1]$ —what we would call the space $C[0, 1]$ in today's terminology. He called the maximum of the absolute value of a function f on $[0, 1]$ the *norm* of f and confirmed its properties that we now know as the standard norm axioms.

Riesz used only these axioms, not the special meaning as the maximum norm.

The concept of a compact operator was not yet available in 1916 either. However, using the notion of compact sets as introduced by Fréchet in 1906, Riesz proved that the integral operator A defined by

$$(A\phi)(x) := \int_0^1 K(x, y)\phi(y) dy, \quad x \in [0, 1], \quad (13)$$

on the space $C[0, 1]$ maps bounded sets into relatively compact sets, i.e., in today's terminology, A is a compact operator.

What is fascinating about the work of Riesz is that his proofs are still usable and can be transferred, almost unchanged, from the case of an integral operator in the space of continuous functions to the general case of a compact operator in a normed space. Riesz knew about the generality of his method, explicitly noting that the restriction to continuous functions was not relevant.

Summarizing the results of Riesz gives us the following theorem, in which I denotes the identity operator.

Theorem 2. *For a compact linear operator $A: X \rightarrow X$ in a normed space X , either $I + A$ is injective and surjective and has a bounded inverse or the null space $N(I + A) := \{\phi: \phi + A\phi = 0\}$ has nonzero finite dimension and the image space $(I + A)(X)$ is a proper subspace of X .*

The central and most valuable part of Riesz's theory is again the equivalence of injectivity and surjectivity. Theorem 2 does not yet completely contain the alternative of Theorem 1 for Fredholm integral equations since a link with an adjoint equation and the characterization of the image space in the second case of the alternative are missing. This gap was closed by results of Schauder from 1929 and by more recent developments from the 1960s.

The following theorem is simply a consequence of the fact that the identity operator on a normed space is compact if and only if X has finite dimension, which we refrain from discussing here. It explains why the difference between the two integral equations (1) and (2) is more than just formal.

Theorem 3. *Let X and Y be normed spaces and let $A: X \rightarrow Y$ be a compact linear operator. Then A cannot have a bounded inverse if X is infinite dimensional.*

5 Numerical Solution

The idea for the numerical solution of integral equations of the second kind that is conceptually the most

straightforward dates back to Nyström in 1930 and consists of replacing the integral in (2) by numerical integration. Using a quadrature formula

$$\int_0^1 g(x) dx \approx \sum_{k=1}^n a_k g(x_k)$$

with quadrature points $x_1, \dots, x_n \in [0, 1]$ and quadrature weights $a_1, \dots, a_n \in \mathbb{R}$, such as the composite trapezoidal or composite Simpson rule, we approximate the integral operator (13) by the numerical integration operator

$$(A_n \phi)(x) := \sum_{k=1}^n a_k K(x, x_k) \phi(x_k) \quad (14)$$

for $x \in [0, 1]$, i.e., we apply the quadrature formula for $g = K(x, \cdot)\phi$. The solution to the integral equation of the second kind, $\phi + A\phi = f$, is then approximated by the solution of $\phi_n + A_n \phi_n = f$, which reduces to solving a finite-dimensional linear system as follows. If ϕ_n is a solution of

$$\phi_n(x) + \sum_{k=1}^n a_k K(x, x_k) \phi_n(x_k) = f(x) \quad (15)$$

for $x \in [0, 1]$, then clearly the values $\phi_{n,j} := \phi_n(x_j)$ at the quadrature points satisfy the linear system

$$\phi_{n,j} + \sum_{k=1}^n a_k K(x_j, x_k) \phi_{n,k} = f(x_j) \quad (16)$$

for $j = 1, \dots, n$. Conversely, if $\phi_{n,j}$ is a solution of the system (16), the function ϕ_n defined by

$$\phi_n(x) := f(x) - \sum_{k=1}^n a_k K(x, x_k) \phi_{n,k} \quad (17)$$

for $x \in [0, 1]$ can be seen to solve equation (15). Under appropriate assumptions on the kernel K and the right-hand side f for a convergent sequence of quadrature rules, it can be shown that the corresponding sequence (ϕ_n) of approximate solutions converges uniformly to the solution ϕ of the integral equation as $n \rightarrow \infty$. Furthermore, it can be established that the error estimates for the quadrature rules carry over to error estimates for the Nyström approximations.

We conclude this short discussion of the numerical solution of integral equations by pointing out that in addition to the Nyström method many other methods are available, such as collocation and Galerkin methods.

6 Ill-Posed Problems

In 1923 Hadamard postulated three requirements for problems in mathematical physics: a solution should

exist, the solution should be unique, and the solution should depend continuously on the data. The third postulate is motivated by the fact that the data will be measured quantities in applications and will therefore always be contaminated by errors. A problem satisfying all three requirements is called *well-posed*. Otherwise, it is called *ill-posed*. If $A: X \rightarrow Y$ is a bounded linear operator mapping a normed space X into a normed space Y , then the equation $A\phi = f$ is well-posed if A is bijective and the inverse operator $A^{-1}: Y \rightarrow X$ is bounded, i.e., continuous. Otherwise it is ill-posed. The main concern with ill-posed problems is *instability*, where the solution ϕ of $A\phi = f$ does not depend continuously on the data f .

As an example of an ill-posed problem we present backward heat conduction. Consider the forward heat equation

$$\frac{\partial u}{\partial t} = \frac{\partial^2 u}{\partial x^2}$$

for the time-dependent temperature u in a rectangle $[0, 1] \times [0, T]$ subject to the homogeneous boundary conditions

$$u(0, t) = u(1, t) = 0, \quad 0 \leq t \leq T,$$

and the initial condition

$$u(x, 0) = \phi(x), \quad 0 \leq x \leq 1,$$

where ϕ is a given initial temperature. By separation of variables the solution can be obtained in the form

$$u(x, t) = \sum_{n=1}^{\infty} a_n e^{-n^2 \pi^2 t} \sin n \pi x, \quad (18)$$

with the Fourier coefficients

$$a_n = 2 \int_0^1 \phi(y) \sin n \pi y dy \quad (19)$$

of the given initial values. This initial-value problem is well-posed: the final temperature $f := u(\cdot, T)$ clearly depends continuously on the initial temperature ϕ because of the exponentially decreasing factors in the series

$$f(x) = \sum_{n=1}^{\infty} a_n e^{-n^2 \pi^2 T} \sin n \pi x. \quad (20)$$

However, the corresponding inverse problem, i.e., determination of the initial temperature ϕ from knowledge of the final temperature f , is ill-posed. From (20) we deduce

$$\phi(x) = \sum_{n=1}^{\infty} b_n e^{n^2 \pi^2 T} \sin n \pi x, \quad (21)$$

with the Fourier coefficients b_n of the final temperature f . Changes in the final temperature will be drastically

amplified by the exponentially increasing factors in the series (21).

Inserting (19) into (18), we see that this example can be put in the form of an integral equation of the first kind (1) with the kernel given by

$$K(x, y) = 2 \sum_{n=1}^{\infty} e^{-n^2\pi^2 T} \sin n\pi x \sin n\pi y.$$

In general, integral equations of the first kind that have continuous kernels provide typical examples of ill-posed problems as a consequence of Theorem 3.

Of course, the ill-posed nature of an equation has consequences for its numerical solution. The fact that an operator does not have a bounded inverse means that the condition numbers of its finite-dimensional approximations grow with the quality of the approximation. Hence, a careless discretization of ill-posed problems leads to a numerical behavior that at first glance seems to be paradoxical: increasing the degree of discretization (that is, increasing the accuracy of the approximation for the operator) will cause the approximate solution to the equation to become more unreliable.

7 Regularization

Methods for obtaining a stable approximate solution of an ill-posed problem are called *regularization methods*. It is our aim to describe a few ideas about regularization concepts for equations of the first kind with a compact linear operator $A: X \rightarrow Y$ between two normed spaces, X and Y . We wish to approximate the solution ϕ to the equation $A\phi = f$ from a perturbed right-hand side f^δ with a known error level $\|f^\delta - f\| \leq \delta$. Using the erroneous data f^δ , we want to construct a reasonable approximation ϕ^δ to the exact solution ϕ of the unperturbed equation $A\phi = f$. Of course, we want this approximation to be stable, i.e., we want ϕ^δ to depend continuously on the actual data f^δ . Therefore, assuming without major loss of generality that A is injective, our task is to find an approximation of the unbounded inverse operator $A^{-1}: A(X) \rightarrow X$ by a bounded linear operator $R: Y \rightarrow X$. With this in mind, a family of bounded linear operators $R_\alpha: Y \rightarrow X$, $\alpha > 0$, with the property of pointwise convergence

$$\lim_{\alpha \rightarrow 0} R_\alpha A\phi = \phi \quad (22)$$

for all $\phi \in X$, is called a *regularization scheme* for the operator A . The parameter α is called the regularization parameter.

The regularization scheme approximates the solution ϕ of $A\phi = f$ by the regularized solution $\phi_\alpha^\delta := R_\alpha f^\delta$. For the total approximation error by the triangle inequality we then have the estimate

$$\|\phi_\alpha^\delta - \phi\| \leq \delta \|R_\alpha\| + \|R_\alpha A\phi - \phi\|.$$

This decomposition shows that the error consists of two parts: the first term reflects the influence of the incorrect data, and the second term is due to the approximation error between R_α and A^{-1} . Assuming that X is infinite dimensional, R_α cannot be uniformly bounded, since otherwise A would have a bounded inverse. Consequently, the first term will be increasing as $\alpha \rightarrow 0$, whereas the second term will be decreasing as $\alpha \rightarrow 0$ according to (22).

Every regularization scheme requires a strategy for choosing the parameter α , depending on the error level δ and the data f^δ , so as to achieve an acceptable total error for the regularized solution. On the one hand, the accuracy of the approximation requires a small error $\|R_\alpha A\phi - \phi\|$; this implies a small parameter α . On the other hand, stability requires a small value of $\|R_\alpha\|$; this implies a large parameter α . A popular strategy is given by the *discrepancy principle*. Its motivation is based on the consideration that, in general, for erroneous data the residual $\|A\phi_\alpha^\delta - f^\delta\|$ should not be smaller than the accuracy of the measurements of f , i.e., the regularization parameter α should be chosen such that $\|A\phi_\alpha^\delta - f^\delta\| \approx \delta$.

We now assume that X and Y are Hilbert spaces and denote their inner products by (\cdot, \cdot) , with the space $L^2[0, 1]$ of Lebesgue square-integrable complex-valued functions on $[0, 1]$ as a typical example. Each bounded linear operator $A: X \rightarrow Y$ has a unique adjoint operator $A^*: Y \rightarrow X$ with the property $(A\phi, g) = (\phi, A^*g)$ for all $\phi \in X$ and $g \in Y$. If A is compact, then A^* is also compact. The adjoint of the compact integral operator $A: L^2[0, 1] \rightarrow L^2[0, 1]$ defined by (13) is given by the integral operator with the kernel $\bar{K}(y, x)$, where the bar indicates the complex conjugate.

Extending the singular value decomposition (SVD) for matrices from linear algebra, for each compact linear operator $A: X \rightarrow Y$ there exists a singular system consisting of a monotonically decreasing null sequence (μ_n) of positive numbers and two orthonormal sequences (ϕ_n) in X and (g_n) in Y such that

$$A\phi_n = \mu_n g_n, \quad A^*g_n = \mu_n \phi_n, \quad n \in \mathbb{N}.$$

For each $\phi \in X$ we have the SVD

$$\phi = \sum_{n=1}^{\infty} (\phi, \phi_n) \phi_n + P\phi,$$

where $P: X \rightarrow N(A)$ is the orthogonal projection operator onto the null space of A and

$$A\phi = \sum_{n=1}^{\infty} \mu_n(\phi, \phi_n) g_n.$$

From the SVD it can be readily deduced that the equation of the first kind, $A\phi = f$, is solvable if and only if f is orthogonal to the null space of A^* and satisfies

$$\sum_{n=1}^{\infty} \frac{1}{\mu_n^2} |(f, g_n)|^2 < \infty. \quad (23)$$

If (23) is fulfilled, a solution is given by

$$\phi = \sum_{n=1}^{\infty} \frac{1}{\mu_n} (f, g_n) \phi_n. \quad (24)$$

The solution (24) clearly demonstrates the ill-posed nature of the equation $A\phi = f$. If we perturb the right-hand side f to $f^\delta = f + \delta g_n$, we obtain the solution $\phi^\delta = \phi + \delta \mu_n^{-1} \phi_n$. Hence, the ratio

$$\frac{\|\phi^\delta - \phi\|}{\|f^\delta - f\|} = \frac{1}{\mu_n}$$

can be made arbitrarily large due to the fact that the singular values tend to zero. This observation suggests that we regularize by damping the influence of the factor $1/\mu_n$ in the solution formula (24). In the *Tikhonov regularization* this is achieved by choosing

$$R_\alpha f := \sum_{n=1}^{\infty} \frac{\mu_n}{\alpha + \mu_n^2} (f, g_n) \phi_n. \quad (25)$$

Computing $R_\alpha f$ does not require the singular system to be used since for injective A it can be shown that

$$R_\alpha = (\alpha I + A^* A)^{-1} A^*.$$

Hence $\phi_\alpha := R_\alpha f$ can be obtained as the unique solution of the well-posed equation of the second kind:

$$\alpha \phi_\alpha + A^* A \phi_\alpha = A^* f.$$

8 Computerized Tomography

In transmission COMPUTERIZED TOMOGRAPHY [VII.19] a cross section of an object is scanned by a thin X-ray beam whose intensity loss is recorded by a detector and processed to produce an image. Denote by f the space-dependent attenuation coefficient within a two-dimensional medium. The relative intensity loss of an X-ray along a straight line L is given by $dI = -If ds$, and by integration, it follows that

$$I_{\text{detector}} = I_{\text{source}} \exp \left(- \int_L f \, ds \right),$$

i.e., in principle, the scanning process provides the line integrals over all lines traversing the scanned cross

section. The transform that maps a function in \mathbb{R}^2 onto its line integrals is called the *Radon transform*, and the inverse problem of computerized tomography requires its inversion. Radon had already given an explicit inversion formula in 1917, but it is not immediately applicable for practical computations.

For the formal description of the Radon transform it is convenient to parametrize the line L by its unit normal vector θ and its signed distance s from the origin in the form $L = \{s\theta + t\theta^\perp : t \in \mathbb{R}\}$, where θ^\perp is obtained by rotating θ counterclockwise by 90° . Now, the two-dimensional Radon transform R is defined by

$$(Rf)(\theta, s) := \int_{-\infty}^{\infty} f(s\theta + t\theta^\perp) dt, \quad \theta \in S^1, s \in \mathbb{R},$$

and it maps $L^1(\mathbb{R}^2)$ into $L^1(S^1 \times \mathbb{R})$, where S^1 is the unit circle. Given the measured line integrals g , the inverse problem of computerized tomography consists of solving

$$Rf = g \quad (26)$$

for f . Although it is not of the conventional form (1) or (2), equation (26) can clearly be viewed as an integral equation. Its solution can be obtained using Radon's inversion formula

$$f = \frac{1}{4\pi} R^* H \frac{\partial}{\partial s} Rf \quad (27)$$

with the Hilbert transform

$$(Hg)(s) := \frac{1}{\pi} \int_{-\infty}^{\infty} \frac{g(t)}{s-t} dt, \quad s \in \mathbb{R},$$

applied with respect to the second variable in Rf . The operator R^* is the adjoint of R with respect to the L^2 inner products on \mathbb{R}^2 and $S^1 \times \mathbb{R}$, which is given by

$$(R^* g)(x) = \int_{S^1} g(\theta, x \cdot \theta) d\theta, \quad x \in \mathbb{R}^2,$$

i.e., it can be considered as an integration over all lines through x and is therefore called the back-projection operator. Because of the occurrence of the Hilbert transform in (27), inverting the Radon transform is not local; i.e., the line integrals through a neighborhood of the point x do not suffice for the reconstruction of $f(x)$. Due to the derivative appearing in (27), the inverse problem of reconstructing the function f from its line integrals is ill-posed.

In practice, the integrals can be measured only for a finite number of lines and, correspondingly, a discrete version of the Radon transform has to be inverted. The most widely used inversion algorithm is the filtered back-projection algorithm, which may be considered as an implementation of Radon's inversion formula with the middle part $H(\partial/\partial s)$ replaced by a convolution,

i.e., a filter in the terminology of image processing. However, so-called algebraic reconstruction techniques are also used where the function f is decomposed into pixels, i.e., where it is approximated by piecewise constants on a grid of little squares. The resulting sparse linear system for the pixel values is then solved iteratively, by Kaczmarz's method, for example.

For the case of a radially symmetric function f (that is, when $f(x) = f_0(|x|)$), Rf clearly does not depend on θ (that is, $(Rf)(\theta, s) = g_0(s)$), where

$$g_0(s) = 2 \int_0^\infty f_0(\sqrt{s^2 + t^2}) dt, \quad s \geq 0.$$

Substituting $t = \sqrt{r^2 - s^2}$, this transforms into

$$g_0(s) = 2 \int_s^\infty f_0(r) \frac{r}{\sqrt{r^2 - s^2}} dr, \quad s \geq 0,$$

which is an Abel-type integral equation again. Its solution is given by

$$f_0(r) = -\frac{1}{\pi} \int_r^\infty g'_0(s) \frac{1}{\sqrt{s^2 - r^2}} ds, \quad r \geq 0.$$

This approach can be extended to a full inversion formula by expanding both f and $g = Rf$ as Fourier series with respect to the polar angle. The Fourier coefficients of f and g are then related by Abel-type integral equations involving Chebyshev polynomials.

X-ray tomography was first suggested and studied by the physicist Allan Cormack in 1963, and due to the efforts of the electrical engineer Godfrey Hounsfield, it was introduced into medical practice in the 1970s. For their contributions to X-ray tomography Cormack and Hounsfield were awarded the 1979 Nobel Prize for Medicine.

9 Inverse Scattering

Scattering theory is concerned with the effects that obstacles and inhomogeneities have on the propagation of waves and particularly time-harmonic waves. Inverse scattering provides the mathematical tools for fields such as radar, sonar, medical imaging, and non-destructive testing.

For time-harmonic waves the time dependence is represented in the form $U(x, t) = \operatorname{Re}\{u(x)e^{-i\omega t}\}$ with a positive frequency ω ; i.e., the complex-valued space-dependent part u represents the real-valued amplitude and phase of the wave and satisfies the Helmholtz equation $\Delta u + k^2 u = 0$ with a positive wave number k . For a unit vector $d \in \mathbb{R}^3$, the function $e^{ikx \cdot d}$ satisfies the Helmholtz equation for all $x \in \mathbb{R}^3$. It is called a plane wave, since $e^{i(kx \cdot d - \omega t)}$ is constant on the planes

$kx \cdot d - \omega t = \text{const}$. Assume that an incident field is given by $u^{\text{in}}(x) = e^{ikx \cdot d}$. Then the simplest obstacle scattering problem is to find the scattered field u^{sc} as a solution to the Helmholtz equation in the exterior of a bounded scatterer $D \subset \mathbb{R}^3$ such that the total field $u = u^{\text{in}} + u^{\text{sc}}$ satisfies the Dirichlet boundary condition $u = 0$ on ∂D modeling a sound-soft obstacle or a perfect conductor. In addition, to ensure that the scattered wave is outgoing, it has to satisfy the Sommerfeld radiation condition

$$\lim_{r \rightarrow \infty} r \left(\frac{\partial u^{\text{sc}}}{\partial r} - ik u^{\text{sc}} \right) = 0, \quad (28)$$

where $r = |x|$ and the limit holds uniformly in all directions $x/|x|$. This ensures uniqueness of the solution to the exterior Dirichlet problem for the Helmholtz equation. Existence of the solution was established in the 1950s by Vekua, Weyl, and Müller via boundary integral equations in the spirit of section 3.

The radiation condition (28) can be shown to be equivalent to the asymptotic behavior

$$u^{\text{sc}}(x) = \frac{e^{ik|x|}}{|x|} \left\{ u_\infty(\hat{x}) + O\left(\frac{1}{|x|}\right) \right\}, \quad |x| \rightarrow \infty,$$

uniformly for all directions $\hat{x} = x/|x|$, where the function u_∞ defined on the unit sphere S^2 is known as the *far-field pattern* of the scattered wave. We indicate its dependence on the incident direction d and the observation direction \hat{x} by writing $u_\infty = u_\infty(\hat{x}, d)$. The inverse scattering problem now consists of determining the scattering obstacle D from a knowledge of u_∞ . As an example of an application, we could think of the problem of determining from the shape of the water waves arriving at the shore whether a ball or a cube was thrown into the water in the middle of a lake. We note that this inverse problem is nonlinear since the scattered wave depends nonlinearly on the scatterer D , and it is ill-posed since the far-field pattern u_∞ is an analytic function on S^2 with respect to \hat{x} .

Roughly speaking, one can distinguish between three groups of methods for solving the inverse obstacle scattering problem: iterative methods, decomposition methods, and sampling methods. Iterative methods interpret the inverse problem as a nonlinear ill-posed operator equation that is solved by methods such as regularized Newton-type iterations. The main idea of decomposition methods is to break up the inverse scattering problem into two parts: the first part deals with the ill-posedness by constructing the scattered wave u^{sc} from its far-field pattern u_∞ , and the second part deals with the nonlinearity by determining the

unknown boundary ∂D of the scatterer as the set of points where the boundary condition for the total field is satisfied. Since boundary integral equations play an essential role in the existence analysis and numerical solution of the direct scattering problem, it is not surprising that they are also an efficient tool within these two groups of methods for solving the inverse problem.

Sampling methods are based on choosing an appropriate indicator function f on \mathbb{R}^3 such that its value $f(z)$ indicates whether z lies inside or outside the scatterer D . In contrast to iterative and decomposition methods, sampling methods do not need any a priori information on the geometry of the obstacle. However, they do require knowledge of the far-field pattern for a large number of incident waves, whereas the iterative and decomposition methods, in principle, work with just one incident field.

For two of the sampling methods—the so-called linear sampling method proposed by Colton and Kirsch and the factorization method proposed by Kirsch—the indicator functions are defined using ill-posed linear integral equations of the first kind involving the integral operator $F: L^2(S^2) \rightarrow L^2(S^2)$ with kernel $u_\infty(\hat{x}, d)$ given by

$$(Fg) := \int_{S^2} u_\infty(\hat{x}, d) g(d) ds(d), \quad \hat{x} \in S^2.$$

With the far-field pattern

$$\Phi_\infty(\hat{x}, z) = (4\pi)^{-1} e^{-ik\hat{x} \cdot z}$$

of the fundamental solution

$$\Phi(x, z) := \frac{e^{ik|x-z|}}{4\pi|x-z|}, \quad x \neq z,$$

of the Helmholtz equation with source point at $z \in \mathbb{R}^3$, the linear sampling method is based on the ill-posed equation

$$Fg_z = \Phi_\infty(\cdot, z), \quad (29)$$

whereas the factorization method is based on

$$(F^* F g_z)^{1/4} = \Phi_\infty(\cdot, z). \quad (30)$$

An essential tool in the linear sampling method is the Herglotz wave function with kernel g , defined as the superposition of plane waves given by

$$v_g(x) := \int_{S^2} e^{ikx \cdot d} g(d) ds(d), \quad x \in \mathbb{R}^3.$$

It can be shown that, if $z \in D$, then the value of the Herglotz wave function $v_{g,z,\alpha}(z)$ with the kernel $g_{z,\alpha}$ given by the solution of (29) obtained by Tikhonov regularization with parameter α remains bounded as $\alpha \rightarrow 0$, whereas it is unbounded if $z \notin D$. Evaluating $v_{g,z,\alpha}(z)$ on a sufficiently fine grid of points z , the scatterer D can

be visualized as the set of those points where $v_{g,z,\alpha}(z)$ is small. The main feature of the factorization method is the fact that equation (30) is solvable in $L^2(S^2)$ if and only if $z \in D$. With the aid of the solubility condition (23) in terms of a singular system of F , this can be utilized to visualize the scatterer D as the set of points z from a grid where the series (23), applied to the equation (30), converges, that is, where its approximation by a finite sum remains small.

Three of the items in the further reading list below are evidence of my enduring love of integral equations.

IV.5 Perturbation Theory and Asymptotics

Peter D. Miller

1 Introduction

Perturbation theory is a tool for dealing with certain kinds of physical or mathematical problems involving parameters. For example, the behavior of many problems of turbulent fluid mechanics is influenced by the value of the Reynolds number, a dimensionless parameter that measures the relative strength of forces applied to the fluid compared with viscous damping forces. Likewise, in quantum theory the Planck constant \hbar is a parameter in the Schrödinger equation that governs dynamics.

The key idea of perturbation theory is to try to take advantage of special values of parameters for which the problem of interest can be solved easily to get information about the solution for nearby values of the parameters. As the parameters are *perturbed* from their original simplifying values, one expects that the solution will also be correspondingly perturbed. Perturbation methods allow one to compute the way in which the

solution changes under perturbation, and perturbation theory explains how the resulting computation is to be properly understood.

Clearly the potential for perturbation theory success is tied to the possibility that a parameter can be regarded as being tunable. Tunability is sometimes rather obvious; for instance, the Reynolds number is tuned in fluid experiments either by changing the applied forces (this changes the numerator) or by using different fluids with different viscosities (this changes the denominator). In quantum mechanics, however, it is not reasonable to tune Planck's constant, as it takes a fixed value: $\hbar \approx 1.05 \times 10^{-34}$ kg m² s⁻¹. Here, tunability can be recovered by nondimensionalizing the problem; one should introduce units M of mass, L of length, and T of time that are characteristic of the problem at hand and then consider the dimensionless ratio $H := Th/ML^2$ instead of \hbar . The dimensionless parameter H then becomes tunable via M , L , and T .

In this introduction we have followed the overwhelming majority of the literature and used the terms "perturbation theory" and "perturbation methods" almost interchangeably. However, we will try to be more precise from now on, referring to perturbation methods when describing the mechanical construction of approximate solutions of perturbed problems, while describing the mathematical analysis of the approximations obtained and their convergence properties as perturbation theory.

1.1 A Basic Example

As a first example of perturbation methods, suppose we want to find real solutions x of the polynomial equation

$$x^5 + a_4x^4 + a_3x^3 + a_2x^2 + a_1x + a_0 = 0. \quad (1)$$

Here, the real coefficients a_j are the parameters of the problem. There is no explicit formula for the roots x of a quintic polynomial in general, but for certain values of the parameters the situation is obviously much better. For example, if $a_4 = a_3 = a_2 = a_1 = 0$ and $a_0 = -1$, then (1) reduces to the problem $x^5 = 1$, which clearly has a unique real solution, $x = 1$. To perturb from this exactly solvable situation, make the replacements $a_j \rightarrow \varepsilon a_j$ for $j = 1, 2, 3, 4$ and $a_0 \rightarrow -1 + \varepsilon(a_0 + 1)$. Then, when $\varepsilon = 0$ we have the simple exactly solvable case, and when $\varepsilon = 1$ we recover the general case. It is traditional for the Greek letter ε to denote a small quantity in perturbation problems. Our problem can therefore

be written in the form

$$P_0(x) + \varepsilon P_1(x) = 0, \quad (2)$$

where $\varepsilon \in [0, 1]$ is our tunable parameter, and

$$P_0(x) := x^5 - 1,$$

$$P_1(x) := a_4x^4 + a_3x^3 + a_2x^2 + a_1x + a_0 + 1.$$

At this point, we have redefined the original problem somewhat, as the goal is now to understand how the known roots of (2) for $\varepsilon = 0$ begin to change for small nonzero ε . (It will be clear that while perturbation methods suffice to solve this redefined problem, they may not be sufficiently powerful to describe the solutions of the original problem (1) as it may not be possible to allow ε to be as large as $\varepsilon = 1$.) In this case, perturbation *theory* amounts to the invocation of the implicit function theorem, which guarantees that, since $P'_0(1) = 5 \neq 0$, there is a unique solution $x = x(\varepsilon)$ of (2) that satisfies $x(0) = 1$ and that can be expanded in a convergent (for $|\varepsilon|$ sufficiently small) power series in powers of ε . On the other hand, perturbation *methods* are concerned with the effective construction of the series itself. We do not attempt to find a closed-form expression for the general term in the series; rather, we find the terms iteratively by the following simple procedure amounting to an algorithm to compute the first $N + 1$ terms. We write

$$x(\varepsilon) = \sum_{n=0}^N x_n \varepsilon^n + R_N(\varepsilon),$$

where the remainder term in the Taylor expansion satisfies $\varepsilon^{-N} R_N(\varepsilon) \rightarrow 0$ as $\varepsilon \rightarrow 0$. By substituting this expression into (2) and expanding out the multinomials $x(\varepsilon)^p$ that occur there, one rewrites (2) in the form

$$\sum_{n=0}^N p_n \varepsilon^n + Q_N(\varepsilon) = 0, \quad (3)$$

where the p_n are certain well-defined expressions in terms of $\{x_0, \dots, x_N\}$ and $Q_N(\varepsilon)$ is a remainder that, like $R_N(\varepsilon)$, satisfies $\varepsilon^{-N} Q_N(\varepsilon) \rightarrow 0$ as $\varepsilon \rightarrow 0$. Since (3) should hold for all sufficiently small ε , it is easy to show that we must have $p_n = 0$ for all $n = 0, \dots, N$. This is a system of equations for the unknown coefficients $\{x_0, \dots, x_N\}$. The first few values of p_n are

$$p_0 := P_0(x_0),$$

$$p_1 := P'_0(x_0)x_1 + P_1(x_0),$$

$$p_2 := 2P'_0(x_0)x_2 + P''_0(x_0)x_1^2 + 2P'_1(x_0)x_1.$$

These display a useful triangular structure, in that p_n depends only on $\{x_0, \dots, x_n\}$, and we also note that p_n is linear in x_n . These features actually hold for all

n , and they allow the construction of the series coefficients in $y(\varepsilon)$ in a completely systematic fashion once the unperturbed solution $x_0 = 1$ is specified. Indeed, considering the equations $p_1 = 0$, $p_2 = 0$, and so on in order, we see that

$$\begin{aligned}x_1 &= -\frac{P_1(x_0)}{P'_0(x_0)}, \\x_2 &= -\frac{P'_1(x_0)x_1}{P'_0(x_0)} - \frac{P''_0(x_0)x_1^2}{2P'_0(x_0)} \\&= \frac{P_1(x_0)P'_1(x_0)}{P'_0(x_0)^2} - \frac{P_1(x_0)^2P''_0(x_0)}{2P'_0(x_0)^3},\end{aligned}$$

and so on. Note that the denominators are nonzero under exactly the same condition that the implicit function theorem applies. In this way, the perturbation series coefficients x_n are systematically determined one after the other. Note also that if we were interested in complex roots x of the quintic, we could equally well have started developing the perturbation series from any of the five complex roots of unity $x_0 = e^{2\pi ik/5}$ for $k = 0, 1, 2, 3, 4$.

This example shows several of the most elementary features of perturbation methods:

- (i) The effect of perturbation of the parameter ε from the special value $\varepsilon = 0$ is to introduce corrections to the unperturbed solution x_0 in the form of an infinite perturbation series of corrections of higher and higher order.
- (ii) Once the leading term of the series has been obtained by solving the reduced problem with $\varepsilon = 0$, the subsequent terms of the perturbation series are all obtained by solving inhomogeneous linear equations of the form $P'_0(x_0)u = f$, where f is given in terms of previously calculated terms and $P'_0(x_0)$ denotes the linearization of the unperturbed problem about its exact solution x_0 .

The latter feature makes perturbation methods an attractive way to attack nonlinear problems, as the procedure for calculating corrections always involves solving only linear problems.

2 Asymptotic Expansions

2.1 Motivation

Consider the second-order differential equation for $y(x)$:

$$-\varepsilon x^3 y''(x) + y(x) = x^2. \quad (4)$$

Let us try to solve (4) for $x > 0$. This equation generally has no elementary solutions, but we may notice

that when $\varepsilon = 0$ it is obvious that $y(x) = x^2$. Taking a perturbative approach to include the effect of the neglected term, we may seek a solution in the form of a power series in ε :

$$y(x) \sim \sum_{n=0}^{\infty} y_n(x) \varepsilon^n, \quad y_0(x) := x^2. \quad (5)$$

The notation “~” will be properly explained below in section 2.2; for now the reader may think of it as “=”.

Substituting this series into (4) and equating the terms with corresponding powers of ε gives the recurrence relation

$$y_n(x) = x^3 y'_{n-1}(x), \quad n > 0. \quad (6)$$

This recurrence is easily solved, and one finds that $y_n(x) = (n+1)! n! x^{n+2}$ for all $n \geq 0$, and therefore the series (5) becomes

$$y(x) \sim \sum_{n=0}^{\infty} (n+1)! n! x^{n+2} \varepsilon^n. \quad (7)$$

Now let us consider carefully the meaning of the power series in ε on the right-hand side of (7). The absolute value of the ratio of successive terms in the series is

$$\left| \frac{y_{n+1}(x) \varepsilon^{n+1}}{y_n(x) \varepsilon^n} \right| = (n+2)(n+1)x|\varepsilon|,$$

and this ratio blows up as $n \rightarrow \infty$ regardless of the value of $x > 0$, unless of course $\varepsilon = 0$. Therefore, by the ratio test, the series on the right-hand side of (7) diverges (has no finite sum) for every value of $x > 0$ unless $\varepsilon = 0$. Another way of saying the same thing is that the error or remainder $R_N(x, \varepsilon)$ upon truncating the series after the term proportional to ε^N ,

$$R_N(x, \varepsilon) := y(x) - \sum_{n=0}^N (n+1)! n! x^{n+2} \varepsilon^n,$$

does not tend to zero (or, for that matter, any finite limit) as $N \rightarrow \infty$, no matter what values we choose for x and ε . It is simply not possible to use partial sums of the series (7) to get better and better approximations to $y(x)$ by including more and more terms in the partial sum.

On the other hand, there does indeed exist a particular solution $y(x)$ of (4) for which the partial sums are good approximations. The key idea is the following: instead of trying to choose the parameter N (the number of terms) to make the remainder $R_N(x, \varepsilon)$ small for fixed $\varepsilon > 0$, try to choose the parameter ε small enough that $R_N(x, \varepsilon)$ is less than some tolerance for N fixed. It turns out that there is a positive constant $K_N(x)$ independent of ε such that

$$|R_N(x, \varepsilon)| \leq K_N(x) \varepsilon^{N+1}. \quad (8)$$

This fact shows that for each given N , the error in approximating $y(x)$ by the N th partial sum of the series (7) tends to zero with ε , and it does so at a rate depending on the number of retained terms in the sum. This is the property that makes the series on the right-hand side of (7) an *asymptotic expansion* of $y(x)$. We must understand that it makes no sense to add up all of the terms in the series, but the partial sums are good approximations of $y(x)$ when ε is small, and the error of approximation goes to zero faster with ε the more terms are kept in the partial sum.

2.2 Definitions and Notation

We begin to formalize some of this notation by introducing some simple standard notation due to Edmund Landau for estimates involving functions of ε . Let $f(\varepsilon, p)$ be a function of ε for ε sufficiently small, depending on some auxiliary parameter p . We write

$$f(\varepsilon, p) = O(g(\varepsilon)), \quad \varepsilon \rightarrow 0,$$

and say that “ f is *big-oh* of g ” if there exists some $K(p) > 0$ such that, for each p ,

$$|f(\varepsilon, p)| \leq K(p)|g(\varepsilon)|, \quad \forall p,$$

and for all ε small enough. If $K(p)$ can be chosen to be independent of p , then f is big-oh of g *uniformly* with respect to p . We write

$$f(\varepsilon, p) = o(g(\varepsilon)), \quad \varepsilon \rightarrow 0,$$

and say that “ f is *little-oh* of g ” if for every $K > 0$ there is some $\delta(p, K) > 0$ such that

$$|\varepsilon| \leq \delta(p, K) \implies |f(\varepsilon, p)| \leq K|g(\varepsilon)|, \quad \forall p.$$

As with big-oh, if δ is independent of p , then f is little-oh of g uniformly with respect to p . If g is a function that is nonzero for all sufficiently small $\varepsilon \neq 0$, then $f = o(g)$ is the same thing as asserting that $f/g \rightarrow 0$ as $\varepsilon \rightarrow 0$. (This is often used in the special case when $g(\varepsilon) \equiv 1$.) Heuristically, $f = O(g)$ means that f “is no bigger than” g in a neighborhood of $\varepsilon = 0$, while $f = o(g)$ means that f “is much smaller than” g in the limit $\varepsilon \rightarrow 0$. The convenience of Landau’s notation is that it avoids reference to various constants that always occur in estimates. For example, (8) could easily be written without reference to the constant $K_N(x)$ in the form $R_N(x, \varepsilon) = O(\varepsilon^{N+1})$ as $\varepsilon \rightarrow 0$.

A sequence of functions $\{\phi_n(\varepsilon)\} = \{\phi_n(\varepsilon)\}_{n=0}^\infty$ is called an *asymptotic sequence* in the limit $\varepsilon \rightarrow 0$ if, for each n , $\phi_{n+1}(\varepsilon) = o(\phi_n(\varepsilon))$ as $\varepsilon \rightarrow 0$. Given an asymptotic sequence $\{\phi_n(\varepsilon)\}$ and an arbitrary numerical

sequence $\{a_n\} = \{a_n\}_{n=0}^\infty$, the purely formal series

$$\sum_{n=0}^{\infty} a_n \phi_n(\varepsilon)$$

is called an *asymptotic series*. Such a series is said to be an *asymptotic expansion* of a function $f(\varepsilon)$, written in the form

$$f(\varepsilon) \sim \sum_{n=0}^{\infty} a_n \phi_n(\varepsilon), \quad \varepsilon \rightarrow 0, \quad (9)$$

if, for each $N = 0, 1, 2, \dots$,

$$f(\varepsilon) - \sum_{n=0}^N a_n \phi_n(\varepsilon) = o(\phi_{N+1}(\varepsilon)), \quad \varepsilon \rightarrow 0. \quad (10)$$

From this relation it follows that, if $f(\varepsilon)$ has an asymptotic expansion with respect to $\{\phi_n(\varepsilon)\}$, then the coefficients $\{a_n\}$ are uniquely determined by the recursive sequence of limits

$$a_n := \lim_{\varepsilon \rightarrow 0} \frac{1}{\phi_n(\varepsilon)} \left[f(\varepsilon) - \sum_{k=0}^{n-1} a_k \phi_k(\varepsilon) \right].$$

Indeed, the existence of each of these limits in turn is equivalent to the assertion that f has an asymptotic expansion with respect to the sequence $\{\phi_n(\varepsilon)\}$. On the other hand, the function f is most certainly not determined uniquely given the asymptotic sequence $\{\phi_n(\varepsilon)\}$ and the coefficients $\{a_n\}$; given $f(\varepsilon)$ satisfying (10), $f(\varepsilon) + g(\varepsilon)$ will also satisfy (10) if $g(\varepsilon) = o(\phi_{N+1}(\varepsilon))$ as $\varepsilon \rightarrow 0$ for all n . This condition by no means forces $g(\varepsilon) = 0$; such a function g that is too small in the limit as $\varepsilon \rightarrow 0$ to have any effect on the coefficients $\{a_n\}$ is said to be *beyond all orders* with respect to $\{\phi_n(\varepsilon)\}$.

The simplest example of an asymptotic sequence, and one that occurs frequently in applications, is the sequence of integer powers $\phi_n(\varepsilon) := \varepsilon^n$. In this context, a function g that is beyond all orders is sometimes called *transcendentally small* or *exponentially small*; indeed, a particular example of such a function is $g(\varepsilon) = \exp(-|\varepsilon|^{-1})$.

Now, the notation used in (9) should be strongly contrasted with the standard notation used for convergent series:

$$f(\varepsilon) = \sum_{n=0}^{\infty} a_n \phi_n(\varepsilon). \quad (11)$$

The use of “=” here implies in particular that the expressions on both sides are the same kind of object: functions of ε with well-defined values. Furthermore, the only way to unambiguously assign a numerical value to the infinite series on the right-hand side given a value of ε is to sum the series, that is, to compute the limit of the sequence of partial sums. By contrast,

the meaning (10) given to the expression (9) in no way implies that the series on the right-hand side can be summed for any ε at all. Therefore, we view the relation (9) as defining an infinite hierarchy of approximations to the function $f(\varepsilon)$ given by (well-defined) partial sums of the formal series; each subsequent partial sum is a better approximation than the preceding one when the error is made small by letting ε tend to zero, precisely because (10) holds and the functions $\{\phi_n(\varepsilon)\}$ form an asymptotic sequence. However, it need not be the case that the error in approximating $f(\varepsilon)$ by the N th partial sum can be made small by fixing some ε and letting N increase. Only in the latter case can we use the convergent series notation (11).

The subject of perturbation *theory* is largely concerned with determining the nature of a series obtained via formal perturbation methods. Some perturbation series are both convergent (for sufficiently small ε) and asymptotic as $\varepsilon \rightarrow 0$; this was the case in the example of the perturbation of the unperturbed root $x_0 = 1$ in the root-finding problem in section 1.1. On the other hand, most perturbation series are divergent, as in the case of the expansion considered in section 2.1, and in such cases proving the validity of the perturbation series requires establishing the existence of a true, ε -dependent solution of the problem at hand to which the perturbation series is asymptotic in the sense of the definition (9), (10). This in turn usually amounts to formulating a mathematical problem (e.g., a differential equation with side conditions) satisfied by the remainder and applying an appropriate fixed-point or iteration argument.

Some related notation used in papers on the subject includes the following. The notation $f \ll g$ is frequently used in place of $f = o(g)$. Also, one sometimes sees the notation $f \lesssim g$ for $f = O(g)$. It should also be remarked that the symbol “ \sim ” often appears as a relation between functions in the following two senses:

- (i) $f(\varepsilon) \sim g(\varepsilon)$ may indicate that both $f(\varepsilon) = O(g(\varepsilon))$ and also $g(\varepsilon) = O(f(\varepsilon))$ (that is, f is bounded both above and below by multiples of g) as $\varepsilon \rightarrow 0$.
- (ii) $f(\varepsilon) \sim g(\varepsilon)$ may indicate that $f(\varepsilon)/g(\varepsilon) \rightarrow 1$ as $\varepsilon \rightarrow 0$, a special case of the above notation.

To avoid any confusion, we will use the symbol “ \sim ” only in the sense defined by (9), (10).

The theory of asymptotic expansions applies in a number of contexts beyond its application to perturbation problems. As just one very important example,

it is the basis for a collection of very well-developed methods for approximating certain types of integrals. Key methods include *Laplace's method* for the asymptotic expansion of real integrals with exponential integrands, Kelvin's *method of stationary phase* for the asymptotic expansion of oscillatory integrals, and the *method of steepest descent* (or saddle-point method) applying to integrals with analytic integrands. Readers can find detailed information about these useful methods in the books of Bleistein and Handelsman (1986), Wong (2001), and Miller (2006).

3 Types of Perturbation Problems

Perturbation problems are frequently categorized as being either regular or singular. The distinction is not a precise one, so there is not much point in giving careful definitions. However, the two kinds of problems often require different methods, so it is worth considering which type a given problem most resembles.

3.1 Regular Perturbation Problems

A regular perturbation problem is one in which the perturbed problem ($\varepsilon \neq 0$) is of the same general “type” as the unperturbed problem ($\varepsilon = 0$) that can be solved easily. Regular perturbation problems often lead to series that are both asymptotic as $\varepsilon \rightarrow 0$ and convergent for sufficiently small ε .

One example of a regular perturbation problem is that of finding the energy levels of a perturbed quantum mechanical system. Consider a particle moving in one space dimension subject to a force $F = -V'(x)$, where x is the position of the particle. The problem is to find nontrivial square-integrable “bound states” $\psi(x)$ and corresponding energy levels $E \in \mathbb{R}$ such that Schrödinger's equation $\mathcal{H}\psi = E\psi$ holds, where $\mathcal{H} = \mathcal{H}_0 + \varepsilon\mathcal{H}_1$ and

$$\begin{aligned}\mathcal{H}_0\psi(x) &:= -\psi''(x) + V_0(x)\psi(x), \\ \mathcal{H}_1\psi(x) &:= V_1(x)\psi(x).\end{aligned}$$

Here we have artificially separated the potential energy function V into two parts, $V = V_0 + \varepsilon V_1$; the idea is to choose V_0 such that when $\varepsilon = 0$ it is easy to solve the problem by finding a nonzero function $\psi_0 \in L^2(\mathbb{R})$ and a number E_0 that satisfy $\mathcal{H}_0\psi_0 = E_0\psi_0$. In this one-dimensional setting it turns out that, given E_0 , all solutions of this equation are proportional to ψ_0 (which makes the energy level E_0 “nondegenerate” in the language of quantum mechanics). By choosing an

appropriate scaling factor, we may assume that ψ_0 is “normalized” to satisfy

$$\int_{\mathbb{R}} \psi_0(x)^2 dx = 1. \quad (12)$$

Now, to calculate the effect of the perturbation, we may suppose that both ψ and E are expandable in asymptotic power series in ε :

$$\psi \sim \sum_{n=0}^{\infty} \varepsilon^n \psi_n, \quad E \sim \sum_{n=0}^{\infty} \varepsilon^n E_n, \quad \varepsilon \rightarrow 0. \quad (13)$$

The coefficients then necessarily satisfy the hierarchy of equations:

$$\mathcal{H}_0 \psi_n - E_0 \psi_n = \sum_{j=1}^n E_j \psi_{n-j} - \mathcal{H}_1 \psi_{n-1}. \quad (14)$$

Denote the right-hand side of this equation by $f_n(x)$. Then (14) has a solution $\psi_n(x)$ if and only if $f_n(x)$ satisfies a *solvability condition* (stemming from the *Fredholm alternative*):

$$\int_{\mathbb{R}} \psi_0(x) f_n(x) dx = 0.$$

This solvability condition is in fact a recursive formula for E_n in disguise:

$$\begin{aligned} E_n &= \int_{\mathbb{R}} \psi_0(x) \mathcal{H}_1 \psi_{n-1}(x) dx \\ &\quad - \sum_{j=1}^{n-1} E_j \int_{\mathbb{R}} \psi_0(x) \psi_{n-j}(x) dx, \end{aligned} \quad (15)$$

where we have used (12). Once E_n is determined from this relation, the equation (14) can be solved for ψ_n , but the latter is only determined modulo multiples of ψ_0 ; one typically chooses the correct multiple of ψ_0 to add in order that ψ_n be orthogonal to ψ_0 in the sense that

$$\int_{\mathbb{R}} \psi_0(x) \psi_n(x) dx = 0, \quad n > 0. \quad (16)$$

Subject to (15), (14) has a *unique* solution determined by the auxiliary condition (16). Note that this condition actually ensures that the sum on the right-hand side of (15) equals zero.

The perturbation expansions (13) of the pair (ψ, E) are known as *Rayleigh-Schrödinger series*. Under suitable conditions on the operators \mathcal{H}_0 and \mathcal{H}_1 it can be shown (by the method of Lyapunov-Schmidt reduction to eliminate the eigenfunction) that the power series (13) are actually convergent series, and hence “~” and “=” can be used interchangeably in this context.

3.2 Singular Perturbation Problems

In a singular perturbation problem, the perturbed and unperturbed problems are different in some essential way. The most elementary examples involve root finding. Consider the problem of finding the roots of the polynomial $P(x) := \varepsilon x^3 - x + 1 = 0$ when ε is small and positive. The unperturbed problem (with $\varepsilon = 0$) is to solve the linear equation $-x + 1 = 0$, which of course has the unique solution $x = 1$. However, the perturbed problem for $\varepsilon \neq 0$ is to find the roots of a cubic, and by the fundamental theorem of algebra there are three such roots. The perturbed and unperturbed problems are of different types because setting $\varepsilon = 0$ changes the degree of the equation.

Somehow, two of the roots disappear altogether from the complex plane as $\varepsilon \rightarrow 0$. Where can they go? Some intuition is obtained in this case simply by looking at a graph of $P(x)$ when ε is very small; while one of the roots looks to be close to $x = 1$ (the unique root of the unperturbed problem), the other two are very large in magnitude and of opposite signs. So the answer is that the two “extra” roots go to infinity as $\varepsilon \rightarrow 0$.

To completely solve this problem using perturbation methods, we need to capture all three roots. The root near $x = 1$ when ε is small can be expanded in a power series in ε whose coefficients can be found recursively using exactly the same methodology as in section 1.1. Finding the remaining two roots requires another idea.

The key idea is to try to pull the two escaping roots back to the finite complex plane by rescaling them by an appropriate power of ε . Let $p > 0$ be given, and write $x = y\varepsilon^{-p}$. This is a change of variables in our problem that takes a large value of x , proportional to ε^{-p} , and produces a value of y that does not grow to infinity as $\varepsilon \rightarrow 0$. In terms of y , the root-finding problem at hand takes the form

$$\varepsilon^{1-3p} y^3 - \varepsilon^{-p} y + 1 = 0. \quad (17)$$

Now, $p > 0$ is undetermined so far, but we will choose it (and hence determine the rate at which the two roots are escaping to infinity) using the *principle of dominant balance*.

By a *balance* we simply mean a pair of terms on the left-hand side of (17) having the same power of ε (by choice of $p > 0$). A balance is called *dominant* if all other terms on the left-hand side are big-oh of the terms involved in the balance. The principle of dominant balance asserts that *only dominant balances lead to possible perturbation expansions*. There are three

pairs of terms to choose from, and hence three possible balances to consider:

- (i) Balancing $\varepsilon^{1-3p}y^3$ with 1 requires choosing $p = \frac{1}{3}$. The terms involved in the balance are then both proportional to ε^0 , while the remaining term is proportional to $\varepsilon^{-1/3}$, so this balance is not dominant.
- (ii) Balancing $\varepsilon^{-p}y$ with 1 requires choosing $p = 0$. The terms involved in the balance are then proportional to ε^0 , making the balance dominant over the remaining term as $\varepsilon \rightarrow 0$. Since $p = 0$ this rescaling has had no effect ($y = x$), and in fact setting the sum of the dominant balance terms to zero recovers the original unperturbed problem. No new information is gained.
- (iii) Balancing $\varepsilon^{1-3p}y^3$ with $\varepsilon^{-p}y$ requires choosing $p = \frac{1}{2}$. The terms involved in the balance are then both proportional to $\varepsilon^{-1/2}$, making the balance dominant over the remaining term as $\varepsilon \rightarrow 0$. This is a new dominant balance.

The new dominant balance will lead to perturbation expansions of the two large roots of the original problem. Indeed, with $p = \frac{1}{2}$, for $\varepsilon \neq 0$ our problem takes the form

$$y^3 - y + \varepsilon^{1/2} = 0, \quad (18)$$

which now appears as a perturbation of the equation $y^3 - y = 0$. The latter has three roots: $y = y_0$ with $y_0 = 0$ or $y_0 = \pm 1$. Obviously, if (18) has solutions y that are close to $y_0 = \pm 1$ when ε is small, then the original problem will have two corresponding solutions that are roughly proportional to $\varepsilon^{-1/2}$. These will then be our two missing roots. The expansion procedure for (18) with $y = y_0 = \pm 1$ for $\varepsilon = 0$ is similar to that described in section 1.1, except that $y(\varepsilon)$ will be a power series in $\varepsilon^{1/2}$. The implicit function theorem applies to (18), showing that the perturbation series for $y(\varepsilon)$ will be convergent for ε sufficiently small, in addition to being asymptotic in the limit $\varepsilon \rightarrow 0$. Scaling y by $\varepsilon^{-1/2}$ then yields series representations for the two large roots x of the original problem in the form

$$x \sim \sum_{n=0}^{\infty} y_n \varepsilon^{(n-1)/2}, \quad \varepsilon \rightarrow 0,$$

with $y_0 = \pm 1$. As already mentioned, in this case “~” could be replaced by “=” if ε is small enough.

Another major category of singular perturbation problems are those involving differential equations in which the small parameter ε multiplies the highest-order derivatives. In such a case, setting $\varepsilon = 0$ replaces

the differential equation by another one of strictly lower order. This is clearly analogous to the algebraic degeneracy described above in that the number of solutions (this time counted in terms of the dimension of some space of integration constants) is different for the perturbed and unperturbed problems. We now discuss some common perturbation methods that are generally applicable to singular perturbation problems of this latter sort.

3.2.1 WKB Methods and Generalizations

WKB methods (named after Wentzel, Kramers, and Brillouin) concern differential equations that are so singularly perturbed that upon setting ε to zero there are no derivatives left at all. A sufficiently rich example equation with this property is the Sturm-Liouville, or stationary Schrödinger, equation

$$\varepsilon^2 \psi''(x) + f(x) \psi(x) = 0, \quad (19)$$

where $f(x)$ is a given coefficient and solutions $\psi = \psi(x; \varepsilon)$ are desired for sufficiently small $\varepsilon > 0$. Obviously, for the two terms on the left-hand side to sum to zero when f is independent of ε , derivatives of ψ must be very large compared with ψ itself. The essence of the WKB method is to take this into account by making a substitution of the form

$$\psi(x; \varepsilon) = \exp\left(\frac{1}{\varepsilon} \int_{x_0}^x u(\xi; \varepsilon) d\xi\right), \quad (20)$$

and in terms of the new unknown u , (19) becomes a first-order nonlinear equation of Riccati type:

$$\varepsilon u'(x; \varepsilon) + u(x; \varepsilon)^2 + f(x) = 0. \quad (21)$$

Unlike (19), this equation admits two nontrivial solutions when $\varepsilon = 0$, namely $u(x; 0) = \pm(-f(x))^{1/2}$. One can now develop a perturbation series for u in powers of ε in the usual way, starting from each of these two solutions. These series can be shown to be asymptotic to certain true solutions of (21) in the sense of (9), (10), but they are nearly always divergent. When partial sums of these two distinct series are substituted into (20), one obtains approximations to two linearly independent solutions of (19).

The WKB method as described above always fails near points x where the coefficient f vanishes. Such x are called *turning points*. What we mean when we say that the method fails is that the little-oh relation (10) does not hold uniformly on any open interval of x with a turning point as an endpoint and, moreover, there is no solution that is accurately approximated by

partial sums of the WKB expansion over a neighborhood of x containing a turning point. An important problem in the theory of equation (19) is the *connection problem*, in which a solution described accurately by a WKB expansion on one side of a turning point is to be approximated on the other side of the turning point by an appropriate linear combination of WKB expansions. This problem can sometimes be solved within the context of the WKB method by analytically continuing a solution ψ into the complex x -plane and around a turning point. Such an approach always requires analyticity of the coefficient function f and in any case fails to describe the solution ψ in any neighborhood of the turning point.

A more satisfactory way of dealing with turning points and solving connection problems is to generalize the WKB method (that is, generalize the ansatz (20)). The following approach is due to Langer.

By a simultaneous change of independent and dependent variables of the form $y = g(x)$ and $\psi(x; \varepsilon) = a(x)\phi(y; \varepsilon)$, respectively, one tries to choose g and a (as smooth functions independent of ε) such that (19) becomes a perturbation of a model equation:

- (i) $\varepsilon^2\phi''(y) \pm \phi(y) = \varepsilon^2\alpha_{\pm}(y)\phi$ in intervals of x where $f(x) \gtrless 0$;
- (ii) $\varepsilon^2\phi''(y) - y^n\phi(y) = \varepsilon^2\beta_n(y)\phi$ in intervals of x where f has a turning point (zero) of order n .

Here, $\alpha_{\pm}(y)$ and $\beta_n(y)$ are smooth functions of y explicitly written in terms of f and its derivatives, and avoiding terms proportional to $\phi'(y)$ requires relating a and g by $a(x) = |g'(x)|^{-1/2}$. In each case, the model equation is obtained by neglecting the terms on the right-hand side (which turn out to be “more” negligible than the singular perturbation term $\varepsilon^2\phi''(y)$).

To solve (19) on an interval without turning points, one may arrive at case (i) via the (Liouville–Green) transformation

$$y = g(x) = \int_{x_0}^x \sqrt{\pm f(\xi)} d\xi.$$

This transformation is smooth and invertible in the absence of turning points. It is easy to confirm that the use of the elementary exponential solutions of the model equation $\varepsilon^2\phi''(y) \pm \phi(y) = 0$ alone immediately reproduces the first two terms of the standard WKB expansion (the coefficient $a(x)$ corresponds to the term in u that is proportional to ε). Treating the error term $\varepsilon^2\alpha_{\pm}(y)\phi(y)$ perturbatively reproduces the rest of the WKB series.

To solve (19) on an interval containing a simple turning point x_0 , one should take $n = 1$ in case (ii). Arriving at this target requires choosing the (Langer) transformation

$$y = g(x) = -\operatorname{sgn}(f(x)) \left| \frac{3}{2} \int_{x_0}^x \sqrt{|f(\xi)|} d\xi \right|^{2/3}.$$

This transformation is smooth and invertible near x_0 precisely because x_0 is a simple zero of f . In this case, the model equation $\varepsilon^2\phi''(y) - y\phi(y) = 0$ is not solvable by elementary functions, but it is solvable in terms of special functions known as *Airy functions*. Airy functions can be expressed as certain contour integrals, and this is enough information to allow the solution of a number of connection problems for simple turning points without detouring into the complex x -plane. For double turning points ($n = 2$) one needs a different transformation $g(x)$ that is again smooth, and instead of Airy functions one has *Weber functions*, but again these can be written as integrals, allowing connection problems to be solved. For $n \geq 3$ the solvability of the model equation (in terms of useful special functions) becomes a more serious issue. Nonetheless, when Langer’s generalization applies it not only allows an alternative approach to connection problems but also provides accurate asymptotic formulas for solutions of (19) in full neighborhoods of turning points where standard WKB methodology fails.

One famous formula that can be obtained with the use of the WKB method and connection formulas for simple turning points is the *Bohr–Sommerfeld quantization rule* of quantum mechanics. Consider the case in which $f(x)$ takes the form $f(x) = E - V(x)$, where V is a potential energy function with $V''(x) > 0$, and therefore its graph has the shape of a “potential well” whose minimum value we take to be $V = 0$. Then (19) with $\varepsilon^2 = \hbar^2/(2m)$ is the equation satisfied by stationary quantum states for a particle of mass m and total energy E , and E should take on a discrete spectrum of values such that there exists a solution ψ that is square integrable on \mathbb{R} . If $E > 0$ then $f(x)$ will have exactly two simple turning points, $x_-(E) < x_+(E)$, and one can use WKB methods and connection formulas to obtain two nonzero solutions $\psi_{\pm}(x)$ that exhibit rapid exponential decay as $x \rightarrow \pm\infty$. E is the energy of a stationary state if and only if ψ_- is proportional to ψ_+ . By computing a Wronskian of these two solutions in the region between the two turning points and equating the result to zero, one obtains the Bohr–Sommerfeld quantization

rule as a condition for $E > 0$ to be an energy eigenvalue:

$$\int_{x_-(E)}^{x_+(E)} \sqrt{E - V(x)} dx = \pi \varepsilon (n + \frac{1}{2}) + O(\varepsilon^2).$$

3.2.2 Multiple-Scale Methods

Another class of perturbation methods deals with singular perturbation problems of a different type in which what makes the problem singular is that an accurate solution of some differential equation is required over a very large range of values of the independent variables. Such problems often masquerade as regular perturbation problems until the need for accuracy over long time intervals or large distances is revealed and understood. A typical example is the weakly anharmonic oscillator, whose displacement $u = u(t; \varepsilon)$ as a function of time t is modeled by the initial-value problem for

$$u'' + \omega_0^2 u = \varepsilon u^3, \quad (22)$$

subject to the initial conditions

$$u(0; \varepsilon) = A \quad \text{and} \quad u'(0; \varepsilon) = \omega_0 B.$$

When $\varepsilon = 0$, u undergoes simple harmonic motion with frequency ω_0 : $u(t; 0) = A \cos(\omega_0 t) + B \sin(\omega_0 t)$. The presence of the cubic perturbation term on the right-hand side does not modify the order of the differential equation, so this appears to be a regular perturbation problem (and indeed it is so for bounded t).

To begin to see the difficulty, we should first observe that (22) conserves the energy:

$$E = \frac{1}{2} u'(t; \varepsilon)^2 + \frac{1}{2} \omega_0^2 u(t; \varepsilon)^2 - \frac{1}{4} \varepsilon u(t; \varepsilon)^4.$$

As the energy function has a local minimum in the phase plane at $(u, u') = (0, 0)$, and as this is the global minimum when $\varepsilon = 0$, it follows that for each initial condition pair (A, B) , if $|\varepsilon|$ is sufficiently small the corresponding solution is time-periodic, following a closed orbit in the phase plane. Now consider solving (22) using a perturbation (power) series in ε . If the assumed series takes the form

$$u(t; \varepsilon) \sim \sum_{n=0}^{\infty} \varepsilon^n u_n(t), \quad \varepsilon \rightarrow 0, \quad (23)$$

with $u_0(t) = u(t; 0)$, then by substitution and collection of coefficients of like powers of ε it follows in particular that the first correction $u_1(t)$ solves

$$u_1'' + \omega_0^2 u_1 = u_0(t)^3, \quad u_1(0) = u_1'(0) = 0. \quad (24)$$

The forcing function $u_0^3 = (A \cos(\omega_0 t) + B \sin(\omega_0 t))^3$ is known, and it contains terms proportional to the first

and third harmonics. Solving for $u_1(t)$ gives

$$\begin{aligned} u_1(t) = & -\frac{A}{32\omega_0^2} (A^2 - 3B^2) \cos(3\omega_0 t) \\ & -\frac{B}{32\omega_0^2} (3A^2 - B^2) \sin(3\omega_0 t) \\ & + \frac{3}{8\omega_0} (A^2 + B^2) [At \sin(\omega_0 t) - Bt \cos(\omega_0 t)] \\ & + \frac{A}{32\omega_0^2} (A^2 - 3B^2) \cos(\omega_0 t) \\ & + \frac{3B}{32\omega_0^2} (7A^2 + 3B^2) \sin(\omega_0 t). \end{aligned}$$

The terms on the first two lines here are the response to the third harmonic forcing terms in $u_0(t)^3$, the terms on the third line are the response to the first harmonic forcing terms in $u_0(t)^3$, and the last two lines constitute a homogeneous solution necessary to satisfy the initial conditions. This procedure can be easily continued, and all of the functions $u_n(t)$ are therefore systematically determined. The trouble with this procedure is that, while we know that the true solution $u(t; \varepsilon)$ is a periodic function of t , we have already found terms in $u_1(t)$ that are linearly growing in t , produced as a resonant response to forcing at the fundamental frequency.

Terms growing in t are not troublesome only because they are nonperiodic; they also introduce nonuniformity with respect to t into the asymptotic condition (10). Indeed, if t becomes as large as ε^{-1} , then the term $\varepsilon u_1(t)$ becomes comparable to the leading term $u_0(t)$, and condition (10) is violated. Such growing terms in an asymptotic expansion are called *secular terms*, from the French word *siecle*, meaning century, because they were first recognized in perturbation problems of celestial mechanics where they would lead to difficulty over long time intervals of about 100 years.

It is not hard to understand what has gone wrong in the particular problem at hand. The point is that, while the exact solution is indeed periodic, its fundamental frequency is not exactly ω_0 but rather is slightly dependent on ε . If we could know what the frequency is in advance, then we might expect the perturbation series to turn out to be a Fourier series in harmonics of the fundamental ε -dependent frequency.

The method of multiple scales is a systematic method of removing secular terms from asymptotic expansions, and in the problem at hand it leads automatically to a power-series expansion of the correct frequency as a function of ε . The “scales” in the name of the method are multiples of the independent variable

of the problem; we introduce a number of variables of the form $T_k := \varepsilon^k t$ for $k = 0, 1, 2, \dots$. Given some finite K , we seek $u(t, \varepsilon)$ in the form $u(t, \varepsilon) = U(T_0, \dots, T_K; \varepsilon)$ so that, by the chain rule, the ordinary differential equation (22) becomes a partial differential equation:

$$\sum_{j=0}^K \sum_{k=0}^K \varepsilon^{j+k} \frac{\partial^2 U}{\partial T_j \partial T_k} + \omega_0^2 U = \varepsilon U^3.$$

Into this equation we now introduce an expansion analogous to (23):

$$U(T_0, \dots, T_K; \varepsilon) \sim \sum_{n=0}^{\infty} \varepsilon^n U_n(T_0, \dots, T_K), \quad \varepsilon \rightarrow 0.$$

The terms proportional to ε^0 are

$$\frac{\partial^2 U_0}{\partial T_0^2} + \omega_0^2 U_0 = 0,$$

the general solution of which is $U_0 = A \cos(\omega_0 T_0) + B \sin(\omega_0 T_0)$, where A and B are undetermined functions of the “slow times” T_1, \dots, T_K . The terms proportional to ε^1 are then

$$\frac{\partial^2 U_1}{\partial T_0^2} + \omega_0^2 U_1 = U_0^3 - 2 \frac{\partial^2 U_0}{\partial T_0 \partial T_1}. \quad (25)$$

Comparing with (24), the final term on the right-hand side is the new contribution from the method of multiple scales. It contains only first harmonics:

$$\frac{\partial^2 U_0}{\partial T_0 \partial T_1} = -\omega_0 \frac{\partial A}{\partial T_1} \sin(\omega_0 T_0) + \omega_0 \frac{\partial B}{\partial T_1} \cos(\omega_0 T_0).$$

Therefore, if the dependence on T_1 of the coefficients A and B is selected so that

$$\left. \begin{aligned} 2\omega_0 \frac{\partial A}{\partial T_1} + \frac{3B}{4}(A^2 + B^2) &= 0, \\ -2\omega_0 \frac{\partial B}{\partial T_1} + \frac{3A}{4}(A^2 + B^2) &= 0, \end{aligned} \right\} \quad (26)$$

then the resonant forcing terms that are proportional to $\cos(\omega_0 T_0)$ and $\sin(\omega_0 T_0)$ and that are responsible for the secular response in U_1 will be removed from the right-hand side of (25), and consequently U_1 will now be a periodic function of T_0 . The dependence of A and B on longer timescales T_2, T_3, \dots, T_K is determined similarly, order by order, so that U_2, U_3, \dots, U_K are periodic functions of T_0 . Once this series has been constructed, the dependence on t may be restored by the substitution $T_k = \varepsilon^k t$. This procedure produces an asymptotic expansion that is uniformly consistent with the ordering relation (10) for times t that satisfy $t = O(\varepsilon^{-K})$ as $\varepsilon \rightarrow 0$.

The interpretation of the system (26) is that, as expected, the frequency of oscillation depends on the amplitude in nonlinear systems. Indeed, from (26) it is

easy to check that the squared amplitude $A^2 + B^2$ is independent of T_1 , and hence A and B undergo simple harmonic motion with respect to T_1 of amplitude-dependent frequency $\omega_1 := -3(A^2 + B^2)/(8\omega_0)$. By standard trigonometric identities it then follows that U_0 is a sinusoidal oscillation of frequency $\omega_0 + \varepsilon\omega_1 + O(\varepsilon^2)$, where ω_1 depends on the amplitude (determined from initial conditions).

3.2.3 Matching of Asymptotic Expansions

Another set of methods for dealing with singularly perturbed differential equations involves using the principle of dominant balance to isolate different domains of the independent variables in which different asymptotic expansions apply and then “matching” the expansions together to produce an approximate solution that is uniformly accurate with respect to the independent variable. A typical context is a singularly perturbed boundary-value problem such as

$$\varepsilon u'' + u' + fu = 0, \quad u(0; \varepsilon) = u(1; \varepsilon) = 1. \quad (27)$$

Here $f = f(x)$ is given, and $u(x; \varepsilon)$ is desired for ε sufficiently small (in which case one can prove that this problem has a unique solution). For the differential equation itself, one dominant balance is that between u' and fu . The expansion based on this balance is just the power-series expansion

$$u(x; \varepsilon) \sim \sum_{n=0}^{\infty} \varepsilon^n u_n(x), \quad \varepsilon \rightarrow 0, \quad (28)$$

and the leading term $u_0(x)$ satisfies the limiting equation $u'_0(x) + f(x)u_0(x) = 0$, which has the general solution

$$u_0(x) = C_0 \exp \left(\int_x^1 f(\xi) d\xi \right). \quad (29)$$

Given $u_0(x)$, the procedure can be continued in the usual way to obtain successively the coefficients $u_n(x)$. At each order, one additional arbitrary constant C_n is generated.

The expansion (28) is insufficient to solve the boundary-value problem (27) because at each order there are two boundary conditions imposed on each of the functions $u_n(x)$ but there is only one constant available to satisfy them. To seek additional expansions, we can introduce scalings of the independent variable to suggest other dominant balances. For example, if we set $x = \varepsilon^p y$ and write $v(y; \varepsilon) = u(x; \varepsilon)$, then the differential equation becomes

$$\varepsilon^{1-2p} v''(y; \varepsilon) + \varepsilon^{-p} v'(y; \varepsilon) + f(\varepsilon^p y)v(y; \varepsilon) = 0.$$

The first two terms balance if $p = 1$, and this is a dominant balance if f is continuous on $[0, 1]$ and hence bounded. Moreover, if f is smooth, $f(\varepsilon y)$ can be expanded in Taylor series for small ε , and it becomes clear that this dominant balance leads to an expansion of v of the form

$$v(y; \varepsilon) \sim \sum_{n=0}^{\infty} \varepsilon^n v_n(y), \quad \varepsilon \rightarrow 0. \quad (30)$$

Here the leading term $v_0(y)$ will satisfy the limiting equation $v_0''(y) + v_0'(y) = 0$, which has the general solution

$$v_0(y) = A_0 e^{-y} + B_0, \quad (31)$$

and the standard perturbation procedure allows one to calculate $v_n(y)$ order by order, introducing two new integration constants each time.

The expansion (28) turns out to be a good approximation for $u(x; \varepsilon)$ for x in intervals of the form $[\delta, 1]$ for $\delta > 0$, as long as the constants are chosen to satisfy the boundary condition at $x = 1$: $u_0(1) = 1$ and $u_n(1) = 0$ for $n \geq 1$. This expansion therefore holds in “most” of the domain; in fluid dynamics problems this corresponds to flow in regions away from a problematic boundary, the so-called outer flow. Hence (28) is called an *outer expansion*.

On the other hand, the expansion (30) provides a good approximation for $u(x; \varepsilon) = v(x/\varepsilon; \varepsilon)$ in the “boundary layer” near $x = 0$ of thickness proportional to ε , provided that

- (i) the integration constants are chosen to satisfy the boundary condition at $x = y = 0$, which forces

$$v_0(0) = 1 \quad \text{and} \quad v_n(0) = 0 \quad \text{for } n \geq 1;$$

and

- (ii) the remaining constant at each order is determined so that the *inner expansion* (30) is compatible with the outer expansion (28) in some common “overlap domain” of x -values.

Choosing the constants to satisfy compatibility of the expansions is called *matching of asymptotic expansions*. In general, matching involves choosing some intermediate scale on which y is large while x is small as $\varepsilon \rightarrow 0$; for example, fixing $z > 0$, we could set $x = \varepsilon^{1/2}z$ and then $y = x/\varepsilon = \varepsilon^{-1/2}z$. With this substitution one writes both inner and outer expansions in terms of the common independent variable z and re-expands both with respect to a suitable asymptotic sequence of functions of ε . Equating these expansions term-by-term then yields relations among the constants

in the two expansions. The common expansion with z fixed is sometimes called an *intermediate expansion*.

In the problem at hand, to satisfy the boundary condition at $x = 1$ we should choose $C_0 = 1$ in (29), while to satisfy $v_0(0) = 1$ we require $A_0 + B_0 = 1$ in (31). The matching condition at this leading order reads $u_0(x = 0) = v_0(y = +\infty)$, which implies that $B_0 = \exp \int_0^1 f(\xi) d\xi$. The constants A_0 , B_0 , and C_0 have clearly thus been determined by a combination of the two imposed boundary conditions and an asymptotic matching condition. The procedure can be continued to arbitrarily high order in ε .

Successful matching of asymptotic expansions for boundary-layer problems yields two different expansions that are valid in different parts of the physical domain. For some purposes it is useful to have a single approximation that is uniformly valid over the whole domain. Matching again plays a role here, as the correct formula for the uniformly valid approximation is the sum of corresponding partial sums of the inner and outer expansions, minus the corresponding terms of the intermediate expansion (which would otherwise be counted twice, it turns out).

Another application of matched asymptotic expansions is to problems involving periodic behavior that is alternately dominated by “fast” and “slow” dynamics, so-called *relaxation oscillations*. The slow parts of the cycle correspond to outer asymptotic expansions, and the rapid parts of the cycle are analyzed by rescaling and dominant balance arguments and resemble the inner expansions from boundary-layer problems. Matching is required to enforce the periodicity of the solution.

IV.6 Calculus of Variations

Irene Fonseca and Giovanni Leoni

1 History

The calculus of variations is a branch of mathematical analysis that studies extrema and critical points of

functionals (or energies). Here, by *functional* we mean a mapping from a function space to the real numbers.

One of the first questions that may be framed within this theory is *Dido's isoperimetric problem* (see section 2.3), finding the shape of a curve of prescribed perimeter that maximizes the area enclosed. Dido was a Phoenician princess who emigrated to North Africa and upon arrival obtained from the native chief as much territory as she could enclose with an ox hide. She cut the hide into a long strip and used it to delineate the territory later known as Carthage, bounded by a straight coastal line and a semicircle.

It is commonly accepted that the systematic development of the theory of the calculus of variations began with the *brachistochrone curve problem* proposed by Johann Bernoulli in 1696. Consider two points A and B on the same vertical plane but on different vertical lines. Assume that A is higher than B and that a particle M is moving from A to B along a curve and under the action of gravity. The curve that minimizes the time it takes M to travel between A and B is called the *brachistochrone*. The solution to this problem required the use of infinitesimal calculus and was later found by Jacob Bernoulli, Newton, Leibniz, and de l'Hôpital. The arguments thus developed led to the development of the foundations of the calculus of variations by Euler. Important contributions to the subject are attributed to Dirichlet, Hilbert, Lebesgue, Riemann, Tonelli, and Weierstrass, among many others.

The common feature underlying Dido's isoperimetric problem and the brachistochrone curve problem is that one seeks to maximize or minimize a functional over a class of competitors satisfying given constraints. In both cases the functional is given by an integral of a density that depends on an underlying field and some of its derivatives, and this will be the prototype we will adopt in what follows. To be precise, we consider a functional

$$u \in X \mapsto F(u) := \int_{\Omega} f(x, u(x), \nabla u(x)) dx, \quad (1)$$

where X is a function space (usually an L^p space or a Sobolev-type space), $u: \Omega \rightarrow \mathbb{R}^d$, with $\Omega \subset \mathbb{R}^N$ an open set, N and d are positive integers, and the density is a function $f(x, u, \xi)$, with $(x, u, \xi) \in \Omega \times \mathbb{R}^d \times \mathbb{R}^{d \times N}$. Here and in what follows, ∇u stands for the $d \times N$ matrix-valued distributional derivative of u .

The calculus of variations is a vast theory, so here we choose to highlight only some contemporary aspects of the field. We conclude the article by mentioning a few

areas that are at the forefront of application and that are driving current research.

2 Extrema

In this section we address fundamental minimization problems and relevant techniques in the calculus of variations. In geometry, the simplest example is the problem of finding the curve of shortest length connecting two points: a *geodesic*. A (continuous) curve joining two points $A, B \in \mathbb{R}^d$ is represented by a (continuous) function $y: [0, 1] \rightarrow \mathbb{R}^d$ such that $y(0) = A$, $y(1) = B$, and its length is given by

$$L(y) := \sup \left\{ \sum_{i=1}^n |y(t_i) - y(t_{i-1})| \right\},$$

where the supremum is taken over all partitions $0 = t_0 < t_1 < \dots < t_n = 1$, $n \in \mathbb{N}$, of the interval $[0, 1]$. If y is smooth, then $L(y) = \int_0^1 |\dot{y}(t)| dt$. In the absence of constraints, the geodesic is the straight segment with endpoints A and B, and so $L(y) = |A - B|$, where $|A - B|$ stands for the magnitude (or length) of the vector $OA - OB$ with 0 being the origin. In applications the curves are often restricted to lie on a given manifold, e.g., a sphere (in this case, the geodesic is the shortest great circle joining A and B).

2.1 Minimal Surfaces

A *minimal surface* is a surface of least area among all those bounded by a given closed curve. The problem of finding minimal surfaces, called the *Plateau problem*, was first solved in three dimensions in the 1930s by Douglas and, separately, by Rado, and then in the 1960s several authors, including Almgren, De Giorgi, Fleming, and Federer, addressed it using geometric measure-theoretical tools. This approach gives existence of solutions in a “weak sense,” and establishing their regularity is significantly more involved. De Giorgi proved that minimal surfaces are analytic except on a singular set of dimension at most $N - 1$. Later, Federer, based on earlier results by Almgren and Simons, improved the dimension of the singular set to $N - 8$. The sharpness of this estimate was confirmed with an example by Bombieri, De Giorgi, and Giusti.

Important minimal surfaces are the *nonparametric* minimal surfaces, which are given as graphs of real-valued functions. To be precise, given an open set $\Omega \subset \mathbb{R}^N$ and a smooth function $u: \Omega \rightarrow \mathbb{R}$, the area of the graph of u , $\{(x, u(x)): x \in \Omega\}$, is given by

$$F(u) := \int_{\Omega} \sqrt{1 + |\nabla u|^2} dx. \quad (2)$$

It can be shown that u minimizes the area of its graph subject to prescribed values on the boundary of Ω if

$$\operatorname{div} \left(\frac{\nabla u}{\sqrt{1 + |\nabla u|^2}} \right) = 0 \quad \text{in } \Omega.$$

2.2 The Willmore Functional

Many smooth surfaces, including tori, have recently been obtained as minima or critical points of certain geometrical functionals in the calculus of variations. An important example is the Willmore (or bending) energy of a compact surface S embedded in \mathbb{R}^3 , namely the surface integral $\mathcal{W}(S) := \int_S H^2 d\sigma$, where $H := \frac{1}{2}(k_1 + k_2)$ and k_1 and k_2 are the principal curvatures of S . This energy has a wide scope of applications, ranging from materials science (e.g., elastic shells, bending energy) to mathematical biology (e.g., cell membranes) to image segmentation in computer vision (e.g., staircasing).

Critical points of \mathcal{W} are called *Willmore surfaces* and satisfy the Euler-Lagrange equation

$$\Delta_S H + 2H(H^2 - K) = 0,$$

where $K := k_1 k_2$ is the Gaussian curvature and Δ_S is the Laplace-Beltrami operator.

In the 1920s it was shown by Blaschke and, separately, by Thomsen that the Willmore energy is invariant under conformal transformations of \mathbb{R}^3 . Also, the Willmore energy is minimized by spheres, with resulting energy value 4π . Therefore, $\mathcal{W}(S) - 4\pi$ describes how much S differs from a sphere in terms of its bending. The problem of minimizing the Willmore energy among the class of embedded tori T was proposed by Willmore, who conjectured in 1965 that $\mathcal{W}(T) \geq 2\pi^2$. This conjecture was proved by Marques and Neves in 2012.

2.3 Isoperimetric Problems and the Wulff Shape

The understanding of the surface structure of crystals plays a central role in many fields of physics, chemistry, and materials science. If the dimension of the crystals is sufficiently small, then the leading morphological mechanism is driven by the minimization of surface energy. Since the work of Herring in the 1950s, a classical problem in this field is to determine the crystalline shape that has the smallest surface energy for a given volume. To be precise, we seek to minimize the surface integral

$$\int_{\partial E} \psi(\nu(x)) d\sigma \tag{3}$$

over all smooth sets $E \subset \mathbb{R}^N$ with prescribed volume and where $\nu(x)$ is the outward unit normal to ∂E at x . The right variational framework for this problem is within the class of sets of finite perimeter. The solution, which exists and is unique up to translations, is called the Wulff shape. A key ingredient in the proof is the Brunn-Minkowski inequality

$$(\mathcal{L}^N(A))^{1/N} + (\mathcal{L}^N(B))^{1/N} \leq (\mathcal{L}^N(A + B))^{1/N}, \tag{4}$$

which holds for all Lebesgue measurable sets $A, B \subset \mathbb{R}^N$ such that $A + B$ is also Lebesgue measurable. Here, \mathcal{L}^N stands for the N -dimensional Lebesgue measure.

3 The Euler-Lagrange Equation

Consider the functional (1), in the scalar case $d = 1$ and where f is of class C^1 and X is the Sobolev space $X = W^{1,p}(\Omega)$, $1 \leq p \leq +\infty$, of all functions $u \in L^p(\Omega)$ whose distributional gradient ∇u belongs to $L^p(\Omega; \mathbb{R}^N)$. Let $u \in X$ be a local minimizer of the functional F ; that is,

$$\int_U f(x, u(x), \nabla u(x)) dx \leq \int_U f(x, v(x), \nabla v(x)) dx$$

for every open subset U compactly contained in Ω , and for all v such that $u - v \in W_0^{1,p}(U)$, where $W_0^{1,p}(U)$ is the space of all functions in $W^{1,p}(U)$ that “vanish” on the boundary of ∂U . Note that v will then coincide with u outside the set U . If $\varphi \in C_c^1(\Omega)$, then $u + t\varphi$, $t \in \mathbb{R}$, are admissible, and thus

$$t \in \mathbb{R} \mapsto g(t) := F(u + t\varphi)$$

has a minimum at $t = 0$. Therefore, under appropriate growth conditions on f , we have that $g'(0) = 0$, i.e.,

$$\int_{\Omega} \left(\sum_{i=1}^N \frac{\partial f}{\partial \xi_i}(x, u, \nabla u) \frac{\partial \varphi}{\partial x_i} + \frac{\partial f}{\partial u}(x, u, \nabla u) \varphi \right) dx = 0. \tag{5}$$

A function $u \in X$ satisfying (5) is said to be a weak solution of the Euler-Lagrange equation associated to (1).

Under suitable regularity conditions on f and u , (5) can be written in the strong form

$$\operatorname{div}(\nabla_{\xi} f(x, u, \nabla u)) = \frac{\partial f}{\partial u}(x, u, \nabla u), \tag{6}$$

where $\nabla_{\xi} f(x, u, \xi)$ is the gradient of the function $f(x, u, \cdot)$.

In the vectorial case $d > 1$, the same argument leads to a system of partial differential equations (PDEs) in place of (5).

4 Variational Inequalities and Free-Boundary and Free-Discontinuity Problems

We now add a constraint to the minimization problem considered in the previous section. To be precise, let $d = 1$ and let ϕ be a function in Ω . If u is a local minimizer of (1) among all functions $v \in W^{1,p}(\Omega)$ subject to the constraint $v \geq \phi$ in Ω , then the variation $u + t\varphi$ is admissible if $\varphi \geq 0$ and $t \geq 0$. Therefore, the function g satisfies $g'(0) \geq 0$, and the Euler-Lagrange equation (5) becomes the variational inequality

$$\int_{\Omega} \left(\sum_{i=1}^N \frac{\partial f}{\partial \xi_i}(x, u, \nabla u) \frac{\partial \varphi}{\partial x_i} + \frac{\partial f}{\partial u}(x, u, \nabla u) \varphi \right) dx \geq 0$$

for all nonnegative $\varphi \in C_c^1(\Omega)$. This is called the *obstacle problem*, and the coincidence set $\{u = \phi\}$ is not known a priori and is called the *free boundary*. This is an example of a broad class of variational inequalities and free boundary problems that have applications in a variety of contexts, including the modeling of the melting of ice (the *Stefan problem*), lubrication, and the filtration of a liquid through a porous medium.

A related class of minimization problems in which the unknowns are both an underlying field u and a subset E of Ω is the class of *free discontinuity problems* that are characterized by the competition between a volume energy of the type (1) and a surface energy, e.g., as in (3). Important examples are in the study of liquid crystals, the optimal design of composite materials in continuum mechanics (see section 13.3), and image segmentation in computer vision (see section 13.4).

5 Lagrange Multipliers

The method of *Lagrange multipliers in Banach spaces* is used to find extrema of functionals $G: X \rightarrow \mathbb{R}$ subject to a constraint

$$\{x \in X: \Psi(x) = 0\}, \quad (7)$$

where $\Psi: X \rightarrow Y$ is another functional and X and Y are Banach spaces. It can be shown that if G and Ψ are of class C^1 and $u \in X$ is an extremum of G subject to (7), and if the derivative $D\Psi(u): X \rightarrow Y$ is surjective, then there exists a continuous, linear functional $\lambda: Y \rightarrow \mathbb{R}$ such that

$$DG(u) + \lambda \circ D\Psi(u) = 0, \quad (8)$$

where \circ stands for the composition operator between functions. The functional λ is called a *Lagrange multiplier*.

In the special case in which $Y = \mathbb{R}$, λ may be identified with a scalar, still denoted by λ , and (8) takes the familiar form

$$DG(u) + \lambda D\Psi(u) = 0.$$

Therefore, candidates for extrema may be found among all critical points of the family of functionals $G + \lambda\Psi$, $\lambda \in \mathbb{R}$.

If G has the form (1) and $X = W^{1,p}(\Omega; \mathbb{R}^d)$, $1 \leq p < +\infty$, then typical examples of Ψ are

$$\Psi(u) := \int_{\Omega} |u|^s dx - c_1 \quad \text{or} \quad \Psi(u) := \int_{\Omega} u dx - c_2$$

for some constants $c_1 \in \mathbb{R}$, $c_2 \in \mathbb{R}^d$, and $1 \leq s < +\infty$.

6 Minimax Methods

Minimax methods are used to establish the existence of *saddle points* of the functional (1), i.e., critical points that are not extrema. More generally, for C^1 functionals $G: X \rightarrow \mathbb{R}$, where X is an infinite-dimensional Banach space, as introduced in section 5, the *Palais-Smale compactness condition* (hereafter simply referred to as the PS condition) plays the role of compactness in the finite-dimensional case. To be precise, G satisfies the PS condition if whenever $\{u_n\} \subset X$ is such that $\{G(u_n)\}$ is a bounded sequence in \mathbb{R} and $DG(u_n) \rightarrow 0$ in the dual of X, X' , then $\{u_n\}$ admits a convergent subsequence.

An important result for the existence of saddle points that uses the PS condition is the *mountain pass lemma* of Ambrosetti and Rabinowitz, which states that, if G satisfies the PS condition, if $G(0) = 0$, and if there are $r > 0$ and $u_0 \in X \setminus \overline{B(0, r)}$ such that

$$\inf_{\partial B(0, r)} G > 0 \quad \text{and} \quad G(u_0) \leq 0,$$

then

$$\inf_{\gamma \in C} \sup_{u \in \gamma} G(u)$$

is a critical value, where C is the set of all continuous curves from $[0, 1]$ into X joining 0 to u_0 .

In addition, minimax methods can be used to prove the existence of multiple critical points of functionals G that satisfy certain symmetry properties, for example, the generalization of the result by Ljusternik and Schnirelmann for symmetric functions to the infinite-dimensional case.

7 Lower Semicontinuity

7.1 The Direct Method

The *direct method* in the calculus of variations provides conditions on the function space X and on a functional

G , as introduced in section 5, that guarantee the existence of minimizers of G . The method consists of the following steps.

Step 1. Consider a *minimizing sequence* $\{u_n\} \subset X$, i.e., $\lim_{n \rightarrow \infty} G(u_n) = \inf_{u \in X} G(u)$.

Step 2. Prove that $\{u_n\}$ admits a subsequence $\{u_{n_k}\}$ converging to some $u_0 \in X$ with respect to some (weak) topology τ in X . When G has an integral representation of the form (1), this is usually a consequence of a priori coercivity conditions on the integrand f .

Step 3. Establish the *sequential lower semicontinuity of G with respect to τ* , i.e., $\liminf_{n \rightarrow \infty} G(v_n) \geq G(v)$ whenever the sequence $\{v_n\} \subset X$ converges weakly to $v \in X$ with respect to τ .

Step 4. Conclude that u_0 minimizes G . Indeed,

$$\begin{aligned} \inf_{u \in X} G(u) &= \lim_{n \rightarrow \infty} G(u_n) = \lim_{k \rightarrow \infty} G(u_{n_k}) \\ &\geq G(u_0) \geq \inf_{u \in X} G(u). \end{aligned}$$

7.2 Integrands: Convex, Polyconvex, Quasiconvex, and Rank-One Convex

In view of step 3 above, it is important to characterize the class of integrands f in (1) for which the corresponding functional F is sequentially lower semicontinuous with respect to τ . In the case in which X is the Sobolev space $W^{1,p}(\Omega; \mathbb{R}^d)$, $1 \leq p \leq +\infty$, and τ is the weak topology (or weak- \star topology $p = +\infty$), this is related to convexity-type properties of $f(x, u, \cdot)$. If $\min\{d, N\} = 1$, then under appropriate growth and regularity conditions it can be shown that convexity of $f(x, u, \cdot)$ is necessary and sufficient. More generally, if $\min\{d, N\} > 1$, then the corresponding condition is called *quasiconvexity*; to be precise, $f(x, u, \cdot)$ is said to be quasiconvex if

$$f(x, u, \xi) \leq \int_{(0,1)^N} f(x, u, \xi + \nabla \varphi(y)) dy$$

for all $\xi \in \mathbb{R}^{d \times N}$ and all $\varphi \in W_0^{1,\infty}((0,1)^N; \mathbb{R}^d)$, whenever the right-hand side in this inequality is well defined. Since this condition is nonlocal, in applications in mechanics one often studies related classes of integrands, such as polyconvex and rank-one convex functions, for which there are algebraic criteria.

8 Relaxation

In most applications, step 3 in section 7.1 fails, and this leads to an important topic at the core of the calculus

of variations, namely, the introduction of a *relaxed*, or *effective*, energy \mathcal{G} that is related to G , as introduced in section 5, as follows.

- (a) \mathcal{G} is sequentially lower semicontinuous with respect to τ .
- (b) $\mathcal{G} \leq G$ and \mathcal{G} inherits coercivity properties from G .
- (c) $\min_{u \in X} \mathcal{G} = \inf_{u \in X} G$.

When G is of the type (1), a central problem is to understand if \mathcal{G} has an integral form of the type (1) for some new integrand h and then, if it has, to understand what the relation between h and the original integrand f is.

If $X = W^{1,p}(\Omega)$, $p \geq 1$, and τ is the weak topology, then under appropriate growth and regularity conditions it can be shown that $h(x, u, \cdot)$ is the *convex envelope* of $f(x, u, \cdot)$, i.e., the greatest convex function less than $f(x, u, \cdot)$. In the vectorial case $d > 1$, the convex envelope is replaced by a similar notion of quasiconvex envelope (see section 7.2).

9 Γ -Convergence

In physical problems the behavior of a system is often described in terms of a sequence $\{G_n\}$, $n \in \mathbb{N}$, of energy functionals $G_n: X \rightarrow [-\infty, +\infty]$, where X is a metric space with a metric d . Is it possible to identify a limiting energy G_∞ that sheds light on the qualitative properties of this family and that has the property that minimizers of G_n converge to minimizers of G_∞ ?

The notion of *Γ -convergence*, which was introduced by De Giorgi, provides a tool for answering these questions. To motivate this concept with an example, consider a fluid confined in a container $\Omega \subset \mathbb{R}^N$. Assume that the total mass of the fluid is m , so that admissible density distributions $u: \Omega \rightarrow \mathbb{R}$ satisfy the constraint $\int_{\Omega} u(x) dx = m$. The total energy is given by the functional $u \mapsto \int_{\Omega} W(u(x)) dx$, where $W: \mathbb{R} \rightarrow [0, \infty)$ is the energy per unit volume. Assume that W supports two phases $a < b$, that is, W is a *double-well potential*, with $\{u \in \mathbb{R}: W(u) = 0\} = \{a, b\}$. Then any density distribution u that renders the body stable in the sense of Gibbs is a minimizer of the following problem:

$$\min \left\{ \int_{\Omega} W(u(x)) dx : \int_{\Omega} u(x) dx = m \right\}. \quad (\mathcal{P}_0)$$

If $\mathcal{L}^N(\Omega) = 1$ and $a < m < b$, then given any measurable set $E \subset \Omega$ with $\mathcal{L}^N(E) = (b - m)/(b - a)$, the function $u = a\chi_E + b\chi_{\Omega \setminus E}$ is a solution of problem (\mathcal{P}_0) . This lack of uniqueness is due to the fact that interfaces between the two phases a and b can be formed

without increasing the total energy. The physically preferred solutions should be the ones that arise as limiting cases of a theory that penalizes interfacial energy, so it is expected that these solutions should minimize the surface area of $\partial E \cap \Omega$.

In the van der Waals–Cahn–Hilliard theory of phase transitions, the energy depends not only on the density u but also on its gradient. To be precise,

$$\int_{\Omega} W(u(x)) dx + \varepsilon^2 \int_{\Omega} |\nabla u(x)|^2 dx.$$

Note that the gradient term penalizes rapid changes in the density u , and thus it plays the role of an interfacial energy. Stable density distributions u are now solutions of the minimization problem

$$\min \left\{ \int_{\Omega} W(u(x)) dx + \varepsilon^2 \int_{\Omega} |\nabla u(x)|^2 dx \right\}, \quad (\mathcal{P}_{\varepsilon})$$

where the minimum is taken over all smooth functions u satisfying $\int_{\Omega} u(x) dx = m$. In 1983 Gurtin conjectured that the limits, as $\varepsilon \rightarrow 0$, of solutions of $(\mathcal{P}_{\varepsilon})$ are solutions of (\mathcal{P}_0) with minimal surface area. Using results of Modica and Mortola, this conjecture was proved independently by Modica and by Sternberg in the setting of Γ -convergence.

The Γ -limit $G_{\infty}: X \rightarrow [-\infty, +\infty]$ of $\{G_n\}$ with respect to a metric d , when it exists, is defined uniquely by the following properties.

(i) The lim inf inequality. For every sequence $\{u_n\} \subset X$ converging to $u \in X$ with respect to d ,

$$G_{\infty}(u) \leq \liminf_{n \rightarrow \infty} G_n(u_n).$$

(ii) The lim sup inequality. For every $u \in X$ there exists a sequence $\{u_n\} \subset X$ converging to $u \in X$ with respect to d such that

$$G_{\infty}(u) \geq \limsup_{n \rightarrow \infty} G_n(u_n).$$

This notion may be extended to the case in which the convergence of the sequences is taken with respect to some weak topology rather than the topology induced by the metric d . In this context, we remark that, when the sequence $\{G_n\}$ reduces to a single energy functional $\{G\}$, under appropriate growth and coercivity assumptions, G_{∞} coincides with the relaxed energy G , as discussed in section 8.

Other important applications of Γ -convergence include the Ginzburg–Landau theory for superconductivity (see section 13.5), homogenization of variational problems (see section 13.3), dimension reduction problems in elasticity (see section 13.2), and free-discontinuity problems in image segmentation in computer vision (see section 13.4) and in fracture mechanics.

10 Regularity

Optimal regularity of minimizers and local minimizers of the energy (1) in the vectorial case $d \geq 2$, and when $X = W^{1,p}(\Omega; \mathbb{R}^d)$, $1 \leq p \leq +\infty$, is mostly an open question. In the scalar case $d = 1$ there is an extensive body of literature on the regularity of weak solutions of the Euler–Lagrange equation (5), stemming from a fundamental result of De Giorgi in the late 1950s that was independently obtained by Nash. For $d \geq 2$, (local) minimizers of (1) are not generally everywhere smooth. On the other hand, and under suitable hypotheses on the integrand f , it can be shown that *partial regularity* holds, i.e., if u is a local minimizer, then there exists an open subset of Ω , Ω_0 , of full measure such that $u \in C^{1,\alpha}(\Omega_0; \mathbb{R}^d)$ for some $\alpha \in (0, 1)$. Sharp estimates of α and of the Hausdorff dimension of the *singular set* $\Sigma_u := \Omega \setminus \Omega_0$ are still unknown.

11 Symmetrization

Rearrangements of sets preserve their measure while modifying their geometry to achieve specific symmetries. In turn, rearrangements of a function u yield new functions that have desired symmetry properties and that are obtained via suitable rearrangements of the *t-superlevel sets* of u , $\Omega_t := \{x \in \Omega: u(x) > t\}$. These tools are used in a variety of contexts, from harmonic analysis and PDEs to the spectral theory of differential operators. In the calculus of variations, they are often found in the study of extrema of functionals of type (1). Among the most common rearrangements we mention the directional monotone decreasing rearrangement, the star-shaped rearrangement, the directional Steiner symmetrization, the Schwarz symmetrization, the circular and spherical symmetrization, and the radial symmetrization.

Of these, we highlight the Schwarz symmetrization, which is the most frequently used in the calculus of variations. If u is a nonnegative measurable function with compact support in \mathbb{R}^N , then its *Schwartz symmetric rearrangement* is the (unique) spherically symmetric and decreasing function u^* such that for all $t > 0$ the *t-superlevel sets* of u and u^* have the same measure.

When $\Omega = \mathbb{R}^N$, it can be shown that u^* preserves the L^p -norm of u and the regularity of u up to first order; that is, if u belongs to $W^{1,p}(\mathbb{R}^N)$, then so does u^* , $1 \leq p \leq +\infty$. Moreover, by the Pólya–Szegő inequality, $\|\nabla u^*\|_p \leq \|\nabla u\|_p$, and we remark that for $p = \infty$

this is obtained using the Brunn–Minkowski inequality discussed in section 2.3.

Another important inequality relating u and u^* is the Riesz inequality, and the Faber–Krahn inequality compares eigenvalues of the Dirichlet problems in Ω and in Ω^* . Classical applications of rearrangements include the derivation of the sharp constant in the Sobolev–Gagliardo–Nirenberg inequality in $W^{1,p}(\mathbb{R}^N)$, $1 < p < N$, as well as in the Young inequality and the Hardy–Littlewood–Sobolev inequality.

Finally, we remark that the first and most important application of Steiner symmetrization is the isoperimetric property of balls (see Dido’s problem in section 1).

12 Duality Theory

Duality theory associates with a minimization problem (\mathcal{P}) a maximization problem (\mathcal{P}^*) , called the *dual problem*, and studies the relation between these two. It has important applications in several disciplines, including economics and mechanics, and different areas of mathematics, such as the calculus of variations, convex analysis, and numerical analysis.

The theory of dual problems is inspired by the notion of duality in convex analysis and by the *Fenchel transform* f^* of a function $f: \mathbb{R}^N \rightarrow [-\infty, +\infty]$, defined as

$$f^*(\eta) := \sup\{\eta \cdot \xi - f(\xi) : \xi \in \mathbb{R}^N\} \quad \text{for } \eta \in \mathbb{R}^N.$$

As an example, consider the minimization problem

$$\inf \left\{ \int_{\Omega} f(\nabla u) dx : u \in W_0^{1,p}(\Omega) \right\}, \quad (\mathcal{P})$$

with $f: \mathbb{R}^N \rightarrow \mathbb{R}$. If f satisfies appropriate growth and convexity conditions, then the dual problem (\mathcal{P}^*) is given by

$$\sup \left\{ - \int_{\Omega} f^*(v(x)) dx : v \in L^q(\Omega; \mathbb{R}^N), \right. \\ \left. \operatorname{div} v = 0 \text{ in } \Omega \right\},$$

where $1/p + 1/q = 1$. The latter problem may be simpler to handle in specific situations, e.g., for nonparametric minimal surfaces and with f given as in (2), where, due to lack of coercivity, (\mathcal{P}) may not admit a solution in X .

13 Some Contemporary Applications

There is a plethora of applications of the calculus of variations. Classical ones include Hamiltonians and Lagrangians, the Hamilton–Jacobi equation, conservation laws, Noether’s theorem, and optimal control.

Below we focus on a few contemporary applications that are pushing the frontiers of the theory in novel directions.

13.1 Elasticity

Consider an elastic body that occupies a domain $\Omega \subset \mathbb{R}^3$ in a given reference configuration. The deformations of the body can be described by maps $u: \Omega \rightarrow \mathbb{R}^3$. If the body is homogeneous, then the total elastic energy corresponding to u is given by the functional

$$F(u) := \int_{\Omega} f(\nabla u(x)) dx, \quad (9)$$

where f is the *stored-energy density* of the material. In order to prevent interpenetration of matter, the deformations should be invertible and it should require an infinite amount of energy to violate this property, i.e.,

$$f(\xi) \rightarrow +\infty \quad \text{as } \det \xi \rightarrow 0^+. \quad (10)$$

Also, f needs to be *frame indifferent*, i.e.,

$$f(R\xi) = f(\xi) \quad (11)$$

for all rotations R and all $\xi \in \mathbb{R}^{3 \times 3}$.

Under appropriate coercivity and convex-type conditions on f (see section 7.2), and under suitable boundary conditions, it can be shown that F admits a global minimizer u_0 . However, the regularity of u_0 is still an open problem, and the Euler–Lagrange equation cannot therefore be derived (see section 3). In addition, the existence of local minimizers remains unsolved.

13.2 Dimension Reduction

An important problem in elasticity is the derivation of models for thin structures, such as membranes, shells, plates, rods, and beams, from three-dimensional elasticity theory. The mathematically rigorous analysis was initiated by Acerbi, Buttazzo, and Percivale in the 1990s for rods, and this was followed by the work of Le Dret and Raoult for membranes. Recent contributions by Friesecke, James, and Müller have allowed us to handle the physical requirements (10) and (11). The main tool underlying these works is Γ -convergence (see section 9).

To illustrate the deduction in the case of membranes, consider a thin cylindrical elastic body of thickness $2\varepsilon > 0$ occupying the reference configuration $\Omega_\varepsilon := \omega \times (-\varepsilon, \varepsilon)$, with $\omega \subset \mathbb{R}^2$. Using the typical rescaling

$$(x_1, x_2, x_3) \mapsto (y_1, y_2, y_3) := (x_1, x_2, x_3/\varepsilon),$$

the deformations u of Ω_ε now correspond to deformation v of the fixed domain Ω_1 , through the formula

$v(y_1, y_2, y_3) = u(x_1, x_2, x_3)$. Therefore,

$$\frac{1}{\varepsilon} \int_{\Omega_\varepsilon} f(\nabla u) dx = \int_{\Omega_1} f\left(\frac{\partial v}{\partial y_1}, \frac{\partial v}{\partial y_2}, \frac{1}{\varepsilon} \frac{\partial v}{\partial y_3}\right) dy.$$

The right-hand side of the previous equality yields a family of functionals to which the theory of Γ -convergence is applied.

13.3 Homogenization

HOMOGENIZATION THEORY [II.17] is used to describe the macroscopic behavior of heterogeneous composite materials, which are characterized by having two or more finely mixed material components. Composite materials have important technological and industrial applications as their effective properties are often better than the corresponding properties of the individual constituents. The study of these materials falls within the so-called *multiscale problems*, with the two relevant scales here being the *microscopic scale* at the level of the heterogeneities and the *macroscopic scale* describing the resulting “homogeneous” material. Mathematically, the properties of composite materials can be described in terms of PDEs with fast oscillating coefficients or in terms of energy functionals that depend on a small parameter ε . As an example, consider a material matrix A with corresponding stored-energy density f_A , with periodically distributed inclusions of another material B with stored-energy density f_B , whose periodicity cell has side-length ε . The total energy of the composite is then given by

$$\int_{\Omega} \left[\left(1 - \chi\left(\frac{x}{\varepsilon}\right)\right) f_A(\nabla u) + \chi\left(\frac{x}{\varepsilon}\right) f_B(\nabla u) \right] dx,$$

where χ is the characteristic function of the locus of material B contained in the unit cube Q of material A , extended periodically to \mathbb{R}^3 with period Q . The goal here is to characterize the “homogenized” energy when $\varepsilon \rightarrow 0^+$ using Γ -convergence (see section 9).

13.4 Computer Vision

Several problems in computer vision can be treated variationally, including image segmentation (e.g., the Mumford-Shah and Blake-Zisserman models), image morphing, image denoising (e.g., the Perona-Malik scheme and the Rudin-Osher-Fatemi total variation model), and inpainting (e.g., recolorization).

The Mumford-Shah model provides a good example of the use of the calculus of variations to treat free discontinuity problems. Let Ω be a rectangle in the plane, representing the locus of the image, with gray levels given by a function $g: \Omega \rightarrow [0, 1]$. We want to find an

approximation of g that is smooth outside a set K of sharp contours related to the set of discontinuities of g . This leads to the minimization of the functional

$$\int_{\Omega \setminus K} (|\nabla u|^2 + \alpha(u - g)^2) dx + \beta \text{length}(K \cap \Omega)$$

over all contour curves K and functions $u \in C^1(\Omega \setminus K)$. The first term in this energy functional is minimized when u is constant outside K , and it therefore forces u not to vary much outside K . The second term is minimized when $u = g$ outside K , and hence u is required to stay close to the original gray level g . The last term is minimized when K has length as short as possible. The existence of a minimizing pair (u, K) was established by De Giorgi, Carriero, and Leaci, with u in a class of functions larger than $C^1(\Omega \setminus K)$, to be precise, the space of functions of special bounded variation. The full regularity of these solutions u and the structure of K remain an open problem.

13.5 The Ginzburg-Landau Theory for Superconductivity

In the 1950s Ginzburg and Landau proposed a mathematical theory to study phase transition problems in superconductivity; there are similar formulations to address problems in superfluids, e.g., helium II, and in XY magnetism. In its simplest form, the Ginzburg-Landau functional reduces to

$$F_\varepsilon(u) := \frac{1}{2} \int_{\Omega} |\nabla u|^2 dx + \frac{1}{4\varepsilon^2} \int_{\Omega} (|u|^2 - 1)^2 dx,$$

where $\Omega \subset \mathbb{R}^2$ is a star-shaped domain, the *condensate wave function* $u \in W^{1,2}(\Omega; \mathbb{R}^2)$ is an order parameter with two degrees of freedom, and the parameter ε is a (small) characteristic length. Given $g: \partial\Omega \rightarrow \mathbb{S}^1$, with \mathbb{S}^1 the unit circle in \mathbb{R}^2 centered at the origin, we are interested in characterizing the limits of minimizers u_ε of F_ε subject to the boundary condition $u_\varepsilon = g$ on $\partial\Omega$. Under suitable geometric conditions on g (related to the winding number), Bethuel, Brezis, and Hélein have shown that there are no limiting functions u in $C(\bar{\Omega}, \mathbb{S}^1)$ that satisfy the boundary condition. Rather, the limiting functions are smooth outside a finite set of singularities, called *vortices*. Γ -convergence techniques may be used to study this family of functionals (see section 9).

13.6 Mass Transport

Mass transportation was introduced by Monge in 1781, studied by the Nobel Prize winner Kantorovich in the 1940s, and revived by Brenier in 1987. Since then, it has surfaced in a variety of areas, from economics to

optimization. Given a pile of sand of mass 1 and a hole of volume 1, we want to fill the hole with the sand while minimizing the cost of transportation. This problem is formulated using probability theory as follows. The pile and the hole are represented by probability measures μ and ν , with supports in measurable spaces X and Y , respectively. If $A \subset X$ and $B \subset Y$ are measurable sets, then $\mu(A)$ measures the amount of sand in A and $\nu(B)$ measures the amount of sand that can fill B . The cost of transportation is modeled by a measurable cost function $c: X \times Y \rightarrow \mathbb{R} \cup +\infty$. Kantorovich's optimal transportation problem consists of minimizing

$$\int_{X \times Y} c(x, y) d\pi(x, y)$$

over all probability measures on $X \times Y$ such that $\pi(A \times Y) = \mu(A)$ and $\pi(X \times B) = \nu(B)$, for all measurable sets $A \subset X$ and $B \subset Y$. The main problem is to establish the existence of minimizers and to obtain their characterization. This depends strongly on the cost function c and on the regularity of the measures μ and ν . There is a multitude of applications of this theory, and here we mention only that it can be used to give a simple proof of the Brunn–Minkowski inequality (see (4)).

13.7 Gradient Flows

Given a function $h: \mathbb{R}^m \rightarrow \mathbb{R}$ of class C^2 , the *gradient flow* of h is the family of maps $S_t: \mathbb{R}^m \rightarrow \mathbb{R}^m$, $t \geq 0$, satisfying the following property. For every $w_0 \in \mathbb{R}^m$, $S_0(w_0) := w_0$ and the curve $w_t := S_t(w_0)$, $t > 0$, is the unique C^1 solution of the Cauchy problem

$$\frac{d}{dt} w_t = -\nabla h(w_t) \quad \text{for } t > 0, \quad \lim_{t \rightarrow 0^+} w_t = w_0, \quad (12)$$

if it exists.

If $D^2 h \geq \alpha \mathbb{I}$ for some $\alpha \in \mathbb{R}$, then it can be shown that the gradient flow exists, that it is unique, and that it satisfies a semigroup property, i.e.,

$$S_{t+s}(w_0) = S_t(S_s(w_0)), \quad \lim_{t \rightarrow 0^+} S_t(w_0) = w_0,$$

for every $w_0 \in \mathbb{R}^m$.

A common way of approximating discretely the solution of (12) is via the *implicit Euler scheme*, as follows. Given a time step $\tau > 0$, consider the partition of $[0, +\infty)$

$$\{0 = t_\tau^0 < t_\tau^1 < \dots < t_\tau^n < \dots\},$$

where $t_\tau^n := n\tau$. Define recursively a discrete sequence $\{W_\tau^n\}$ as follows: assuming that W_τ^{n-1} has already been defined, let W_τ^n be the unique minimizer of the function

$$w \mapsto \frac{1}{2\tau} |w - W_\tau^{n-1}|^2 + h(w). \quad (13)$$

Introduce the piecewise-linear function $W_\tau: [0, +\infty) \rightarrow \mathbb{R}^m$ given by

$$W_\tau(t) = \frac{t - t_\tau^{n-1}}{\tau} W_\tau^{n-1} + \frac{t_\tau^n - t}{\tau} W_\tau^n$$

for $t \in [t_\tau^{n-1}, t_\tau^n]$. If $W_\tau^0 \rightarrow w_0$ as $\tau \rightarrow 0^+$, then it can be shown that $\{W_\tau\}_{\tau > 0}$ converges to the solution of (12) as $\tau \rightarrow 0^+$.

This approximation scheme, here described for the finite-dimensional vector space \mathbb{R}^d , may be extended to the case in which \mathbb{R}^d is replaced by an infinite-dimensional metric space X , the function h is replaced by a functional $G: X \rightarrow \mathbb{R}$, and the minimization procedure in (13) is now a variational minimization problem of the type addressed in section 7. This method is known as *De Giorgi's minimizing movements*. Important applications include the study of a large class of parabolic PDEs.

IV.7 Special Functions

Nico M. Temme

1 Introduction

Usually we call a function “special” when, like the logarithm, the exponential function, and the trigonometric functions (the elementary transcendental functions), it belongs to the toolbox of the applied mathematician, the physicist, the engineer, or the statistician. Each function has particular notation associated with it and has a great number of known properties.

The study of special functions is a branch of mathematics with a distinguished history involving great names such as Euler, Gauss, Fourier, Legendre, Bessel, and Riemann. Much of their work was inspired by problems from physics and by the resulting differential equations. This activity culminated in the publication in 1927 of the standard, and greatly influential, work *A Course of Modern Analysis* by Whittaker and Watson.

Many other monographs are now available, some that contain the formulas without explanation and others that explain how the special functions arise in problems from physics and statistics. A major project called the Digital Library of Mathematical Functions recently culminated in the *NIST Handbook of Mathematical Functions* (a successor to Abramowitz and Stegun’s famed *Handbook of Mathematical Functions*), which is also readily accessible online.

In physics, special functions arise as solutions of the linear second-order differential equations that result from separating the variables in a partial differential equation in some special coordinate system (such as spherical or cylindrical). In this way solutions of the wave equation, the diffusion equation, and so on are written in the form of series or integrals.

In statistics, special functions arise as cumulative distribution functions (gamma and beta distributions, for example). In number theory, zeta functions, Dirichlet series, and modular forms are used.

Some topics that fall outside the scope of this article are mentioned in the final section.

2 Bernoulli Numbers, Euler Numbers, and Stirling Numbers

The Bernoulli numbers B_n are defined by the generating function

$$\frac{z}{e^z - 1} = \sum_{n=0}^{\infty} \frac{B_n}{n!} z^n, \quad |z| < 2\pi.$$

Because the function $z/(e^z - 1) - 1 + \frac{1}{2}z$ is even, all B_n with odd index $n \geq 3$ vanish: $B_{2n+1} = 0$, $n = 1, 2, 3, \dots$. The first nonvanishing numbers are

$$B_0 = 1, \quad B_1 = -\frac{1}{2}, \quad B_2 = \frac{1}{6}, \quad B_4 = -\frac{1}{30}, \quad B_6 = \frac{1}{42}.$$

The Bernoulli numbers are named after Jakob Bernoulli, who mentioned them in his posthumous *Ars Conjectandi* of 1713. He discussed *summae potestatum*, sums of equal powers of the first n integers; for a nonnegative integer p ,

$$\sum_{m=0}^{n-1} m^p = \frac{1}{p+1} \sum_{k=0}^p \binom{p+1}{k} B_k n^{p+1-k},$$

where $\binom{n}{k} = n!/[k!(n-k)!]$. The Bernoulli numbers occur in practically every field of mathematics and particularly in combinatorial theory, finite-difference calculus, numerical analysis, analytic number theory, and probability theory.

The Bernoulli polynomials are defined by the generating function

$$\frac{ze^{xz}}{e^z - 1} = \sum_{n=0}^{\infty} \frac{B_n(x)}{n!} z^n, \quad |z| < 2\pi.$$

The first few polynomials are

$$B_0(x) = 1, \quad B_1(x) = x - \frac{1}{2}, \quad B_2(x) = x^2 - x + \frac{1}{6}.$$

For the Euler numbers E_n , we have the generating function

$$\frac{1}{\cosh z} = \frac{2e^z}{e^{2z} + 1} = \sum_{n=0}^{\infty} \frac{E_n}{n!} z^n, \quad |z| < \frac{1}{2}\pi.$$

In contrast to the Bernoulli numbers, the Euler numbers are integers. The first few are

$$E_0 = 1, \quad E_2 = -1, \quad E_4 = 5, \quad E_6 = -61,$$

while those with odd index are zero.

The numbers $s(n, k)$ in the generating function

$$\sum_{n=0}^{\infty} s(n, k) \frac{x^n}{n!} = \frac{(\ln(1+x))^k}{k!}, \quad |x| < 1,$$

and the numbers $S(n, k)$ in the generating function

$$\sum_{n=0}^{\infty} S(n, k) \frac{x^n}{n!} = \frac{(e^x - 1)^k}{k!}$$

are called Stirling numbers of the first and second kind, respectively. They are defined for $0 \leq k \leq n$ and are named after James Stirling. The Stirling numbers of the second kind have the following combinatorial interpretation: $S(n, k)$ is the number of partitions

of $\{1, 2, \dots, n\}$ into exactly k nonempty subsets. For example, $S(4, 2) = 7$, since

$$\begin{aligned} \{1, 2, 3, 4\} &= \{1\} \cup \{2, 3, 4\} = \{2\} \cup \{1, 3, 4\} \\ &= \{3\} \cup \{1, 2, 4\} = \{4\} \cup \{1, 2, 3\} \\ &= \{1, 2\} \cup \{3, 4\} = \{1, 3\} \cup \{2, 4\} \\ &= \{1, 4\} \cup \{2, 3\}. \end{aligned}$$

3 The Gamma Function and Related Functions

The triangular numbers $T_n = 1 + 2 + \dots + n$ can be written as $\frac{1}{2}n(n+1)$. Euler thought that it must be possible to express $n! = 1 \cdot 2 \cdot \dots \cdot (n-1) \cdot n$ as a simple formula (the factorial notation was not used by Euler). In 1729 he proved that for $n!$ such a simple formula does not exist, but he did come up with the formula $n! = \int_0^1 (-\ln x)^n dx$. Nowadays, this integral is written as

$$\Gamma(z) = \int_0^\infty t^{z-1} e^{-t} dt, \quad \operatorname{Re} z > 0, \quad (1)$$

which is obtained when we use the values $t = -\ln x$ and $n = z - 1$. This notation was formulated by Legendre in 1809, and he also coined the term “gamma function” for Γ .

The fundamental property $\Gamma(z+1) = z\Gamma(z)$ follows easily by integrating by parts in (1), and this relation shows that the singularities at $z = 0, -1, -2, \dots$ are poles of first order. From the Maclaurin expansion of e^{-t} and the Plemelj decomposition

$$\Gamma(z) = \int_0^1 t^{z-1} e^{-t} dt + \int_1^\infty t^{z-1} e^{-t} dt,$$

we obtain the expansion due to Mittag-Leffler

$$\Gamma(z) = \sum_{n=0}^{\infty} \frac{(-1)^n}{n!(n+z)} + \int_1^\infty t^{z-1} e^{-t} dt,$$

where $z \neq 0, -1, -2, \dots$. As the integral is an entire function of z , we see that the pole at $z = -n$ has a residue $(-1)^n/n!$.

There is another definition as an infinite product,

$$\frac{1}{\Gamma(z)} = ze^{\gamma z} \prod_{n=0}^{\infty} \left(\left(1 + \frac{z}{n}\right) e^{-z/n} \right),$$

where γ is Euler's constant, defined by the limit

$$\gamma = \lim_{N \rightarrow \infty} \left(\sum_{n=1}^N \frac{1}{n} - \ln N \right) = 0.5772 \dots \quad (2)$$

From the infinite product it follows that

$$\Gamma(z) = \lim_{n \rightarrow \infty} \frac{n! n^z}{z(z+1) \cdots (z+n)}.$$

Important properties are the reflection formula (due to Euler (1771))

$$\Gamma(z)\Gamma(1-z) = \frac{\pi}{\sin(\pi z)}, \quad z \neq \text{an integer}, \quad (3)$$

and the duplication formula

$$\Gamma(\frac{1}{2})\Gamma(2z) = 2^{2z-1}\Gamma(z)\Gamma(z+\frac{1}{2}),$$

where $z \neq 0, -1, -2, \dots$ and $\Gamma(\frac{1}{2}) = \sqrt{\pi}$.

A closely related special function is the beta integral, defined for $\operatorname{Re} p > 0$ and $\operatorname{Re} q > 0$ by

$$B(p, q) = \int_0^1 t^{p-1} (1-t)^{q-1} dt. \quad (4)$$

The relationship between the beta integral and the gamma function is given by

$$B(p, q) = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)}.$$

The derivative of the gamma function itself does not play an important role in the theory and applications of special functions. It is not a very manageable function. Much more interesting is the logarithmic derivative:

$$\psi(z) = \frac{d}{dz} \ln \Gamma(z) = \frac{\Gamma'(z)}{\Gamma(z)}.$$

It satisfies the recursion relation $\psi(z+1) = \psi(z) + 1/z$ and it has an interesting series expansion:

$$\psi(z) = -\gamma + \sum_{n=0}^{\infty} \left(\frac{1}{n+1} - \frac{1}{z+n} \right),$$

for $z \neq 0, -1, -2, \dots$

Stirling's asymptotic formula for factorials

$$n! \sim \sqrt{2\pi n} n^n e^{-n}, \quad n \rightarrow \infty, \quad (5)$$

has several refinements, first in the form

$$\Gamma(z) = \sqrt{2\pi/z} z^z e^{-z+\mu(z)}, \quad \mu(z) = \theta/z, \quad (6)$$

with $0 < \theta < 1$, if $z > 0$, and second in the form

$$\Gamma(z) \sim \sqrt{2\pi/z} z^z e^{-z} \sum_{n=0}^{\infty} \frac{a_n}{z^n}, \quad (7)$$

which is valid for large z inside the sector $-\pi < \operatorname{ph} z < \pi$ (where $\operatorname{ph} z = \arg z$ is the phase or argument of z). The first few coefficients are

$$a_0 = 1, \quad a_1 = \frac{1}{12}, \quad a_2 = \frac{1}{288}, \quad a_3 = -\frac{139}{51840}.$$

For the asymptotic expansion of the logarithm of the gamma function the coefficients are explicitly known in terms of Bernoulli numbers:

$$\begin{aligned} \ln \Gamma(z) &\sim (z - \frac{1}{2}) - z + \frac{1}{2} \ln(2\pi) \\ &\quad + \sum_{n=1}^{\infty} \frac{B_{2n}}{2n(2n-1)z^{2n-1}}, \end{aligned} \quad (8)$$

which is again valid for large z inside the sector $-\pi < \operatorname{ph} z < \pi$. This expansion is more efficient than the one in (7) because it is in powers of z^{-2} . Moreover, estimates of the remainder in the expansion in (8) are available.

4 The Riemann Zeta Function

The Riemann zeta function is defined by the series

$$\zeta(s) = \sum_{n=1}^{\infty} \frac{1}{n^s}, \quad \operatorname{Re} s > 1. \quad (9)$$

This function was known to Euler, but its main properties were discovered by Riemann. A well-known result in analysis is the divergence of the harmonic series $\sum_{n=1}^{\infty} (1/n)$ (see (2)), and indeed, the Riemann zeta function has a singular point at $s = 1$, a pole of order 1. The limit $\lim_{s \rightarrow 1}(s-1)\zeta(s)$ exists and equals 1. Apart from this pole, $\zeta(s)$ is analytic throughout the complex s -plane.

The relationship between the Riemann zeta function and the gamma function is shown in the reflection formula:

$$\zeta(1-s) = 2(2\pi)^{-s} \Gamma(s) \zeta(s) \cos(\tfrac{1}{2}\pi s), \quad s \neq 0. \quad (10)$$

The most remarkable thing about $\zeta(s)$ is its relationship with the theory of prime numbers. We demonstrate one aspect of this relationship here. Assume that $\operatorname{Re} s > 1$. Subtract the series for $2^{-s}\zeta(s)$ from the one in (9). We then obtain

$$(1 - 2^{-s})\zeta(s) = \frac{1}{1^s} + \frac{1}{3^s} + \frac{1}{5^s} + \frac{1}{7^s} + \dots$$

Similarly, we obtain

$$(1 - 2^{-s})(1 - 3^{-s})\zeta(s) = \sum \frac{1}{n^s},$$

where the summation now runs over $n \geq 1$, except for multiples of 2 and 3. Now, let p_n denote the n th prime number, starting with $p_1 = 2$. By repeating the above procedure we obtain

$$\zeta(s) \prod_{n=1}^m (1 - p_n^{-s}) = 1 + \sum \frac{1}{n^s},$$

where the summation runs over integers $n > 1$, except for multiples of the primes p_1, p_2, \dots, p_m . The sum of this series vanishes as $m \rightarrow \infty$ (since $p_m \rightarrow \infty$). From this we obtain the result:

$$\frac{1}{\zeta(s)} = \prod_{n=1}^{\infty} (1 - p_n^{-s}), \quad \operatorname{Re} s > 1. \quad (11)$$

This formula is of fundamental importance to the relationship between the Riemann zeta function and the theory of prime numbers.

An immediate consequence is that $\zeta(s)$ does not have zeros in the half-plane $\operatorname{Re} s > 1$. The reflection formula (10) makes it clear that the only zeros in the half-plane $\operatorname{Re} s < 0$ occur at the points $-2, -4, -6, \dots$. These are called the trivial zeros of the zeta function.

Riemann conjectured that all the zeros in the strip $0 \leq \operatorname{Re} s \leq 1$ (it is known that there are infinitely many of them) are located on the line $\operatorname{Re} s = \frac{1}{2}$. This conjecture, the Riemann hypothesis, has not yet been proved or disproved. An important part of number theory is based on this conjecture. Much time has been spent on attempting to verify or disprove the Riemann hypothesis, both analytically and numerically. It is one of the seven Millennium Prize Problems of the Clay Mathematics Institute, with a prize of \$1 000 000 on offer for its resolution.

5 Gauss Hypergeometric Functions

The Gauss hypergeometric function,

$$F(a, b; c; z) = 1 + \frac{ab}{c} z + \frac{a(a+1)b(b+1)}{c(c+1)2!} z^2 + \dots,$$

plays a central role in the theory of special functions. (We always assume that $c \neq 0, -1, -2, \dots$) With more compact notation,

$$F(a, b; c; z) = \sum_{n=0}^{\infty} \frac{(a)_n (b)_n}{(c)_n n!} z^n, \quad |z| < 1, \quad (12)$$

where Pochhammer's symbol $(a)_n$ is defined by

$$(a)_n = \frac{\Gamma(a+n)}{\Gamma(a)} = \frac{(-1)^n \Gamma(1-a)}{\Gamma(1-a-n)},$$

using (3). Many special cases arise in the area of orthogonal polynomials (see section 7), in probability theory (as distribution functions: see section 6), and in physics (as Legendre functions: see section 10).

When $a = 0, -1, -2, \dots$, the power series in (12) terminates and $F(a, b; c; z)$ becomes a polynomial of degree $-a$. The same holds for b ; note the symmetry $F(a, b; c; z) = F(b, a; c; z)$.

Euler knew of the hypergeometric function, but Gauss made a more systematic study of it. The name "hypergeometric series" was introduced by John Wallis in 1655.

The geometric series $1/(1-z) = 1 + z + z^2 + \dots$ is the simplest example, and more generally we have

$$(1-z)^{-a} = \sum_{n=0}^{\infty} \frac{(a)_n}{n!} z^n = F(a, b; b; z), \quad |z| < 1, \quad (13)$$

for any b . Other elementary examples are

$$\begin{aligned} F\left(\frac{1}{2}, 1; \frac{3}{2}; z^2\right) &= \frac{1}{2}z^{-1} \ln([1+z]/[1-z]), \\ F\left(\frac{1}{2}, 1; \frac{3}{2}; -z^2\right) &= z^{-1} \arctan z, \\ F\left(\frac{1}{2}, \frac{1}{2}; \frac{3}{2}; z^2\right) &= z^{-1} \arcsin z, \\ F\left(\frac{1}{2}, \frac{1}{2}; \frac{3}{2}; -z^2\right) &= z^{-1} \ln(z + \sqrt{1+z^2}), \end{aligned}$$

as well as complete elliptic integrals. We have

$$K(k) = \int_0^{\pi/2} \frac{d\theta}{\sqrt{1-k^2 \sin^2 \theta}} = \frac{\pi}{2} F\left(\frac{1}{2}, \frac{1}{2}; 1; k^2\right)$$

for $0 \leq k^2 < 1$. Similarly, for $0 \leq k^2 \leq 1$,

$$E(k) = \int_0^{\pi/2} \sqrt{1-k^2 \sin^2 \theta} d\theta = \frac{\pi}{2} F\left(-\frac{1}{2}, \frac{1}{2}; 1; k^2\right).$$

The integral representation

$$\begin{aligned} F(a, b; c; z) &= \frac{\Gamma(c)}{\Gamma(b)\Gamma(c-b)} \\ &\times \int_0^1 t^{b-1}(1-t)^{c-b-1}(1-tz)^{-a} dt \end{aligned} \quad (14)$$

can be used when $\operatorname{Re} c > \operatorname{Re} b > 0$ and for $|\operatorname{ph}(1-z)| < \pi$. This representation extends the z -domain of the function defined by the power series in (12) considerably. The relationship between the integral in (14) and the hypergeometric function follows if we expand $(1-tz)^{-a}$ as in (13) and using the beta integral (4). Several other integral representations along contours in the complex plane that have fewer or no restrictions on the parameters a , b , and c can be obtained from (14).

The function $F(a, b; c; z)$ satisfies the differential equation (given by Gauss)

$$z(1-z)F'' + (c - (a+b+1)z)F' - abF = 0. \quad (15)$$

From the theory of differential equations it follows that (15) has three regular singular points, at $z = 0$, $z = 1$, and $z = \infty$.

A function may be expressed in terms of hypergeometric functions in several different ways. The example $(1-z)^{-1} = F(1, b; b; z)$ demonstrates the basic idea. We can write

$$\frac{1}{1-z} = \frac{-1}{z(1-1/z)} = -\frac{1}{z} F(1, b; b; 1/z). \quad (16)$$

We therefore have a second representation of $(1-z)^{-1}$ but with a different domain of convergence of the power series, $|z| > 1$. In the general case, $F(a, b; c; z)$ can be written as a linear combination of other F -functions, with different a , b , and c , and power series in z , $1/z$, $1-z$, $z/(z-1)$, $1/(1-z)$, or $1-1/z$.

The simplest general set of such relations is

$$\begin{aligned} F(a, b; c; z) &= (1-z)^{-a} F(a, c-b; c; z/(z-1)) \\ &= (1-z)^{-b} F(c-a, b; c; z/(z-1)) \\ &= (1-z)^{-a-b} F(c-a, c-b; c; z). \end{aligned}$$

The first of these follows most easily from changing the variable of integration in (14), $t \mapsto (1-t)$, the second from the symmetry in $F(a, b; c; z)$ with respect to a and b , and the third from using the first or second relation twice. This gives another way of extending the z -domain of the function defined by the power series in (12).

The Gauss hypergeometric function has many generalizations, of which we mention the most natural one, which takes the form

$$\begin{aligned} {}_pF_q\left(\begin{matrix} a_1, a_2, \dots, a_p \\ b_1, b_2, \dots, b_q \end{matrix}; z\right) \\ = \sum_{n=0}^{\infty} \frac{(a_1)_n (a_2)_n \cdots (a_p)_n}{(b_1)_n (b_2)_n \cdots (b_q)_n} \frac{z^n}{n!}, \end{aligned} \quad (17)$$

which is convergent for $|z| < 1$ if $p = q+1$ or for all z when $p \leq q$. All b_j should be different from $0, -1, -2, \dots$. Note that the Gauss hypergeometric function $F = {}_2F_1$.

6 Probability Functions

An essential concept in probability theory is the cumulative distribution function $F(x)$. It is defined on the real line, and it is nondecreasing with $F(-\infty) = 0$ and $F(\infty) = 1$. Other intervals are also used. The normal or Gaussian distribution

$$P(x) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^x e^{-t^2/2} dt$$

is a major example. The error functions

$$\operatorname{erf} x = \frac{2}{\sqrt{\pi}} \int_0^x e^{-t^2} dt, \quad \operatorname{erfc} x = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-t^2} dt$$

are also used, and the following relationship holds: $\operatorname{erf} x + \operatorname{erfc} x = 1$. $P(x)$ and the complementary function $Q(x) = 1 - P(x)$ are related to erfc in the following ways:

$$P(x) = \frac{1}{2} \operatorname{erfc}(-x/\sqrt{2}), \quad Q(x) = \frac{1}{2} \operatorname{erfc}(x/\sqrt{2}).$$

Error functions occur in other branches of applied mathematics, heat conduction, for example. Extra parameters such as mean and variance can be included in the basic forms. An extensive introduction to probability functions can be found in Johnson et al. (1994, 1995).

More degrees of freedom are available in the incomplete beta function ratio $I_x(p, q)$, which is based on the beta integral in (4) and is given by

$$I_x(p, q) = \frac{1}{B(p, q)} \int_0^x t^{p-1} (1-t)^{q-1} dt,$$

with $x \in [0, 1]$ and $p, q > 0$. Special cases are the F -variance-ratio distribution and Student's t -distribution. The function $I_x(p, q)$ can be written as a Gauss hypergeometric function.

For the gamma distribution we split up the integral in (1) that defines the gamma function. This gives the incomplete gamma function ratios

$$\begin{aligned} P(a, x) &= \frac{1}{\Gamma(a)} \int_0^x t^{a-1} e^{-t} dt, \\ Q(a, x) &= \frac{1}{\Gamma(a)} \int_x^\infty t^{a-1} e^{-t} dt, \end{aligned}$$

where $a > 0$. The functions $P(a, x)$ and $Q(a, x)$ can be written in terms of confluent hypergeometric functions (see section 8).

A further generalization is the noncentral χ^2 distribution, which can be defined by the integral

$$P_\mu(x, y) = \int_0^y \left(\frac{z}{x}\right)^{(\mu-1)/2} e^{-x-z} I_{\mu-1}(2\sqrt{xz}) dz, \quad (18)$$

where I_μ is a modified Bessel function (see section 9). The complementary function is $Q_\mu = 1 - P_\mu$, and this function also plays a role in physics, for instance in problems on radar communications, where it is called the generalized Marcum Q -function.

In terms of the incomplete gamma function ratios we have the expansions

$$P_\mu(x, y) = e^{-x} \sum_{n=0}^{\infty} \frac{x^n}{n!} P(\mu + n, y),$$

$$Q_\mu(x, y) = e^{-x} \sum_{n=0}^{\infty} \frac{x^n}{n!} Q(\mu + n, y).$$

In statistics and probability theory one is more familiar with the definition through the χ^2 probability functions, which are defined by

$$P(\chi^2 | \nu) = P(a, x), \quad Q(\chi^2 | \nu) = Q(a, x),$$

where $\nu = 2a$ and $\chi^2 = 2x$. The noncentral χ^2 distribution functions are then defined by

$$P(\chi^2 | \nu, \lambda) = \sum_{n=0}^{\infty} e^{-\lambda/2} \frac{(\frac{1}{2}\lambda)^n}{n!} P(\chi^2 | \nu + 2n),$$

$$Q(\chi^2 | \nu, \lambda) = \sum_{n=0}^{\infty} e^{-\lambda/2} \frac{(\frac{1}{2}\lambda)^n}{n!} Q(\chi^2 | \nu + 2n),$$

where $\lambda \geq 0$ is called the noncentrality parameter.

7 Orthogonal Polynomials

These special functions arise in many branches of pure and applied mathematics. For example, the Hermite polynomials H_n play a role in the form $e^{-x^2/2} H_n(x)$ as eigenfunctions of the Schrödinger equation for a linear harmonic oscillator.

Let p_n be a polynomial of degree n defined on (a, b) , a real interval, where $a = -\infty$ and/or $b = +\infty$ are allowed. Let w be a nonnegative weight function defined on (a, b) . Suppose that

$$\int_a^b p_n(x) p_m(x) w(x) dx = 0 \quad (19)$$

if and only if $n \neq m$. Then the family $\{p_n\}$ constitutes a system of orthogonal polynomials on (a, b) with respect to weight w .

Orthogonal polynomials can also be defined with Lebesgue measures, on curves in the complex plane (such as the unit circle), and with respect to discrete weight functions or measures. In the last case, the integral in (19) becomes a sum.

The families of polynomials associated with the names of Jacobi, Gegenbauer, Chebyshev, Legendre, Laguerre, and Hermite are called the *classical orthogonal polynomials*. They share many features, and they have the following characteristics:

- (i) the family $\{p'_n\}$ is also an orthogonal system;
- (ii) the polynomial p_n satisfies a second-order linear differential equation $A(x)y'' + B(x)y' + \lambda_n y = 0$, where A and B do not depend on n and λ_n does not depend on x ; and
- (iii) there is a *Rodrigues formula* of the form

$$p_n(x) = \frac{1}{K_n w(x)} \frac{d^n}{dx^n} (w(x) X^n(x)),$$

where $X(x)$ is a polynomial with coefficients not depending on n , and K_n does not depend on x .

These three properties are so characteristic that any system of orthogonal polynomials that has them can be reduced to classical orthogonal polynomials.

Classical orthogonal polynomials satisfy recurrence relations of the form

$$p_{n+1}(x) = (a_n x + b_n) p_n(x) - c_n p_{n-1}(x) \quad (20)$$

for $n = 1, 2, \dots$

In 1815, Gauss introduced the use of orthogonal polynomials in numerical quadrature for the Legendre case $a = -1$, $b = 1$, $w(x) = 1$. The general formula

for a family $\{p_n\}$ of polynomials that are orthogonal on the interval (a, b) with weight $w(x)$ is

$$\int_a^b w(x)f(x) dx = \sum_{k=1}^n \lambda_{k,n} f(x_{k,n}) + R_n,$$

where $x_{k,n}$ (the nodes) are the zeros of p_n . Several forms are available for the weights $\lambda_{k,n}$; if the p_n are orthonormal ($\int_a^b p_n^2(x)w(x) dx = 1$),

$$\frac{1}{\lambda_{k,n}} = \sum_{j=1}^{n-1} p_j^2(x_{k,n}).$$

The remainder $R_n = 0$ for an arbitrary polynomial $f(x) = q_m(x)$ with degree m not exceeding $2n - 1$.

As an example, consider the Hermite polynomials $H_n(x)$. They have weight function e^{-x^2} on $(-\infty, \infty)$; they follow from the Rodrigues formula

$$H_n(x) = (-1)^n e^{x^2} \frac{d^n}{dx^n} e^{-x^2};$$

they satisfy the differential equation $y'' - 2xy' + 2ny = 0$; they satisfy the recursion (20) with $a_n = 2$, $b_n = 0$, $c_n = 2n$ and initial values $H_0(x) = 1$, $H_1(x) = 2x$; and they have the generating function

$$e^{2xz-z^2} = \sum_{n=0}^{\infty} \frac{H_n(x)}{n!} z^n.$$

Jacobi, Gegenbauer, Legendre, and Chebyshev polynomials are special cases of the Gauss hypergeometric function. Laguerre and Hermite polynomials are special cases of the confluent hypergeometric function (see section 8).

8 Confluent Hypergeometric or Kummer Functions

When we take $b \rightarrow \infty$ in $F(a, b; c; z/b)$, using the series (12) and $\lim_{n \rightarrow \infty} (b)_n / b^n = 1$, the result is ${}_1F_1(a; c; z)$ (put $p = q = 1$ in (17)):

$${}_1F_1(a; c; z) = \sum_{n=0}^{\infty} \frac{(a)_n}{(c)_n} \frac{z^n}{n!}. \quad (21)$$

This series converges for all complex z , with the usual exception $c = 0, -1, -2, \dots$. When $a = c$, ${}_1F_1(a; a; z) = e^z$.

The function $F(a, b; c; z/b)$ satisfies a differential equation with three regular singularities: at $z = 0$, $z = b$, and $z = \infty$. In the limit as $b \rightarrow \infty$, two singularities merge. This limiting process is called a *confluence*, and so ${}_1F_1(a; c; z)$ is called the confluent hypergeometric function. It satisfies the differential equation

$$zF'' + (c - z)F' - aF = 0, \quad (22)$$

which has a regular singularity at $z = 0$ and an irregular singularity at $z = \infty$.

We have the integral representation

$${}_1F_1(a; c; z) = \frac{\Gamma(c)}{\Gamma(a)\Gamma(c-a)} \int_0^1 t^{a-1} (1-t)^{c-a-1} e^{zt} dt,$$

which is valid when $\operatorname{Re} c > \operatorname{Re} a > 0$. When we expand the exponential function, we obtain the series in (21).

For a second solution of (22), we have

$$U(a, c, z) = \frac{1}{\Gamma(a)} \int_0^\infty t^{a-1} (1+t)^{c-a-1} e^{-zt} dt,$$

where we assume $\operatorname{Re} z > 0$ and $\operatorname{Re} a > 0$.

The functions ${}_1F_1(a; c; z)$ and $U(a, c, z)$ are named after Kummer. Special cases are Coulomb functions, Laguerre polynomials, Bessel functions, parabolic cylinder functions, incomplete gamma functions, Fresnel integrals, error functions, and exponential integrals.

The Whittaker functions are an alternative pair of Kummer functions and they have the following definitions:

$$M_{\kappa, \mu}(z) = e^{-z/2} z^{1/2+\mu} {}_1F_1(\frac{1}{2} + \mu - \kappa; 1 + 2\mu; z), \\ W_{\kappa, \mu}(z) = e^{-z/2} z^{1/2+\mu} U(\frac{1}{2} + \mu - \kappa, 1 + 2\mu, z).$$

These functions satisfy the differential equation

$$w'' + \left(-\frac{1}{4} + \frac{\kappa}{z} + \frac{\frac{1}{4} - \mu^2}{z^2} \right) w = 0.$$

Solutions of the differential equation

$$w'' - (\frac{1}{4}z^2 + a)w = 0 \quad (23)$$

can be expressed in terms of Kummer functions, but they are often called Weber parabolic cylinder functions, after Heinrich Weber, because they arise when solving the Laplace equation $\Delta V = 0$ by separating the variables into parabolic cylindrical coordinates, (ξ, η, z) . These parabolic cylindrical coordinates are related to rectangular coordinates (x, y, z) through the equations $x = \frac{1}{2}c(\xi^2 - \eta^2)$ and $y = c\xi\eta$, where c is a scale factor. When ξ or η are kept constant, say $\xi = \xi_0$ or $\eta = \eta_0$, then we have

$$y^2 = -c\xi_0^2(2x - c\xi_0^2), \quad y^2 = c\eta_0^2(2x - c\eta_0^2),$$

which are parabolas with foci at the origin.

Solutions of (23) can first be written in terms of Kummer functions, and then linear combinations give the Weber functions, $U(a, \pm z)$ and $V(a, \pm z)$. One can also use the notation $D_v(z) = U(-\frac{1}{2} - v, z)$; this function can be written in terms of a Hermite polynomial when $v = 0, 1, 2, \dots$

9 Bessel Functions

Bessel functions show up in many physics and engineering problems, in Fourier theory and abstract harmonic analysis, and in statistics and probability theory. Most frequently they occur in connection with differential equations. The earliest systematic study was undertaken by Bessel in 1824 for a problem connected with planetary motion. For historical notes and an extensive treatment, see Watson (1944).

We have seen the modified Bessel function $I_\mu(z)$ in the noncentral χ^2 distribution, (18). In mathematical physics Bessel functions are most commonly associated with the partial differential equations of the potential problem, wave motion, or diffusion, in cylindrical or spherical coordinates. By separating the variables with respect to these coordinates in the time-independent wave equation (the Helmholtz equation) $\Delta v + k^2 v = 0$, several differential equations are obtained and one of them can be put in the form of the *Bessel differential equation*:

$$z^2 w'' + z w' + (z^2 - \nu^2) w = 0. \quad (24)$$

Proper normalizations and combinations of solutions of (24) give the ordinary Bessel functions

$$J_\nu(z), \quad Y_\nu(z), \quad H_\nu^{(1)}(z), \quad H_\nu^{(2)}(z), \quad (25)$$

also called *cylinder functions*, where ν is the order of these functions. The modified Bessel functions $I_\nu(z)$ and $K_\nu(z)$ follow from these with z replaced by $\pm iz$.

In physical problems with circular or cylindrical symmetry Bessel functions with order $\nu = n$, an integer, are used, while in spherical coordinates the Bessel functions arise with $\nu = n + \frac{1}{2}$.

Bessel functions of order $\pm \frac{1}{3}$ with argument $\frac{2}{3}z^{3/2}$ are named Airy functions after George Biddell Airy, a British astronomer, who used them when studying rainbow phenomena. Airy functions are solutions of the differential equation $w'' = zw$. The real solutions are oscillatory for $z < 0$ and exponential for $z > 0$. Airy's equation is the simplest second-order linear differential equation that shows such a turning point (at $z = 0$).

Other special functions with turning-point behavior can be approximated in terms of Airy functions. The function $w(z) = \sqrt{z}C_\nu(\nu z)$, where $C_\nu(z)$ is any cylinder function that appears in (25), satisfies the differential equation

$$w'' + \left(\nu^2 \frac{1-z^2}{z^2} - \frac{1}{4z^2}\right) w = 0.$$

For large values of ν this equation has turning points at $z = \pm 1$. In fact, the cylinder functions $C_\nu(z)$ of large order ν show turning-point behavior at $z = \nu$. Airy functions can be used to give powerful asymptotic approximations (Olver 1997).

10 Legendre Functions

The associated Legendre functions $P_\nu^\mu(z)$ and $Q_\nu^\mu(z)$ satisfy Legendre's differential equation

$$(1-z^2)w'' - 2zw' + \left(\nu(\nu+1) - \frac{\mu^2}{1-z^2}\right)w = 0. \quad (26)$$

This equation has regular singularities at ± 1 and ∞ , and it can therefore be transformed into the equation of the Gauss hypergeometric functions (15). In fact,

$$P_\nu^\mu(z) = \frac{\zeta^{\mu/2}}{\Gamma(1-\mu)} F(-\nu, \nu+1; 1-\mu; \frac{1}{2} - \frac{1}{2}z), \quad (27)$$

where $\zeta = (z+1)/(z-1)$ and the branch cut is such that $\text{ph } \zeta = 0$ if $z \in (1, \infty)$. When $z = x \in (-1, 1)$, a real solution is defined by replacing ζ with $(1+x)/(1-x)$ in (27).

We describe a few special cases that are relevant in boundary-value problems for special choices of Legendre functions and for specific domains: spheres, cones, and tori. Many problems in other domains, however, such as in a spheroid or a hyperboloid of revolution, can be solved using Legendre functions.

10.1 Spherical Harmonics

These functions arise in a variety of applications, in particular in investigating gravitational wave signals from a pulsar and in tomographic reconstruction of signals from outer space.

First we consider the subclass of associated Legendre functions defined by the Rodrigues-type formula

$$P_n^m(x) = (-1)^m \frac{(1-x^2)^{m/2}}{2^n n!} \frac{d^{n+m}}{dx^{n+m}} (x^2 - 1)^n,$$

where n, m are nonnegative integers and $x \in (-1, 1)$. For fixed order m they are orthogonal with respect to the degree n , with weight function $w(x) = 1$ on $(-1, 1)$. For $m = 0$ they become the well-known Legendre polynomials, $P_n(x)$.

The $P_n^m(x)$ are used in representations of spherical harmonics, which are given by

$$Y_n^m(\theta, \phi) = N_n^m P_n^m(\cos \theta) e^{im\phi}, \quad (28)$$

where N_n^m is used for normalization and does not depend on θ or ϕ . These variables represent colatitude

and longitude, respectively, on the sphere in the intervals $\theta \in [0, \pi]$ (from north pole to south pole) and $\phi \in [0, 2\pi]$ (also called the azimuth).

The general bounded solution to Laplace's equation, $\Delta f = 0$, inside the unit sphere centered at the origin, $r = 0$, is a linear combination

$$f(r, \theta, \phi) = \sum_{n=0}^{\infty} \sum_{m=-n}^n f_n^m r^n Y_n^m(\theta, \phi). \quad (29)$$

The constants f_n^m can be computed when boundary values on the sphere are given using orthogonality relationships for $P_n^m(x)$ and the trigonometric elements. When the boundary values are given as a real square-integrable function, the expansion (29) converges inside the unit sphere.

10.2 Conical Functions

Conical functions $P_{-1/2+i\tau}^\mu(x)$ and $Q_{-1/2+i\tau}^\mu(x)$ appear in a large number of applications in engineering, applied physics, cosmology, and quantum physics. They occur in boundary-value problems involving configurations of a conical shape. They are also the kernel of the Mehler-Fock transform, which has numerous applications. The functions were introduced by Gustav Ferdinand Mehler in 1868, when he was working with series that express the distance of a point on the axis of a cone to a point located on the surface of the cone.

The integral representation

$$P_{-1/2+i\tau}^\mu(\cos \theta) = \sqrt{\frac{2}{\pi}} \frac{(\sin \theta)^\mu}{\Gamma(\frac{1}{2} - \mu)} \int_0^\theta \frac{\cosh(\tau t) dt}{(\cos t - \cos \theta)^{\mu+1/2}},$$

with real τ , $0 < \theta < \pi$, and $\operatorname{Re} \mu < \frac{1}{2}$, shows that this function is real for these values of the parameters.

The specific focus in physics is on the case when $\mu = m$, an integer. When this is the case, we can use

$$P_{-1/2+i\tau}^m(x) = (\frac{1}{2} + i\tau)_m (\frac{1}{2} - i\tau)_m P_{-1/2+i\tau}^{-m}(x)$$

to obtain representations for all m .

10.3 Toroidal Harmonics

Toroidal harmonics are used to solve the potential problem in a region bounded by a torus. The toroidal coordinates (ξ, η, ϕ) , with $0 \leq \xi < \infty$, $-\pi < \eta, \phi \leq \pi$, are related to the rectangular coordinates x, y, z (or r, ϕ, z in cylindrical coordinates) through $x = r \cos \phi$, $y = r \sin \phi$,

$$r = \frac{c \sinh \xi}{\cosh \xi - \cos \eta}, \quad z = r \frac{\sin \eta}{\sinh \xi},$$

where c is a scale factor. The coordinates are chosen so that $\xi = \xi_0$ represents the toroidal surface.

The general solution of $\Delta \Psi = 0$ in toroidal coordinates can be written in the form

$$\begin{aligned} Y(\xi, \eta, \phi) &= \sqrt{\cosh \xi - \cos \eta} \\ &\times \sum_{n,m=0}^{\infty} \cos n(\eta - \eta_{mn}) \cos m(\phi - \phi_{mn}) \\ &\times (A_{mn} P_{n-1/2}^m(\cosh \xi) + B_{mn} Q_{n-1/2}^m(\cosh \xi)), \end{aligned}$$

where A_{mn} , B_{mn} , η_{mn} , and ϕ_{mn} have to be determined from the boundary condition.

11 Functions from Other Boundary-Value Problems

The special functions mentioned in sections 5–10 are all of hypergeometric type. All these functions were known by 1850, usually as a result of the interaction between mathematicians and physicists. In 1868, Mathieu used a different curvilinear coordinate system from those used up to that point when he considered elliptic cylinder coordinates. Other, more general systems (such as oblate and prolate spheroidal and ellipsoidal systems) were introduced soon after.

Actually, there are eleven three-dimensional coordinate systems in which the time-independent wave equation, $\Delta v + k^2 v = 0$, is separable. The Laplace equation, $\Delta v = 0$, is separable in two more systems (the bipolar and bispherical systems).

The systems introduced since the time of Mathieu can be solved in terms of special functions, but these functions are not of hypergeometric type.

MATHIEU'S DIFFERENTIAL EQUATION [III.21] is

$$w'' + (\lambda - 2h^2 \cos 2x) w = 0.$$

The substitution $t = \cos x$ transforms this equation into an algebraic form that has two regular singularities at $t = \pm 1$ and one irregular singularity at infinity. This implies that, in general, the solutions of Mathieu's equation cannot be expressed in terms of hypergeometric functions.

Another special feature is that, in general, no explicit representations of solutions of Mathieu's equation (in the form of integrals, say) are known. Nor can explicit power-series expansions or Fourier expansions be derived: the coefficients are solutions of three-term recurrence relations, and with a given value of h , convergent expansions can be obtained for an infinite number of eigenvalues λ . These features also apply for other

differential equations that follow from the boundary-value problems with solutions that are beyond the class of hypergeometric functions.

12 Painlevé Transcendents

For linear second-order differential equations the location and nature of the singularities of the equation can be investigated easily; we need only know the coefficients in the differential equations.

For nonlinear equations this is not the case, as we see from the simple example $y' = 1 + y^2$. No singularities occur in the coefficients of this equation. The solution $y = \tan(x - x_0)$, however, has poles galore. In the example $y' = -y^2$, we have the solution $y = 1/(x - x_0)$, where x_0 is again a free constant.

The properties of these nonlinear equations are also found in PAINLEVÉ EQUATIONS [III.24], a topic that has attracted many researchers in recent decades. The solutions of the simple equations just mentioned are analytic except for poles. In the context of Painlevé equations, the poles of $y = \tan(x - x_0)$ and $y = 1/(x - x_0)$ are called movable poles: their locations change according to the initial values. Types of singularities other than poles, such as branch points and logarithmic singularities, may occur in other examples.

In 1900, Painlevé found the six equations now named after him by classifying second-order ordinary differential equations in a certain class. Painlevé equations have the property that all movable singularities in the complex plane of all solutions are poles, and this property is called the Painlevé property. The first three equations are

$$\begin{aligned} y'' &= 6y^2 + x, & y'' &= 2y^3 + xy + \alpha, \\ y'' &= \frac{(y')^2}{y} - \frac{y'}{x} + \frac{1}{x}(\alpha y^2 + \beta) + \gamma y^3 + \frac{\delta}{y}, \end{aligned}$$

where α , β , γ , and δ are constants.

We have already discussed the important role that special functions (Bessel, Kummer, and so on) play in mathematical physics as solutions of linear differential equations. The Painlevé transcendents play an analogous role for nonlinear ordinary differential equations, and applications can be found in many areas of physics including nonlinear waves, plasma physics, statistical mechanics, nonlinear optics, and fibre optics.

13 Concluding Remarks

We have given an overview of a selection of the classical special functions, but there are many other func-

tions we could have chosen to look at. We mention a few other important topics.

The theory of Lie groups, and in particular their representation theory, has shown how special functions can be interpreted from a completely different point of view. In the setting of q -functions, difference equations become a source for special functions. In recent decades we have seen a boom in q -hypergeometric function research.

Other areas of active research are the study of Jacobi elliptic functions, the study of theta functions, and the study of Weierstrass elliptic and related functions. Since the turn of the century the relationship between the theory of elliptic functions and the theory of elliptic curves has been extensively explored, and this relationship was used by Andrew Wiles to prove Fermat's last theorem. A class of elliptic curves is used in some cryptographic applications as well as for integer factorization. Applications of theta functions are found in physics, where they are used as solutions of diffusion equations.

In the further reading list below we mention only a few key works. In the *NIST Handbook of Mathematical Functions*, nearly all of the formulas we have discussed are given with extensive references to the relevant literature, including where to find a proof. Graphs of the functions are also shown.

IV.8 Spectral Theory

E. Brian Davies

1 Introduction

Applications of spectral theory arise in a wide range of areas in applied mathematics, physics, and engineering, but there are also applications to geometry, probability, and many other fields. The origins of spectral theory can be traced to Laplace at the start of the nineteenth century and, if one includes its connections with musical harmonies, back to Pythagoras 2500 years ago. Its present-day manifestations cover everything from the design and testing of mechanical structures to the algorithms that are used in the Google search engine. There is an extensive mathematical theory behind the subject, and there are computer packages (some highly specialized but others, such as MATLAB, of a more general character) that enable scientists and engineers to determine the spectral features of the problems that they are studying. Spectral theory is often important for its own sake, but it can also be used as a way of writing the solution of a problem as a linear combination of the solutions of a sequence of eigenvalue problems.

The word *eigenvalue* is a combination of the German root “eigen,” meaning characteristic or distinctive, and the English word “value,” which suggests that one is seeking a numerical quantity λ that is naturally associated with the application being considered. This number is often interpreted as the energy or frequency of some nonzero solution f of an equation of the form

$$Lf = \lambda f. \quad (1)$$

The symbol L refers to the linear operator that describes the particular problem being considered. The solution f of the equation is called the *eigenfunction* (or *eigenvector*, depending on the context) corresponding to the eigenvalue λ , and it may be a function of one or more variables. Although much of the literature concentrates on determining the eigenvalues of some model, the eigenfunctions carry much more information.

Depending on the particular evolution equation involved, if an eigenvalue $\lambda = u + iv$ associated with some problem is complex, then u is interpreted as the *frequency of oscillation* or vibration of the system being studied. If $v < 0$ then the vibration being considered is stable and v is interpreted as its *rate of decay*. If $v > 0$

then the vibration is unstable and the size of v determines how unstable; unstable vibrations in engineering structures can lead to catastrophic failure.

We conclude the introduction by mentioning INVERSE PROBLEMS [IV.15], in which one seeks to determine important features of some problem from measurements of its associated spectrum. This field has a wide variety of important applications, ranging from engineering to seismology.

2 Some Applications

In this section we describe a few applications of spectral theory. These applications raise issues of great importance in their respective subjects as presently practised. Further applications are mentioned at the end of the section, but these by no means exhaust the possibilities.

Many physical structures, from violin strings and drums to turbines and skyscrapers, vibrate under suitable circumstances, and in general the larger the structure, the more slowly it vibrates. It is often important to know what the precise frequency of vibration is going to be before manufacturing a structure because adjustments after construction may be very expensive or even impossible. Calculating the frequencies of the important modes of vibration is now a well-developed branch of engineering. Nevertheless, mistakes are occasionally made.

As an example we mention the Millennium Bridge, which crosses the Thames river in London and was opened on June 10, 2000. Two days later it was closed, for two years, because of an unexpected flaw in its design. The problem was that when a large number of pedestrians were on the bridge, they experienced a lateral wobble, and this wobble caused them to adjust their steps in order to stay upright. Unfortunately, this caused them to start walking in synchrony, with the effect that the lateral vibrations were enhanced until they became potentially dangerous—to the people on the bridge rather than to the bridge itself. The modeling of the vibrations of the bridge had clearly not been adequate. The problem was eventually resolved by inserting a number of specially designed viscous dampers underneath the structure. In spectral terms the effect was to move the eigenvalues further away from the real axis so that there was still a damping effect even when the oscillations were driven by pedestrian effects. This solved the problem, but at a cost of about £5 million.

The design of aircraft involves similar problems but in a much more serious form. Since the cost of a modern airliner can be over 100 million dollars, it is imperative that unstable vibrations in the wings and control surfaces be anticipated and eliminated before manufacturing starts. Aircraft have to operate over a wide range of speeds and altitudes and with different loadings. Because an airliner uses so much fuel, its landing weight can be a third less than it was when taking off. The relevant eigenvalue calculations are time-consuming and expensive, and one cannot repeat them for every possible set of parameters that might be encountered in operation. The best that one can do is to try to ensure that all of the relevant eigenvalues have large enough negative imaginary parts for a range of plausible values of the operational parameters. For commercial airliners, going too far in this direction reduces the efficiency of the design and hence the profitability.

We turn to applications of spectral theory in chemistry. In the nineteenth century, Joseph von Fraunhofer and others discovered that if one heated a chemical element until it glowed and then passed the light emitted through a spectroscope, one could see a series of sharp lines. The frequencies of these lines could be measured precisely, and they could be used to identify the elements involved.

The *spectroscopic lines* for hydrogen have frequencies of the form

$$E_{m,n} = c \left(\frac{1}{m^2} - \frac{1}{n^2} \right),$$

where m and n are positive integers, but no reason was known for the validity of this formula until quantum theory was invented in 1925/26; we shall refer below to energies, which are proportional to frequencies in this context. It was found that the element hydrogen was described by a differential operator whose (discrete, or bound state) eigenvalues were given by $\lambda_n = -c/n^2$, where c is the same constant as above. The spectroscopic energies are not the eigenvalues of the operator but differences of eigenvalues, the reason being that they measure the energy of the photon emitted by an atom when it makes a transition between one energy level and another. By the law of conservation of energy, this equals the difference between the two relevant energy levels of the hydrogen atom.

The new QUANTUM THEORY [IV.23] was fully accepted when the energy levels of helium were calculated and found to be in agreement with spectroscopic observations. Since that time, tens of thousands of

spectral lines of elements and chemical compounds have been calculated and observed. If relativistic effects are included in the models, the calculations agree with observation in great detail.

The fact that such calculations are now possible depends on the astonishing growth of computer power over the last fifty years. In 1970 theoretical chemists were often dismissed by “real” chemists, who knew that their problems would never be solved by purely theoretical methods. Some people persisted in spite of this discouragement, and in the end two theoretical chemists, Walter Kohn and John Pople, were awarded a joint Nobel Prize in 1998 for their work developing computational quantum chemistry over three decades. The hard grind of these pioneers has now placed them at the center of chemistry and molecular biology.

One of the stranger “applications” of spectral theory is the apparent connection between the distribution of the zeros of the Riemann zeta function and the distribution of the eigenvalues of a large random self-adjoint matrix. There is no known rigorous argument relating the zeros of the Riemann zeta function to the eigenvalues of any self-adjoint matrix or operator, but the numerical similarities observed in the two fields have led to a number of deep conjectures, some of which have been proved rigorously. There is no basis for assuming that this line of investigation will lead to a proof of the Riemann hypothesis, but anything that prompts worthwhile conjectures must be taken seriously.

Finally, we mention that this volume contains a separate article on RANDOM-MATRIX THEORY [IV.24], in which spectral theory is only one of several techniques involved. We have also avoided any discussion of spectral issues in FLUID MECHANICS [IV.28] and SOLID MECHANICS [IV.32].

3 The Mathematical Context

Spectral theory involves finding the spectra of linear operators that approximate the behavior of a variety of systems; we mention some nonlinear eigenvalue problems in the final section. The subject has a body of general theory, some of which is quite difficult, but also a large range of techniques that are applicable only in particular cases. These are constantly being refined, and completely new ways of approaching problems also appear at irregular intervals.¹

1. A variety of recent developments in the subject are described in Davies (2007).

Applications of spectral theory require the introduction of appropriate mathematical models. The choice of model always involves a compromise between simplicity and accuracy. Pure mathematicians are more interested in obtaining insights that can be applied to a range of similar operators, and they tend to consider simple generic models. Obtaining insights has traditionally been associated with the proof of theorems, but experimental mathematicians also obtain insights by testing a wide range of examples using appropriate software. The ultimate goal of numerical analysts is to produce software that can be used by a wide variety of people who have no interest in how it works and who may use it for purposes that were never envisaged when it was written. On the other hand, applied mathematicians and physicists may be willing to spend months or even years studying particular problems that are of crucial importance for their group of researchers.

3.1 Finite Matrices

We start by considering the simplest case, in which one wishes to solve $Af = \lambda f$, where A is a general $n \times n$ matrix and f is a column vector with length n . The existence of a nonzero solution f is equivalent to λ being a solution of the equation

$$\det(A - \lambda I) = 0.$$

This is a polynomial equation of degree n , so it must have n solutions $\lambda_1, \dots, \lambda_n$ by the fundamental theorem of algebra. The simplest case arises when these solutions are all different. If this happens, let v_r be an eigenvector associated with λ_r for each r . Then v_1, \dots, v_n is a basis for \mathbb{C}^n and A has a diagonal matrix with respect to this basis.

In general, no such basis exists. At the other extreme, the *Jordan block*

$$\begin{pmatrix} c & 1 & 0 & 0 \\ 0 & c & 1 & 0 \\ 0 & 0 & c & 1 \\ 0 & 0 & 0 & c \end{pmatrix}$$

has only one eigenvalue, namely c , and only one eigenvector, up to scalar multiples. Every finite matrix is similar to a sum of such Jordan blocks (see JORDAN CANONICAL FORM [II.22]).

It used to be argued that such pathologies are irrelevant in the real world; generically, all roots of a polynomial are different, and hence all eigenvalues of an $n \times n$ matrix are generically distinct. Unfortunately, highly non-self-adjoint matrices of even moderate size

are often ill-conditioned, in the sense that the attempt to diagonalize them leads to highly unstable computations, in spite of the fact that the eigenvalues are all distinct. Numerical analysts have to take ill-conditioning into account for all algorithms that might be applied to non-self-adjoint matrices. One of the ways of doing this involves *pseudospectral theory*, a new branch of the subject that investigates the implications of, and connections between, different types of ill-conditioning (see Trefethen and Embree 2005).

Problems of the above type do not occur for *self-adjoint* or *normal* matrices, i.e., those that satisfy $A = A^*$ or $AA^* = A^*A$, respectively. In both cases one has

$$\|(\lambda I - A)^{-1}\| = \text{dist}(\lambda, \text{Spec}(A))^{-1}$$

for all λ that do not lie in the spectrum $\text{Spec}(A)$ of A , provided $\|\cdot\|$ is the operator norm, defined below. This is in sharp contrast to the general case, in which the left-hand side may be vastly bigger than the right-hand side, even for fairly small and “reasonable” matrices. In such cases, it has been argued that the value of determining the spectrum is considerably reduced.

3.2 Formalism

Most of the operators considered in spectral theory act in infinite-dimensional vector spaces over the complex number field. The detailed study of such operators is rather technical, not because analysts like technicalities but because spectra can have properties that do not conform to one’s naive intuitions. One starts with a complex HILBERT OR BANACH SPACE [I.2 §19.4] \mathcal{B} , with norm $\|\cdot\|$. A linear operator $A: \mathcal{B} \rightarrow \mathcal{B}$ is said to be *bounded* if its *operator norm*

$$\|A\| = \sup\{\|Af\|: \|f\| \leq 1\}$$

is finite. One says that $\lambda \in \mathbb{C}$ lies in the *spectrum* $\text{Spec}(A)$ of A if $\lambda I - A$ does not have a two-sided inverse in the set of all bounded operators on \mathcal{B} . The spectrum of a bounded linear operator is always closed, bounded, and nonempty. It contains any eigenvalues that A might have, but can be larger than the set of all eigenvalues. The *spectral radius* of A is defined by

$$\rho(A) = \max\{|\lambda|: \lambda \in \text{Spec}(A)\},$$

and it satisfies

$$\rho(A) = \lim_{n \rightarrow \infty} \|A^n\|^{1/n} \leq \|A\|.$$

The above definitions are not directly applicable to differential operators or other unbounded linear operators. In such cases one considers a linear operator

$A: \mathcal{D} \rightarrow \mathcal{B}$, where the *domain* \mathcal{D} of A is a norm-dense linear subspace of \mathcal{B} . One needs to assume or prove that A is *closed* in the sense that, if $\lim_{n \rightarrow \infty} \|f_n - f\| = 0$ and $\lim_{n \rightarrow \infty} \|Af_n - g\| = 0$, then $f \in \mathcal{D}$ and $Af = g$. The definition of the spectrum of an unbounded operator is similar to that in the bounded case but also involves reference to its domain. The spectrum of an unbounded linear operator may be empty and it may equal \mathbb{C} , but it is always a closed set.

The spectrum of a linear operator is often hard to determine. The fact that the spectrum of an arbitrarily small perturbation of A may differ radically from the spectrum of A implies that one has to be extremely cautious about using numerical methods to determine spectra unless one knows that this extreme sensitivity does not arise for the operator of interest. A simple example of this phenomenon is obtained as follows. Given $s \in \mathbb{R}$, one defines the bounded linear operator A_s acting on the space $\ell^2(\mathbb{Z})$ by

$$(A_s f)_n = \begin{cases} sf_{n+1} & \text{if } n = 0, \\ f_{n+1} & \text{otherwise.} \end{cases}$$

Some routine calculations establish that $\text{Spec}(A_s) = \{z: |z| = 1\}$ if $s \neq 0$ but $\text{Spec}(A_0) = \{z: |z| \leq 1\}$. Indeed, every z such that $|z| < 1$ is an eigenvalue of A_0 , in the sense that the corresponding eigenvector lies in $\ell^2(\mathbb{Z})$.

3.3 Self-adjoint Operators

A bounded linear operator L acting on a Hilbert space \mathcal{H} with inner product $\langle \cdot, \cdot \rangle$ is said to be *self-adjoint* if

$$\langle Av, w \rangle = \langle v, Aw \rangle \quad (2)$$

for all $v, w \in \mathcal{H}$. The definition of self-adjointness for unbounded operators is more technical. It implies that (2) holds for all v, w in the domain of A , but it is not implied by that condition, which is called *symmetry* by specialists. The difference between self-adjointness and symmetry was emphasized by John von Neumann in the early days of quantum mechanics. It is often evident that an operator of interest is symmetric, but proving that it is self-adjoint can be very hard; indeed, much of the literature before 1970 was devoted to this question. The spectral theory of self-adjoint operators is much more detailed and well understood than that of non-self-adjoint operators.

The center point of the self-adjoint theory is the *spectral theorem*, which was proved around 1930 by von Neumann. There are various statements of this, some easier to understand than others. Perhaps the

simplest is the statement that, if H is a self-adjoint operator on the abstract Hilbert space \mathcal{H} , then there exists a unitary operator U from $L^2(X, dx)$ to \mathcal{H} for some measure space (X, dx) and a function $f: X \rightarrow \mathbb{R}$ such that

$$(U^{-1}HU\phi)(x) = f(x)\phi(x)$$

for all $\phi \in L^2(X, dx)$ and almost every $x \in X$. Expressed more simply, H is unitarily equivalent to the *multiplication operator* associated with f . This is an analogue of the spectral theorem for self-adjoint matrices because multiplication operators are the infinite-dimensional analogue of diagonal matrices. The spectral theorem implies that the spectrum of H is real; in particular, every eigenvalue of H is real. The implications of this theorem are wide-ranging: it reduces proofs of many of the properties of self-adjoint operators to the status of obvious trivialities, and its absence makes the spectral theory of non-self-adjoint operators far less transparent.

Another version of the spectral theorem introduces the *functional calculus* formula

$$H = \int_{\mathbb{R}} \lambda dP(\lambda),$$

where $P(\lambda)$ is a *spectral projection* of H for every choice of $\lambda \in \mathbb{R}$. This leads to the formula

$$f(H) = \int_{\mathbb{R}} f(\lambda) dP(\lambda)$$

for a wide variety of bounded and unbounded functions f provided one masters the technicalities involved. This version is more attractive, at least to mathematicians, than the previous one, but it is somewhat less easy to use.

If the spectrum of the operator H consists of a countable set of eigenvalues λ_n , where $n \in \mathbb{N}$, then the spectral theorem may also be written in the form

$$H = \sum_{n=1}^{\infty} \lambda_n P_n.$$

In this formula each P_n is an orthogonal projection whose range is the subspace consisting of all eigenvectors associated with the eigenvalue λ_n . The rank of P_n equals the multiplicity of the eigenvalue λ_n . The projections are orthogonal in the sense that $P_m P_n = P_n P_m = 0$ if $m \neq n$, and $\sum_{n=1}^{\infty} P_n = I$.

A more general formulation of the spectral theorem applies to several commuting self-adjoint operators simultaneously. However, there is nothing analogous for even two self-adjoint operators that do not commute. Von Neumann's theory of operator algebras was

an attempt to understand the complexities involved in the study of noncommuting families of operators.

3.4 Classification of the Spectrum

In infinite dimensions the spectrum of a self-adjoint operator may be divided into parts that have different qualitative features. These include the absolutely continuous spectrum, the singular continuous spectrum, the essential spectrum, the point spectrum, and the discrete spectrum. The definitions are technical and will be avoided here except for the following. One says that λ lies in the *discrete spectrum* of a self-adjoint operator H if it is an isolated eigenvalue with finite multiplicity. The rest of the spectrum is called the *essential spectrum*. For many operators the essential spectrum coincides with the continuous spectrum, but this is not true for the Anderson model, which is discussed below.

For non-self-adjoint operators the situation is even more complicated. Spectral theorists are aware that there are several distinct definitions of the essential spectrum, but many have contented themselves with using only one. This suffices for many purposes, but in some situations the others are of real importance.

Let H be a self-adjoint differential operator acting in $L^2(\mathbb{R}^N)$. For many *but not all* such operators, one can divide classical solutions of the differential equation $Hg = \lambda g$ into three types. For some λ , g may decay rapidly at infinity and λ then lies in the discrete spectrum of H . For other λ this may be false, but g is bounded at infinity and λ lies in the essential spectrum of H . If neither case pertains for any solution g of $Hg = \lambda g$, then λ does not lie in the spectrum of H . The discrete spectrum of H is a finite or countable set, while the essential spectrum is typically an infinite interval or a union of several disjoint intervals. In many cases the essential spectrum can be determined in closed form by using perturbation arguments, but the analysis of the discrete spectrum is almost always harder, whether one approaches this task from the theoretical end or the computational one.

A further issue is that the spectrum of an operator can depend on the Banach space in which it operates. For example, the spectrum of the Laplace–Beltrami operator on the hyperbolic space H_n of dimension $n \geq 2$ depends in an essential way on p when considered as acting in $L^p(H_n)$. This phenomenon is much less common for differential operators acting in $L^2(\mathbb{R}^N)$.

3.5 The Variational Approach

One can obtain valuable upper and lower bounds on the eigenvalues of many self-adjoint operators by using *variational methods*, which go back to Rayleigh and Ritz in the early years of the twentieth century (see VARIATIONAL PRINCIPLE [II.35]). The simplest context assumes that H has a complete orthonormal sequence of eigenvectors ϕ_n , where $n \in \mathbb{N}$, that the corresponding eigenvalues satisfy $\lambda_n \leq \lambda_{n+1}$ for all n , and that $\lim_{n \rightarrow \infty} \lambda_n = +\infty$.

The variational formula involves the set \mathcal{L} of all finite-dimensional subspaces L of the domain of H . It is not directly useful, but it leads to rigorous spectral inequalities that have great value. Given $L \in \mathcal{L}$, one first defines

$$\lambda(L) = \sup \{\langle Hf, f \rangle : f \in L \text{ and } \|f\| = 1\}.$$

The variational formula is then

$$\lambda_n = \inf \{\lambda(L) : \dim(L) = n\}.$$

Applications of the variational formula depend on comparing the eigenvalues of two self-adjoint operators. If H_1 and H_2 have the same domain, then one writes $H_1 \leq H_2$ if $\langle H_1 f, f \rangle \leq \langle H_2 f, f \rangle$ for all f in the common domain. Many important applications require one to define the notion $H_1 \leq H_2$ even when they do not have the same domain, and this can be done by using the theory of quadratic forms.

It follows immediately from the variational formula for the eigenvalues that $H_1 \leq H_2$ implies that $\lambda_n^{(1)} \leq \lambda_n^{(2)}$ for all n , using an obvious notation. If the eigenvalues of H_1 or H_2 are already known, this leads to rigorous upper or lower bounds on the eigenvalues of the other operator.

This idea can be recast in several ways, and it allows one to obtain rigorous numerical upper and lower bounds on the eigenvalues of some types of self-adjoint operator. It also has the following theoretical consequence. Let Ω_r , $r = 1, 2$, be two bounded regions on \mathbb{R}^N such that $\Omega_2 \subseteq \Omega_1$, and let $H_r = -\Delta$ act in $L^2(\Omega_r)$ subject to Dirichlet boundary conditions. The eigenvalues of the two operators then satisfy $\lambda_n^{(1)} \leq \lambda_n^{(2)}$ for all n , as above. This is called *domain monotonicity* and is one ingredient in the proof of Weyl's law, which dates from 1913 and states the following.

Let H be the Laplacian acting in $L^2(\Omega)$ subject to Dirichlet boundary conditions, where Ω is any bounded region in \mathbb{R}^N . Let

$$N_H(s) = \#\{\lambda \in \text{Spec}(H) : \lambda \leq s\},$$

where each eigenvalue is counted according to its multiplicity. Then

$$N_H(s) = c_N s^{N/2} |\Omega| + o(s^{N/2})$$

as $s \rightarrow \infty$, where

$$c_N = (4\pi)^{-N/2} \Gamma(N/2 + 1)^{-1},$$

and Γ is the Gamma function.

A rigorous analysis of the next term in the asymptotic expansion of $N_H(s)$ was given by Victor Ivrii and Richard Melrose in the above context, but the general solution of this problem for a much wider class of operators was obtained only in the 1980s by Safarov and Vassiliev (1996).

Unfortunately, the domain monotonicity mentioned above holds only for Dirichlet boundary conditions, and the Weyl law can be false for $K = -\Delta$ acting in $L^2(\Omega)$ subject to Neumann or other boundary conditions unless one assumes that the boundary $\partial\Omega$ has some regularity properties. Assuming always that Ω is bounded, if $\partial\Omega$ is Lipschitz continuous, then K has discrete spectrum and the asymptotic eigenvalue distribution of K follows the same Weyl law as it does for Dirichlet boundary conditions. If $\partial\Omega$ is Hölder continuous, then K has discrete spectrum, but its spectral asymptotics may be non-Weyl. If one makes no assumptions on $\partial\Omega$, then K need not have discrete spectrum; indeed, the spectrum of K may equal $[0, \infty)$.

We finally comment that there is no obvious analogue of the variational method for non-self-adjoint operators. When self-adjoint theorems have non-self-adjoint analogues, this is often because one can use analytic continuation arguments or some other aspect of analytic function theory. However, the most interesting aspects of non-self-adjoint spectral theory are those that have no self-adjoint analogues.

3.6 Evolution Equations

Applied mathematics and physics yield many examples of systems that evolve over time according to one of the following equations.

- The wave equation: $d^2f/dt^2 = Lf$.
- The evolution equation: $df/dt = Lf$, which is also called the heat equation when appropriate.
- The Schrödinger equation: $df/dt = -iLf$, where i is the square root of -1 .

In these equations L is commonly a self-adjoint operator, but non-self-adjoint applications are of increasing interest and involve radically new ideas. In many

applications f is a function on some region U in \mathbb{R}^N , or possibly on a Riemannian manifold, and L is a partial differential operator. Solving these evolution equations starts with specifying the precise class of functions that is to be considered. If U has a boundary, then all admissible f must satisfy certain boundary conditions, which are intrinsic to the model. The same evolution equation has entirely different solutions if one changes the boundary conditions. Once one has specified the problem in sufficient technical detail, one may look for solutions that vary very simply in time. For example, solutions of the wave equation that are of the form $f(t) = e^{ikt} g$, where $g = f(0)$, correspond to solutions of the eigenvalue problem $Lg = \lambda g$, where $\lambda = -k^2$.

We finally mention that the abstract study of evolution equations has led to a well-developed theory of one-parameter semigroups.

4 Schrödinger Operators

Spectral theory can help one to understand differential operators of any order, whether or not they are self-adjoint. These operators can act on $L^2(U)$, where U is a region in Euclidean space or in a manifold, if the manifold is provided with a measure. This section focuses on one class of differential operators, which have been studied with great intensity because of their applications to quantum theory.

4.1 Spectral Theory of Schrödinger Operators

Schrödinger operators are self-adjoint second-order partial differential operators. They play a fundamental role in describing the properties of elementary particles, atoms, and molecules as well as in describing the collisions between particles that occur continually inside fluids. There is a separate article in this volume on the underlying physics (see QUANTUM THEORY [IV.23]), and we restrict attention here to the qualitative properties of a few simple examples, in which Planck's constant \hbar and the masses, charges, and spins of the particles do not appear. If relativistic effects are important, one needs to use the Dirac operator, whose spectral properties are quite different.

Quantum theory has a special vocabulary because of its history. For example, eigenvectors in the relevant Hilbert space are called *bound states* and eigenvalues are often called *energy levels*, but this is not a substantial problem, and we shall use both languages.

At the above level of simplification a *Schrödinger operator* is a differential operator of the form

$$(Hf)(x) = -\frac{1}{2}\Delta f(x) + V(x)f(x)$$

acting on functions $f \in L^2(\mathbb{R}^N)$, where Δ is the Laplace operator. The function V is called the *potential*. For quantum particles moving in three dimensions, one puts $N = 3$, while the case $N = 2$ describes particles moving on a flat interface between two media. Both of these are subjects of great current interest in connection with electronic components and computers.

The spectral properties of H depend heavily on the choice of the potential V . Much, but by no means all, of the analysis to date has focused on one of the following classes of potential. (All of the results below, and many other that we cannot state here, have rigorous proofs under suitable technical assumptions.)

If $V(x) \rightarrow +\infty$ as $|x| \rightarrow \infty$, then H has discrete spectrum. In other words, there exists a complete orthonormal sequence of eigenfunctions ϕ_n of H whose corresponding eigenvalues λ_n are monotonically increasing with $\lim_{n \rightarrow \infty} \lambda_n = +\infty$. The smallest eigenvalue λ_1 has multiplicity 1 and the corresponding eigenfunction ϕ_1 is strictly positive, after multiplying by a suitable constant.

If $V(x) \rightarrow 0$ as $|x| \rightarrow \infty$, then the spectrum is the union of $[0, \infty)$ and a (possibly empty) sequence of negative eigenvalues λ_n that can be written in increasing order. If there are infinitely many eigenvalues, then they must converge to 0 as $n \rightarrow \infty$. If there exist positive constants c and ε such that $|V(x)| \leq c/|x|^{2+\varepsilon}$ for all large enough x , then there can only be a finite number of negative eigenvalues.

One says that H is *periodic* if there exists a discrete group G of translations acting on \mathbb{R}^N such that $V(x+y) = V(x)$ for all $x \in \mathbb{R}^N$ and all $y \in G$. It may be proved that $\text{Spec}(H)$ is the union of a finite or infinite sequence of intervals $[a_n, b_n]$ called *bands* that are separated by *gaps* (b_n, a_{n+1}) . One may label the bands and gaps so that $a_1 < b_1 < a_2 < b_2 < a_3 < \dots$. If $N = 1$ then generically there are infinitely many gaps, and the conditions on V under which there are only finitely many have been studied in great detail. In higher dimensions it is known that there are only finitely many gaps.

In the *Anderson model* one studies Schrödinger operators for which the potential V is random in the sense that it is any potential chosen from a precisely defined class, which is provided with a probability measure. The class and the probability measure are assumed to be

invariant under a discrete group of translations of \mathbb{R}^N , but individual potentials are not. An ergodicity assumption implies that the spectrum of H almost surely does not depend on the choice of V within the class. The spectrum almost surely does not contain any isolated eigenvalues. However, its detailed structure depends on the dimension N and is not fully understood at a rigorous level, in spite of very substantial progress for $N = 1$.

A simple *waveguide* is obtained by considering a Schrödinger operator on $\mathbb{R} \times U$, where U is a bounded set in \mathbb{R}^{N-1} ; most of the publications on this problem assume that $N = 2$ or $N = 3$. This model is called a quantum waveguide if one imposes Dirichlet boundary conditions on $\mathbb{R} \times (\partial U)$; there is also a substantial literature on similar operators subject to Neumann boundary conditions because of their applications in fluid mechanics. The two ends of the waveguide may point in different asymptotic directions and the shape of the waveguide may vary substantially in a bounded region within \mathbb{R}^N . However, it is usually assumed that the potential and the cross section of the waveguide are asymptotically constant far enough away from the origin. Standard methods in spectral and scattering theory allow one to determine the continuous or essential spectrum of such operators, but there may also be eigenvalues. The dependence of the eigenvalues on the geometry of the waveguide has been studied in some detail because of its potential applications to quantum devices.

All of the above problems have discrete analogues, but the case $N = 1$ has had the most attention. One replaces $L^2(\mathbb{R})$ by $\ell^2(\mathbb{Z})$ and considers discrete Schrödinger operators of the form

$$(Hf)_n = f_{n-1} + v_n f_n + f_{n+1}.$$

These operators are simpler to analyze than the usual type of Schrödinger operators because they are usually bounded and one may often base proofs on inductive arguments that are not possible in the continuous context or in higher dimensions.

4.2 Scattering Theory

Scattering theory is a difficult subject to explain at an elementary level, but it has important spectral implications. The subject may be studied at an abstract operator-theoretic level, using trace class operators or other technology, but this section will describe the theory only for the time-dependent Schrödinger equation under very standard conditions. The idea is to

compare the evolution of a system with respect to two different Schrödinger operators, $H_0 = -\frac{1}{2}\Delta$ and $H = -\frac{1}{2}\Delta + V$, assuming that the potential $V(x)$ decreases rapidly enough as $|x| \rightarrow \infty$.² If V is central (rotationally invariant), it is possible to obtain a very explicit analysis by decomposing the Hilbert space $L^2(\mathbb{R}^N)$ with respect to the irreducible representations of the rotation group. Current research focuses on more general potentials and multibody scattering. There is also a well-developed scattering theory for the wave equation.

The above assumptions imply that the spectrum of H_0 equals $[0, \infty)$ while the spectrum of H equals $[0, \infty)$ together with a finite or infinite set of negative eigenvalues. Solving the Schrödinger equation $i f'(t) = Hf(t)$ leads to the unitary operators

$$f(t) = e^{-iHt} f(0).$$

If there exist positive constants c, ε such that $|V(x)| \leq c/|x|^{1+\varepsilon}$ for all large enough x , then it may be shown that the *wave operators* W_{\pm} , defined by

$$W_{\pm}f = \lim_{t \rightarrow \pm\infty} e^{-iHt} e^{iH_0 t} f,$$

exist for all $f \in L^2(\mathbb{R}^N)$. The wave operators are isometries mapping $L^2(\mathbb{R}^N)$ one-one onto the linear subspace \mathcal{L} of $L^2(\mathbb{R}^N)$ that consists of all f that are orthogonal to every eigenvector of H . The wave operators W_{\pm} intertwine H and H_0 in the sense that $HW_{\pm} = W_{\pm}H_0$, and this implies that the nonnegative spectra of H and H_0 are identical in a very strong sense. It may be shown that the *scattering operator* S defined by

$$S = W_-^* W_+ = \lim_{t \rightarrow +\infty} e^{iH_0 t} e^{-2iHt} e^{iH_0 t}$$

is a unitary operator that commutes with H_0 . By using Fourier transforms, one may now analyze S in great detail, and in simple cases this yields a complete analysis of H in the sense of the spectral theorem for self-adjoint operators.

This section has not considered the complete analysis of short-range N -body scattering by Sigal and Soffer, with important simplifications by Graf and others. This outstanding result was achieved in 1987, but even describing the result informally would take far more space than is available here.

4.3 Resonances

In this section we consider only Schrödinger operators H , although it will be clear that some aspects of the theory can be developed at a greater level of

generality. The theory is based on the discovery that certain classes of Schrödinger operators have pseudo-eigenvalues, usually called *resonances*, with nonzero imaginary parts; resonances are supposed to describe unstable states and their imaginary parts determine the decay rates of the corresponding states. However, every Schrödinger operator is self-adjoint, so its spectrum is necessarily real and one seems to have a contradiction. In fact, a resonance λ is associated with a “resonance eigenfunction” according to the equation $Hf = \lambda f$, but the function f satisfies a condition at infinity that implies that it does not lie in the Hilbert space \mathcal{H} . Because of this, a number of mathematicians still feel dissatisfied with the foundational aspects of resonance theory. Nevertheless, the calculated resonances correspond to quantities that can be measured experimentally, and some comments are called for. The most important is that any definition of resonance must depend not only on the operator of interest but also on some further background data.

Let H be a Schrödinger operator acting on $L^2(\mathbb{R}^N)$ and suppose that the potential V decays at infinity rapidly enough. The resolvent operators $(zI - H)^{-1}$ are then integral operators for all $z \notin \mathbb{R}$. In other words,

$$((zI - H)^{-1} f)(x) = \int_{\mathbb{R}^N} G_z(x, y) f(y) d^N y$$

for all $z \notin \mathbb{R}$ and all sufficiently well-behaved $f \in L^2(\mathbb{R}^N)$; G is called the *Green function* for the resolvent operator. The resolvent operators are norm-analytic functions of z and the Green functions $G_z(x, y)$ are pointwise analytic functions of z for every x, y (excluding the case $x = y$, for which the Green function is infinite unless $N = 1$).

Under certain reasonable conditions one can prove that the Green function (but not the associated resolvent operator) can be analytically continued through the real axis into a region in the lower half of the complex plane called the “unphysical sheet.” In this region it may have isolated poles, and by definition these are the resonances of the operator. It can be proved that the positions of the poles do not depend on the choice of x, y and that they coincide with the poles of analytic functions that are associated with the scattering operator for H .

5 Calculating Eigenvalues

5.1 Exactly Soluble Problems

Much of the nineteenth-century research in spectral theory was devoted to finding problems that could be

2. For a much more systematic account, see Yafaev (2010).

solved in closed form, often by using a variety of special functions. In many cases we can now see that the ultimate explanation for this was the presence of some group symmetry. Some spectral problems for ordinary differential equations are soluble using orthogonal polynomials, but the theory of orthogonal polynomials has now grown far beyond the confines of spectral theory or differential equations.

A typical exactly soluble example is provided by *circulant matrices*. These are $n \times n$ matrices A whose entries obey

$$A_{r,s} = \begin{cases} a_{r-s} & \text{if } r \geq s, \\ a_{r-s+n} & \text{if } r \leq s, \end{cases}$$

for some coefficients a_r . The eigenvalues of A may be computed by using the finite Fourier transform to diagonalize A . They are the numbers

$$\lambda_r = \sum_{s=1}^n a_s e^{2\pi i rs/n},$$

where $1 \leq r \leq n$. The obvious infinite generalization of this is the operator $Af = a * f$ acting on $L^2(\mathbb{R})$, where $*$ denotes *convolution*, defined by

$$(Af)(x) = \int_{-\infty}^{\infty} a(x-y)f(y) dy.$$

Every convolution operator commutes with the group of all translations $(T_s f)(x) = f(x+s)$. A may be diagonalized by using the Fourier transform, the spectrum of A being 0 together with the set of all

$$\lambda_k = \int_{\mathbb{R}} a(x) e^{-ixk} dx,$$

where $k \in \mathbb{R}$.

Convolution operators lie at the heart of problems involving digital signal processing and image enhancement. The FAST FOURIER TRANSFORM [II.10] algorithm of Cooley and Tukey, which was actually first described by Gauss in 1805, was seminal in enabling computations to be carried out.

Any constant-coefficient partial differential operator commutes with the group of all translations on \mathbb{R}^N and may similarly be diagonalized, i.e., represented as a multiplication operator, by means of Fourier transforms.

5.2 Perturbation Techniques

Before the advent of computers, calculating the eigenvalues of problems that are not exactly soluble was

extremely laborious, and much effort was devoted to reducing the work involved. Inevitably, the results obtained were only applicable in special situations. Perturbation theory allows one to calculate the eigenvalues of an operator $A + tB$ for small $t \in \mathbb{C}$ when the eigenvalues and eigenvectors of A are already known. There are two approaches to the theory, applicable in different situations.

Analytic perturbation theory provides theorems that prove, under suitable assumptions, that every eigenvalue of $A + tB$ may be written as a convergent series of the form

$$\lambda(t) = a_0 + a_1 t + a_2 t^2 + \dots,$$

where a_0 is an eigenvalue of A and a_n may be calculated directly from A and B . In practice, one often needs to calculate only a few terms of the series to obtain a reasonable approximation (see Kato 1995).

If the eigenvalue of A that is being studied has multiplicity greater than 1, the above method needs modification. The power series above has to be replaced by a series involving fractional powers of t , as one may see by calculating the eigenvalues of the matrix

$$A + tB = \begin{pmatrix} 0 & t \\ 1 & 0 \end{pmatrix}$$

in closed form. The technology for dealing with such problems was well established by the 1960s.

The use of perturbation expansions of the above type is easiest to justify in finite dimensions. If the Hilbert or Banach space \mathcal{H} is infinite dimensional, then some condition is needed and the easiest is the assumption that B is bounded or relatively bounded with respect to A . The latter condition requires the existence of a constant $a \in (0, 1)$ and a constant $b > 0$ such that

$$\|Bf\| \leq a\|Af\| + b\|f\|$$

for all $f \in \text{Dom}(A)$.

Asymptotic perturbation theory allows one to treat certain situations in which convergent perturbation expansions do not exist. An alternative approach to some such problems depends on what is called semi-classical analysis (see Zworski 2012). This involves much more geometrical input than most theorems in analytic perturbation theory. Much of the literature in this field involves the theory of pseudodifferential operators, but an impression of the issues involved can be conveyed by the following example, in which the operator involved acts in $L^2(\mathbb{R}^N)$.

One assumes that the operator H_h is self-adjoint and that it depends on a small parameter in a rather

special manner; the parameter is normally denoted by h because of the origins of the subject in quantum mechanics, where h is Planck's constant. One assumes that H_h is obtained by the "quantization" of a classical Hamiltonian $H_{\text{cl}}(p, q)$, where $p, q \in \mathbb{R}^N$. There are, in fact, several types of quantization, and the difference between these needs to be taken into account. A typical example is the Schrödinger operator

$$(H_h f)(x) = -h^2(\Delta f)(x) + V(x)f(x)$$

obtained by quantizing $H_{\text{cl}}(p, q) = p^2 + V(q)$. The idea is that one can understand the $h \rightarrow 0$ asymptotics of various features of H_h by utilizing intuitions that come from differential geometry; for example, by an analysis of neighborhoods of the critical points of the potential. The nature of the results obtained precludes our delving more deeply into this important field. However, it should be stated that, when perturbation expansions in powers of h exist, they are usually asymptotic series rather than convergent series.

5.3 Numerical Analysis

This is not the place to discuss methods for computing the eigenvalues of partial differential operators in detail, but some general remarks may be in order. We assume that one wishes to determine several eigenvalues of a self-adjoint differential operator A that is known to have an infinite sequence of eigenvalues λ_n that can be listed in increasing order, each eigenvalue being repeated according to its multiplicity, with λ_n diverging as $n \rightarrow \infty$ at a known rate.

There are special methods that enable one to calculate large numbers of eigenvalues of an ordinary differential operator in one dimension with great accuracy. Most general-purpose programs concentrate on two-dimensional problems. In three dimensions all methods are computationally very demanding, because of the large size of the matrix approximations needed. As a result these programs are often optimized for a specific problem that is of commercial, military, or scientific importance.

There are two general approaches to the calculation of eigenvalues, which we call *a priori* and *a posteriori*, and each of them depends on calculating the eigenvalues associated with the truncation of A to a finite-dimensional subspace L of high dimension.

The *a priori* method is far older and depends on theorems that state that, if one carries out the computations for a properly selected increasing sequence of subspaces L_h , where $h > 0$ is a small parameter, then

the computed eigenvalues converge to the true eigenvalues of A as $h \rightarrow 0$. Such theorems also provide an estimate of the convergence rate. The weakness of this approach is that the apparent convergence is usually far faster than that yielded by the theorems.

Assuming that the differential operator acts in a bounded region U in \mathbb{R}^2 , the FINITE-ELEMENT METHOD [II.12] is a prescription for generating a large finite-dimensional space of functions on U starting from a mesh, i.e., a subdivision of U into a collection of small triangles, whose sizes are of order h (see Boffi 2010). This is carried out by the program, as is the next stage, which is the construction of a large sparse matrix, whose eigenvalues approximate a substantial number of the smaller eigenvalues of the differential operator. Under favorable circumstances one can make a priori estimates of the difference between the computed eigenvalues and the true eigenvalues. However, programs of this type often try to determine which part of the mesh is responsible for most of the error and then refine the mesh locally. It is known that one has to pay particular attention to corners of the region, particularly reentrant corners, so the mesh is usually made much finer there from the start.

A posteriori methods obtain rigorous upper and lower bounds on the eigenvalues of A from numerical computations; these bounds might be based on the variational method described earlier (see Rump 2010, part 3). This method has three major differences from the *a priori* method. The first is that implementing the method has a considerably higher computational cost than that of the *a priori* method. If it is implemented using interval arithmetic, then one needs to avoid various computational traps that are by now well known to experts. The final feature is that one does not need to prove that the upper and lower bounds converge to the eigenvalue of interest as $h \rightarrow 0$. One simply performs the calculation for smaller and smaller h until either one obtains a result for which the error bounds are sufficiently small, or one accepts that the method is not useful with the available computational resources.

Which of the two methods one uses must depend on the circumstances. A lot of ready-made code exists for the *a priori* method. Results obtained by using the *a priori* method may be the starting point even if one intends to use the *a posteriori* method eventually, because it is always useful to have a good idea about the approximate location of the solution before carrying out further rigorous calculations.

6 Other Applications of Spectral Theory

In this section we gather together a miscellaneous collection of applications. Although it is far from complete, it may serve to illustrate the vigor of the field.

6.1 Fredholm Operators

The results below can be extended to unbounded operators and to Banach spaces, but it is easiest to explain them in a more restricted context.

A bounded operator A acting on a Hilbert space \mathcal{H} is said to be *Fredholm* if its kernel $\text{Ker}(A)$ is finite dimensional, its range is closed, and the orthogonal complement $\text{Coker}(A)$ of its range is also finite dimensional. The integer

$$\text{Ind}(A) = \text{Dim}(\text{Ker}(A)) - \text{Dim}(\text{Coker}(A))$$

is called the *index* of A . The index is a very useful invariant of an operator because of the following fact. If A is Fredholm then any small enough perturbation of A is also Fredholm and the perturbation has the same index as A . Hence, if A_s is a one-parameter family of operators depending norm continuously on s , and each A_s is Fredholm, then $\text{Ind}(A_s)$ does not depend on s . This may be used to prove that the index of an elliptic differential operator acting on the space of sections of a vector bundle does not depend on the detailed values of its coefficients. This fact is a key ingredient in the Atiyah–Singer index theorem, which has ramifications throughout global analysis.

Under the same hypotheses, if $\text{Ind}(A_0) \neq 0$ then $\text{Ind}(A_s) \neq 0$, so 0 is an eigenvalue of A_s or of A_s^* . In either case, $0 \in \text{Spec}(A_s)$. This type of argument can enable one to determine more about the spectra of non-self-adjoint operators than one could by more elementary methods.

A particular example of this is afforded by Toeplitz operators, whose applications spread far and wide (see Böttcher and Silbermann 2006). Given a sequence $a \in \ell^1(\mathbb{Z}_+)$, one can define the associated *Toeplitz operator* A on $\ell^2(\mathbb{Z}_+)$ by

$$(Af)_n = \sum_{m=0}^{\infty} a_{n-m} f_m$$

for all $f \in \ell^2(\mathbb{Z}_+)$. It may be shown that $\|A\| \leq \|a\|_1$. The function

$$\sigma(\theta) = \sum_{n=0}^{\infty} a_n e^{-in\theta}$$

is called the *symbol* of A , and under the above assumptions it is a bounded continuous function that is

periodic with period 2π . One may in fact define a Toeplitz operator associated with any bounded measurable periodic symbol, but the technicalities become much greater, and some of the key results are different.

Under the present assumptions one has

$$\{\sigma(\theta) : 0 \leq \theta \leq 2\pi\} \subseteq \text{Spec}(A),$$

but more is actually true. If a complex number λ does not lie in the range of σ , then A is Fredholm and its index equals the winding number of the closed curve σ around λ . A theorem of Gohberg states that the spectrum of A consists of $S = \{\sigma(\theta) : 0 \leq \theta \leq 2\pi\}$ together with every $\lambda \notin S$ for which the winding number is nonzero.

All of these results can be generalized to vector-valued Toeplitz operators—a fact that extends their possible applications substantially.

6.2 Spectral Geometry

In this subject one investigates the relationship between the geometry of a Riemannian manifold, or a bounded region in Euclidean space, and the eigenvalues λ_n of the associated Laplace–Beltrami operator $H = -\Delta$ (see Gilkey 2005). The Weyl law, already described, establishes that one may determine the volume of a region in \mathbb{R}^N from the eigenvalues of a related Laplace operator, but far more than this is possible. In this context it turns out to be easier to investigate the small t asymptotics of

$$\text{tr}(e^{-Ht}) = \sum_{n=1}^{\infty} e^{-\lambda_n t}$$

than the large s asymptotics of the spectral counting function $N_H(s)$ defined earlier. In 1966 Mark Kac asked whether one can “hear the shape of a drum”; more specifically he asked whether the size and shape of a bounded Euclidean region U are uniquely determined by the eigenvalues of the associated Laplace operator, assuming Dirichlet boundary conditions. Many positive results of great interest were obtained in the course of studying this problem, but in 1992, Gordon, Webb, and Wolpert constructed a very simple counterexample in which the two plane regions concerned are fairly simple polygons.

6.3 Graph Laplacians

The spectral analysis of graphs has many aspects, but the first problem is that the word “graph” has more than one meaning. The following two interpretations lead to different mathematical results.

One may define a GRAPH [II.16] to be a finite or countable set X of vertices together with a set \mathcal{E} of undirected edges. In this case the *adjacency matrix* A is defined by putting $A_{x,y} = 1$ if $(x,y) \in \mathcal{E}$, and $A_{x,y} = 0$ otherwise. It may be seen that A is associated with a bounded operator on $\ell^2(X)$ provided the *degrees* of the vertices are uniformly bounded, where the degree of a vertex x is defined to be $\#\{y : (x,y) \in \mathcal{E}\}$. The spectrum of (X, \mathcal{E}) is by definition the spectrum of A , which is real because A is self-adjoint. The spectrum provides a set of invariants of a graph. The spectral theory of finite graphs is now a subject in its own right (see Brouwer and Haemers 2012).

Physicists are also interested in *quantum graphs*, in which the edges are continuous intervals of given lengths (see Berkolaiko and Kuchment 2013). The Hilbert space of interest is then $L^2(E)$, where E is the union of the edges in \mathcal{E} . One considers the second-order differential operator on $L^2(E)$ given by $(Af)(x) = -f''(x)$ on each edge. In order to obtain a self-adjoint operator one has to impose appropriate boundary conditions at each of the vertices. The simplest way of doing this is to require that if f lies in the domain of A , then f is continuous at each vertex and the sum of the outward-pointing first derivatives at each vertex vanishes. These are called free or *Kirchhoff* boundary conditions.

There are two reasons for studying quantum graphs. The first is that they are mild generalizations of the one-dimensional theory on \mathbb{R} , and there is some interest in determining how the geometry of the graph affects the spectral theory of the operator A . The second is that quantum graphs arise as limits of quantum waveguides as the width of the waveguide decreases to zero. People are interested in quantum waveguides because of their potential applications, and quantum graphs provide a useful first approximation to their properties.

6.4 Nonlinear Eigenvalue Problems

This article has concentrated on linear spectral theory, which is by far the best-developed part of the subject. There are two types of generalization of this theory to a nonlinear context. In the first, one attempts to solve $Af = \lambda f$ when f lies in some Banach or Hilbert space of functions and A is a nonlinear operator. The earliest and best-known problem of this type is called the Korteweg-de Vries equation. It is exactly soluble, subject to the solution of an associated linear inverse scattering problem. There are many papers that generalize specified spectral properties of linear second-order

elliptic eigenvalue problems to the nonlinear context, under suitable hypotheses. However, nonlinear problems are much harder, whether one approaches them analytically or numerically, and current methods of solution depend heavily on the equation of interest.

Another type of nonlinear eigenvalue problem looks for solutions f of equations such as

$$\lambda^2 A_2 f + \lambda A_1 f + A_0 f = 0,$$

where $\lambda \in \mathbb{C}$ and A_0, A_1, A_2 are all linear operators. This is called a QUADRATIC EIGENVALUE PROBLEM [IV.10 §5.8], and it is the most important case of the more general polynomial eigenvalue problem. It has applications to engineering, the wave equation, control theory, nonlinear boundary-value problems, oceanography, and other fields.

If A_2 is invertible then the above problem is equivalent to a standard eigenvalue problem for the block matrix

$$\begin{pmatrix} -A_1 A_2^{-1} & I \\ -A_0 A_2^{-1} & 0 \end{pmatrix}. \quad (3)$$

This transformation does not reduce the theory to a triviality because qualitative properties of the spectrum may be less easy to deduce from (3) than from the original problem. For example, even if A_0, A_1, A_2 are all self-adjoint, the matrix (3) is non-self-adjoint, with no obvious special structure. There is a rich theory of finite-dimensional quadratic pencils, which classifies them into many different types, each with its own special features.

IV.9 Approximation Theory

Annie Cuyt

1 Introduction

Approximation theory is an area of mathematics that has become indispensable to the computational sciences. The approximation of magnitudes and functions describing some physical behavior is an integral part of scientific computing, queueing problems, neural networks, graphics, robotics, network traffic, financial trading, antenna design, floating-point arithmetic, image processing, speech analysis, and video signal filtering, to name just a few areas.

The idea of seeking a simple mathematical function that describes some behavior approximately has two sources of motivation. The exact behavior that one is studying may not be able to be expressed in a closed mathematical formula. But even if an exact description is available it may be far too complicated for practical use. In both cases a best and simple approximation is required. What is meant by best and simple depends on the application at hand.

The approximation is often used in a computer implementation, and therefore its evaluation needs to be efficient. The simplest and fastest functions for implementation are polynomials because they use only the fast hardware operations of addition and multiplication. Next come rational functions, which also need the hardware operation of division, one or more depending on their representation as a quotient of polynomials or as a continued fraction. Rational functions offer the clear advantage that they can reproduce asymptotic behavior (vertical, horizontal, slant), which is something polynomials are incapable of doing. For periodic phenomena, linear combinations of trigonometric functions make good candidates. For growth

models or decaying magnitudes, linear combinations of exponentials can be used.

In approximation theory one distinguishes between interpolation and best approximation problems. In the former one wants the approximate model to take exactly the same values as prescribed by data given at precise argument values. In the latter a set of data (not necessarily discrete) is regarded as a trend and approximated by a simple model in one or other best sense. The difference is formalized in the following sections.

Besides constructing a good and efficient mathematical model, one should also take the following two issues into account.

- What can be said about the convergence of the selected mathematical model? In more practical terms: does the model improve when one adds more data?
- How sensitive is the mathematical model to perturbations in the input data? Data errors are usually unavoidable, and one wishes to know how much they can be magnified in the approximation process.

In the following sections we comment on both issues where appropriate. We do not aim to discuss convergence or undertake a sensitivity analysis for every technique.

Despite the need for and interest in multidimensional models and simulations, we restrict ourselves here mostly to one-dimensional approximation problems. In the penultimate section we include some brief remarks on multivariate interpolation and approximation and its additional complexity.

2 Numerical Interpolation

Let data f_i be given at points $x_i \in [a, b]$, where $i = 0, \dots, n$. We assume that if some of the points x_i are repeated, then it is not only the value of some underlying function $f(x)$ that is given (or measured) at x_i but also as many higher derivatives $f^{(j)}(x_i)$ as there are copies of the point x_i . The interpolation problem is to find a function of a specified form that matches all the data at the points. In this section we deal with the two extreme cases: the one in which all the points x_i are mutually distinct and no derivative information is available, and the one in which the value of the function and that of the first n derivatives are all given at one single point x_0 . Of course, intermediate situations can also be dealt with. The approximating functions

that we consider are polynomials, piecewise polynomials (splines), and rational functions, each of which has particular advantages. Finally, we present the connection between exponential models and sparse interpolation, on the one hand, and exponential models and Padé approximation, on the other.

2.1 Polynomial Interpolation

For $n + 1$ given values $f_i = f(x_i)$ at mutually distinct points x_i , the polynomial interpolation problem of degree n ,

$$p_n(x) = \sum_{j=0}^n a_j x^j, \quad p_n(x_i) = f_i, \quad i = 0, \dots, n, \quad (1)$$

has a unique solution for the coefficients a_j . Now let us turn to the computation of $p_n(x)$. Essentially, two approaches can be used, depending on the intended subsequent use of the polynomial interpolant. If one is interested in easily updating the polynomial interpolant by adding an extra data point and consequently increasing the degree of $p_n(x)$, then Newton's formula for the interpolating polynomial is very suitable. If one wants to use the interpolant for several sets of values f_i while keeping the points x_i fixed, then Lagrange's formula is most appropriate. A simple rearrangement of the Lagrange form as in (2) below results in the barycentric form, which combines the advantages of both approaches.

In the Newton form one writes the interpolating polynomial $p_n(x)$ as

$$\begin{aligned} p_n(x) &= b_0 + b_1(x - x_0) + b_2(x - x_0)(x - x_1) \\ &\quad + \dots + b_n(x - x_0) \cdots (x - x_{n-1}). \end{aligned}$$

The coefficients b_j then equal the *divided differences* $b_j = f[0, \dots, j]$ obtained from the recursive scheme

$$\begin{aligned} f[j] &= f_j, \quad j = 0, \dots, n, \\ f[0, j] &= \frac{f_j - f_0}{x_j - x_0}, \quad j = 1, \dots, n, \\ f[0, 1, \dots, k-1, k, j] &= \frac{f[0, 1, \dots, k-1, j] - f[0, 1, \dots, k-1, k]}{x_j - x_k}, \\ &\quad k, j = 2, \dots, n. \end{aligned}$$

Newton's form for the interpolating polynomial is very handy when one wants to update the interpolation with an additional point (x_{n+1}, f_{n+1}) . It suffices to add the term

$$b_{n+1}(x - x_0) \cdots (x - x_n)$$

to $p_n(x)$ (which does not destroy the previous interpolation conditions since it evaluates to zero at all the previous x_i) and to complement the recursive scheme for the computation of the divided differences with the computation of the

$$f[0, 1, \dots, k, n+1], \quad k = 0, \dots, n.$$

In the Lagrange form, which is especially suitable if the interpolation needs to be repeated for different sets of f_i at the same points x_i , another form for $p_n(x)$ is used. We write

$$p_n(x) = \sum_{j=0}^n c_j \beta_j(x), \quad \beta_j(x) = \prod_{\substack{k=0 \\ k \neq j}}^n \frac{(x - x_k)}{(x_j - x_k)}.$$

The basis functions $\beta_j(x)$ satisfy a simple interpolation condition themselves, namely,

$$\beta_j(x_i) = \begin{cases} 0 & \text{for } j \neq i, \\ 1 & \text{for } j = i. \end{cases}$$

The choice $c_j = f_j$ for the coefficients therefore solves the interpolation problem. So when altering the f_i , without touching the x_i that make up the basis functions $\beta_j(x)$, it takes no computation at all to get the new coefficients c_j .

The *barycentric form* of the interpolation polynomial,

$$\left. \begin{aligned} p_n(x) &= (x - x_0) \cdots (x - x_n) \sum_{j=0}^n \frac{w_j}{x - x_j} f_j, \\ w_j &= \left(\prod_{\substack{k=0 \\ k \neq j}}^n (x_j - x_k) \right)^{-1}, \end{aligned} \right\} \quad (2)$$

is easy to update and is BACKWARD STABLE [I.2 §23] for evaluation of $p_n(x)$.

The sensitivity of the polynomial interpolant expressed in the Lagrange form is measured by the value

$$L_n = \max_{a \leqslant x \leqslant b} \sum_{j=0}^n |\beta_j(x)|, \quad (3)$$

which is also known as the *Lebesgue constant*. The growth rate of L_n with n is only logarithmic when the interpolation points are as in (5) below. This is the slowest possible growth for polynomial interpolation.

Despite the simplicity and elegance of polynomial interpolation, the technique has a significant drawback, as we discuss next: it may not converge for data $f_i = f(x_i)$ given at arbitrary points x_i , even if $f(x)$ is continuous on $[a, b]$.

2.2 The Runge Phenomenon

What happens if we continue updating the interpolation problem with new data? In other words, what happens if we let the degree n of the interpolating polynomial $p_n(x)$ increase? Will the interpolating polynomial of degree n become better and better? The answer is no, at least not for freely chosen points x_i . To see what can go wrong, consider

$$f(x) = \frac{1}{1 + 25x^2}, \quad -1 \leq x \leq 1, \quad (4)$$

and take equidistant interpolation points $x_i = -1 + 2i/n$, $i = 0, \dots, n$. The error $(f - p)(x)$ toward the endpoints of the interval then increases dramatically with n . Take a look at the bell-shaped $f(x)$ and the interpolating polynomial $p_n(x)$ for $n = 10$ and $n = 20$ in figure 1.

This phenomenon is called *Runge's phenomenon*, after Carl Runge, who described this behavior for real-valued interpolation in 1901. An explanation for it can be found in the fundamental theorem of algebra, which states that a polynomial has as many zeros as its degree. Each of these zeros can be real or complex. So if n is large and the zeros are all real, the polynomial under consideration displays rather oscillatory behavior.

On the other hand, under certain simple conditions for $f(x)$ besides continuity in $[a, b]$, it can be proved that if the interpolation points x_i equal

$$x_i = \frac{a+b}{2} + \frac{b-a}{2} \cos\left(\frac{(2i+1)\pi}{2(n+1)}\right), \quad i = 0, \dots, n, \quad (5)$$

where the values $\cos((2i+1)/(n+1)(\pi/2))$ are the zeros of the Chebyshev polynomial of the first kind of degree $n+1$ (defined in section 3.3), then

$$\lim_{n \rightarrow \infty} \|f - p_n\|_\infty = \lim_{n \rightarrow \infty} \max_{x \in [-1, 1]} |(f - p_n)(x)| = 0.$$

The effect of this choice of interpolation points is illustrated in figure 2(a). A similar result holds if the zeros of the Chebyshev polynomial of degree $n+1$ are replaced by the extrema $\cos(i\pi/n)$, $i = 0, \dots, n$, of the Chebyshev polynomial of degree n .

In order to make use of this result in real-world applications, where the interpolation points x_i cannot usually be chosen arbitrarily, interpolation at the Chebyshev zeros is mimicked, for instance by selecting a proper subset of interpolation points \tilde{x}_i from a fine equidistant grid, with $\tilde{x}_i \approx x_i$ from (5). The grid is considered to be sufficiently fine when the distance

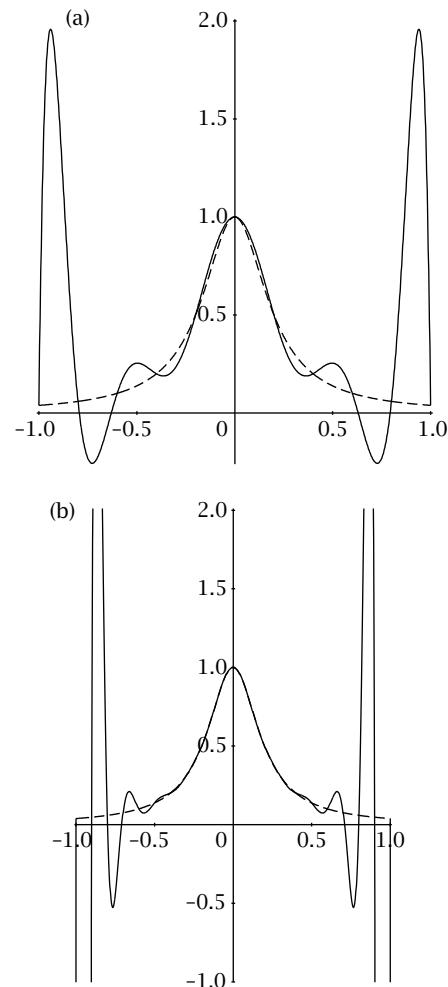

Figure 1 (a) Degree-10 and (b) degree-20 equidistant interpolation (solid lines) for function f in (4) (dashed lines).

between the points ensures that a grid point nearest to a Chebyshev zero x_i is never repeated. In a coarse grid, the same grid point may be the closest one to more than one Chebyshev zero, especially toward the ends of the interval $[-1, 1]$.

This technique is called *mock-Chebyshev interpolation*. For comparison, in figure 2(b) we display the degree-20 mock-Chebyshev interpolant with the interpolation points selected from an equispaced grid with gap 1/155.

If a lot of accurate data points have to be used in an interpolation scheme, then splines, which are discussed in the next section, offer a better alternative than a monolithic high-degree polynomial interpolant.

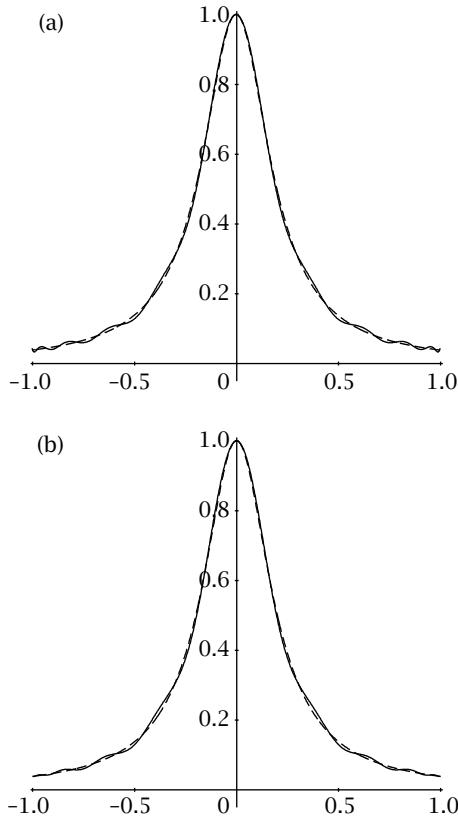

Figure 2 Degree-20 (a) Chebyshev and (b) mock-Chebyshev interpolation (solid lines) for function f in (4) (dashed lines).

2.3 Spline Interpolation

In order to avoid the Runge phenomenon when interpolating large data sets, piecewise polynomials, also called splines, can be used. To this end we divide the data set of $n + 1$ points into smaller sets, each containing two data points. Rather than interpolating the full data set by one polynomial of degree n , we interpolate each of the smaller data sets by a low-degree polynomial. These separate polynomial functions are then pieced together in such a way that the resulting function is as continuously differentiable as possible.

Take, for instance, the data set (x_i, f_i) and consider linear polynomials interpolating every two consecutive (x_i, f_i) and (x_{i+1}, f_{i+1}) . These linear polynomial pieces can be joined together at the data points (x_i, f_i) to produce a piecewise-linear continuous function or polygonal curve. Note that this function is continuous but not differentiable at the interpolation points since it is polygonal.

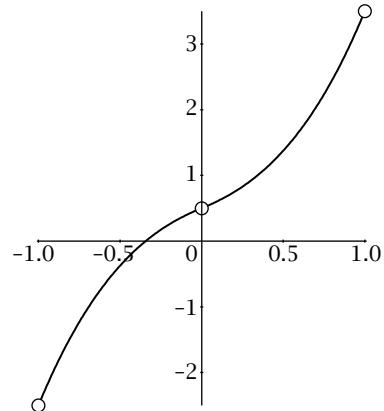

Figure 3 A piecewise-cubic function that is not twice continuously differentiable.

If we introduce two parameters, Δ and D , to respectively denote the degree of the polynomial pieces and the differentiability of the overall function, where obviously $D \leq \Delta$ (even $D < \Delta$ to avoid an overdetermined system of defining equations, as explained below), then, for the polygonal curve, $\Delta = 1$ and $D = 0$. With $\Delta = 2$ and $D = 1$, a piecewise-quadratic and smooth (meaning continuously differentiable in the entire interval $[x_0, \dots, x_n]$) function is constructed. The slope of a smooth function is a continuous quantity. With $\Delta = 3$ and $D = 2$, a piecewise-cubic and twice continuously differentiable function is obtained. Twice continuously differentiable functions also enjoy continuous curvature. Can the naked eye distinguish between continuous and discontinuous curvature in a function? The untrained eye certainly cannot! As an example we take the cubic polynomial pieces

$$c_1(x) = x^3 - x^2 + x + 0.5, \quad x \in [-1, 0], \\ c_2(x) = x^3 + x^2 + x + 0.5, \quad x \in [0, 1],$$

and join these together at $x = 0$ to obtain a new piecewise-cubic function $c(x)$ on $[-1, 1]$. The result is a function that is continuous and differentiable at the origin, but for the second derivatives at the origin, we have $\lim_{x \rightarrow 0^-} c^{(2)}(0) = -2$ and $\lim_{x \rightarrow 0^+} c^{(2)}(0) = 2$. Nevertheless, the result of the gluing procedure shown in figure 3 is a very pleasing function that at first sight looks fine. But while Δ equals 3, D is only 1.

Since a trained eye can spot these discontinuities, the most popular choice for piecewise-polynomial interpolation in industrial applications is $\Delta = 3$ and $D = 2$. Indeed, for manufacturing the continuity of the curvature is important.

Let us take a look at the general situation where $\Delta = m$ and $D = m - 1$, for which the resulting piecewise polynomial is called a *spline*. Assume we are given the interpolation points x_0, \dots, x_n . With these $n + 1$ points we can construct n intervals $[x_i, x_{i+1}]$. The points x_0 and x_n are the endpoints, and the other $n - 1$ interpolation points are called the internal points. If $\Delta = m$, then for every interval $[x_i, x_{i+1}]$ we have to determine $m + 1$ coefficients because the explicit formula for the spline on $[x_i, x_{i+1}]$ is a polynomial of degree m :

$$S(x) = s_i(x), \quad x \in [x_i, x_{i+1}], \quad i = 0, \dots, n - 1,$$

$$s_i(x) = \sum_{j=0}^m a_j^{(i)} x^j.$$

So, in total, $n(m + 1)$ unknown coefficients $a_j^{(i)}$ have to be computed. From which conditions? There are the $n + 1$ interpolation conditions $S(x_i) = f_i$, and we have the smoothness or continuity requirements at the internal points, meaning that a number of derivatives of $s_{i-1}(x)$ evaluated at the right endpoint of the domain $[x_{i-1}, x_i]$ should coincide with the derivatives of $s_i(x)$ when evaluated at the left endpoint of the domain $[x_i, x_{i+1}]$:

$$s_{i-1}^{(k)}(x_i) = s_i^{(k)}(x_i), \quad i = 1, \dots, n - 1, \quad k = 0, \dots, m - 1.$$

The latter requirements add another $(n - 1)m$ continuity conditions. This brings us to a total of $n + 1 + (n - 1)m = n(m + 1) - m + 1$ conditions for $n(m + 1)$ unknowns. In other words, we lack $m - 1$ conditions to determine the degree- m piecewise-polynomial interpolant with overall smoothness of order $m - 1$. When $m = 1$, which is the case for the piecewise-linear spline or the polygonal curve, no conditions are lacking. When $m = 2$, a value for $s'_0(x_0)$ is usually given as an additional piece of information. When $m = 3$, which is the case for the widely used cubic spline, values for $s''_0(x_0)$ and $s''_{n-1}(x_n)$ are often provided (the cubic spline with clamped end conditions) or they are set to zero (the natural cubic spline).

The natural cubic spline interpolant has a very elegant property, namely, that it avoids oscillatory behavior between interpolation points. More precisely, for every twice continuously differentiable function $f(x)$ defined on $[a, b]$ and satisfying $f(x_i) = f_i$ for all i , we have

$$\int_a^b S''(x)^2 dx \leq \int_a^b f''(x)^2 dx.$$

A simple illustration is given in figure 4 for $n = 6$ with $x_i = i$, $i = 1, \dots, 6$.

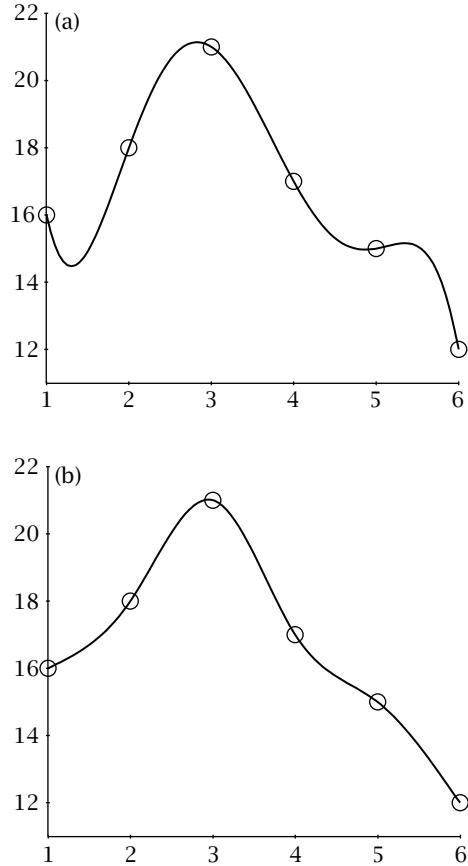

Figure 4 (a) The polynomial interpolant and (b) the natural cubic spline.

2.4 Padé Approximation

The rational equivalent of the Taylor series partial sum is the irreducible rational function $r_{k,\ell}(x) = p_{k,\ell}(x)/q_{k,\ell}(x)$ with numerator of degree at most k and denominator of degree at most ℓ that satisfies

$$r_{k,\ell}^{(i)}(x_0) = f^{(i)}(x_0), \quad i = 0, 1, \dots, n, \quad (6)$$

with n as large as possible. It is also called the $[k/l]$ *Padé approximant*. The aim is to have $n = k + \ell$. Note that we are imposing one fewer condition than the total number $k + \ell + 2$ of coefficients in $r_{k,\ell}$. The reason is that one degree of freedom is lost because multiplying $p_{k,\ell}$ and $q_{k,\ell}$ by a scalar does not change $r_{k,\ell}$.

A key question is whether n can be less than $k + \ell$. The answer to this question requires some analysis. Computing the numerator and denominator coefficients of $r_{k,\ell}(x)$ from (6) gives rise to a nonlinear system of equations. So let us explore whether the Padé

approximant can also be obtained from the linearized approximation conditions

$$(f q_{k,\ell} - p_{k,\ell})^{(i)}(x_0) = 0, \quad i = 0, 1, \dots, k + \ell. \quad (7)$$

We denote $f^{(j)}(x_0)/j!$ by d_j , where $d_j = 0$ for $j < 0$. The linearized conditions (7) always have at least one nontrivial solution for the numerator coefficients a_0, \dots, a_k and the denominator coefficients b_0, \dots, b_ℓ because they form a homogeneous linear system of $k + \ell + 1$ conditions in $k + \ell + 2$ unknowns:

$$\begin{aligned} d_0 b_0 &= a_0, \\ d_1 b_0 + d_0 b_1 &= a_1, \\ &\vdots \\ d_k b_0 + \dots + d_{k-\ell} b_\ell &= a_k, \\ d_{k+1} b_0 + \dots + d_{k-\ell+1} b_\ell &= 0, \\ &\vdots \\ d_{k+\ell} b_0 + \dots + d_k b_\ell &= 0. \end{aligned}$$

Moreover, all solutions $p_{k,\ell}(x)$ and $q_{k,\ell}(x)$ of (7) are equivalent in the sense that they have the same irreducible form. Every solution of (6) with $n = k + \ell$ therefore also satisfies (7), but not vice versa. From $p_{k,\ell}(x)$ and $q_{k,\ell}(x)$ satisfying (7) we find, for the unique irreducible form $p_{k,\ell}^*(x)/q_{k,\ell}^*(x)$, that

$$\begin{aligned} (f - r_{k,\ell})^{(i)}(x_0) &= 0, \quad i = 0, \dots, k' + \ell' + r, \\ k' &= \partial p_{k,\ell}^*, \quad \ell' = \partial q_{k,\ell}^*, \quad r \geq 0, \end{aligned}$$

where ∂p denotes the degree of the polynomial p . In some textbooks, the $[k/l]$ Padé approximation problem is said to have no solution if $k' + \ell' + r < k + \ell$; in others, the Padé approximant $r_{k,\ell}$ is identified with $r_{k',\ell'} = p_{k,\ell}^*/q_{k,\ell}^*$ if that is the case (this is the convention we adopt here). Let us illustrate the situation with a simple example. Take $x_0 = 0$ with $d_0 = 1$, $d_1 = 0$, $d_2 = 1$, and $k = 1 = \ell$. The linearized conditions (7) are then

$$b_0 = a_0, \quad b_1 = a_1, \quad b_0 = 0.$$

A solution is given by $p_{1,1}(x) = x$ and $q_{1,1}(x) = x$. We therefore find $r_{1,1}(x) = 1$, $k' = 0$, $\ell' = 0$, and

$$(f - r_{1,1})^{(2)}(x_0) = 2 \neq 0.$$

Since $r = 1$, we have $k' + \ell' + r = 1 < k + \ell = 2$.

This kind of complication does not occur when $\ell = 0$. The Padé approximant $r_{k,0}(x)$ is then merely the Taylor series partial sum of degree k . But when asymptotic behavior needs to be reproduced, a polynomial function is not very useful. In figure 5 one can compare the Taylor series partial sum of degree 9 with the $[5/4]$ Padé approximant for the function $f(x) = \arctan(x)$.

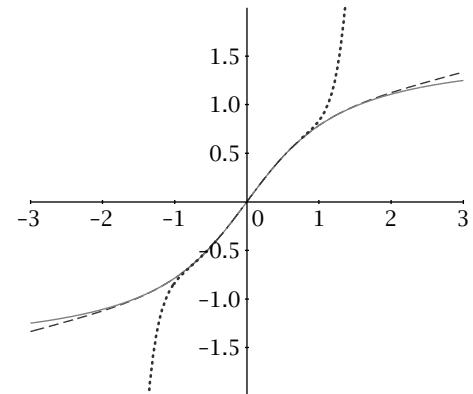

Figure 5 Padé approximants $r_{9,0}(x)$ (dotted line) and $r_{5,4}(x)$ (dashed line) for $\arctan(x)$ (solid line).

Table 1 The Padé table for $\sin(x)$.

	0	1	2	
1	x	x	$\frac{x}{1 + \frac{1}{6}x^2}$...
2	x	x	$\frac{x}{1 + \frac{1}{6}x^2}$...
3	$x - \frac{1}{6}x^3$	$x - \frac{1}{6}x^3$	$\frac{(-\frac{7}{60}x^3 + x)}{(1 + \frac{1}{20}x^2)}$...
	⋮	⋮	⋮	⋮

Padé approximants can be organized in a table, where the numerator degree indicates the row and the denominator degree the column. To illustrate this we give part of the Padé table for $f(x) = \sin(x)$ in table 1. A sequence of Padé approximants in the Padé table can converge uniformly or in measure only to a function $f(x)$ that is meromorphic in a substantial part of its domain.

2.5 Rational Interpolation

The rational equivalent of polynomial interpolation at mutually distinct interpolation points x_i consists of finding an irreducible rational function $r_{k,\ell}(x)$, of numerator degree at most k and denominator degree at most ℓ , that satisfies

$$r_{k,\ell}(x_i) = f_i, \quad i = 0, \dots, k + \ell, \quad (8)$$

where $f_i = f(x_i)$. Instead of solving (8) one considers the linearized equations

$$(f q_{k,\ell} - p_{k,\ell})(x_i) = 0, \quad i = 0, \dots, k + \ell, \quad (9)$$

where $p_{k,\ell}(x)$ and $q_{k,\ell}(x)$ are polynomials of respective degree k and ℓ . Condition (9) is a homogeneous linear system of $k + \ell + 1$ equations in $k + \ell + 2$ unknowns, and it therefore always has a nontrivial solution. Moreover, as in the Padé approximation case, all solutions of (9) are equivalent in the sense that they deliver the same unique irreducible rational function.

In the construction of the irreducible form $r_{k,\ell}(x)$ of $p_{k,\ell}(x)/q_{k,\ell}(x)$, common factors in numerator and denominator are canceled, and it may well be that $r_{k,\ell}$ does not satisfy the interpolation conditions (8) anymore, despite $p_{k,\ell}$ and $q_{k,\ell}$ being solutions of (9), because one or more of the canceled factors may be of the form $x - x_i$ with x_i an interpolation point. A simple example illustrates this. Let $x_0 = 0$, $x_1 = 1$, $x_2 = 2$ with $f_0 = 0$, $f_1 = 3$, $f_2 = 3$, and take $k = 1 = \ell$. The homogeneous linear system of interpolation conditions is then

$$\begin{aligned} a_0 &= 0, \\ 3(b_0 + b_1) - (a_0 + a_1) &= 0, \\ 3(b_0 + 2b_1) - (a_0 + 2a_1) &= 0. \end{aligned}$$

A solution is given by $p_{1,1}(x) = 3x$ and $q_{1,1}(x) = x$. Hence, $r_{1,1}(x) = 3$ and clearly $r_{1,1}(x_0) \neq f_0$. The interpolation point x_0 is then called unattainable. This problem can be fixed only by increasing the degrees k and/or ℓ until the interpolation point is attainable. Note that unattainable interpolation points do not occur in polynomial interpolation ($\ell = 0$).

A well-known problem with rational interpolation and Padé approximation is the occurrence of undesirable poles in the interpolant $r_{k,\ell}(x)$. One way to avoid this is to work with preassigned poles, either explicitly or implicitly, by determining the denominator polynomial $q_{k,\ell}(x)$ a priori. All $k + \ell + 1$ interpolation conditions are then imposed on the coefficients of the numerator polynomial, and consequently the degree of the numerator is raised to $k + \ell$.

Let the interpolation points x_i be ordered such that $x_0 < x_1 < \dots < x_n$ with $k + \ell = n$. A popular choice for the denominator polynomial that guarantees a pole-free real axis, unless the location of the poles needs to be controlled by other considerations, is

$$q_{n,n}(x) = \sum_{j=0}^n (-1)^j \prod_{\substack{k=0 \\ k \neq j}}^n (x - x_k).$$

With this choice, the rational interpolant can be written in a barycentric form similar to that in (2):

$$r_{n,n}(x) = \frac{\sum_{j=0}^n f_j (-1)^j / (x - x_j)}{\sum_{j=0}^n (-1)^j / (x - x_j)}.$$

Again, this form is very stable for interpolation. Its numerical sensitivity is measured by

$$M_n = \max_{a \leq x \leq b} \sum_{i=0}^n \frac{|q_{n,n}(x_i) \beta_i(x)|}{|q_{n,n}(x)|}.$$

And there is more good news now: in the case of equidistant interpolation points, M_n grows as slowly with n as the Lebesgue constant L_n in (3) for polynomial interpolation in the Chebyshev zeros. The latter makes the technique very useful in practice.

More practical choices for the denominator polynomial $q_{n,n}(x)$ are possible, guaranteeing other features, such as rapid convergence, comonotonicity, or coconvexity (coconcavity).

2.6 Sparse Interpolation

When interpolating

$$f(x) = \alpha_1 + \alpha_2 x^{100}$$

by a polynomial, the previous techniques require 101 samples of $f(x)$ to determine that $f(x)$ is itself a polynomial, while only four values need to be computed from the data points, namely the two exponents 0 and 100 and the two coefficients α_1 and α_2 . So it would be nice if we could solve this polynomial reconstruction problem from only four samples.

The above is a special case of the more general *sparse interpolation*, which was studied as long ago as 1795, by Gaspard de Prony, in which the complex values ϕ_j and α_j in the interpolant

$$\phi(x) = \sum_{j=1}^n \alpha_j e^{\phi_j x}, \quad \alpha_j, \phi_j \in \mathbb{C}, \quad (10)$$

are to be determined from only $2n$ samples of $\phi(x)$.

While the nonlinear interpolation problems of Padé approximation and rational interpolation are solved by linearizing the conditions as in (7) and (9), the nonlinear problem of sparse interpolation is solved by separating the computation of the ϕ_j and the α_j into two linear algebra subproblems. Let $\phi(x)$ be sampled at the equidistant points $x_i = i\Delta$, $i = 0, \dots, 2n - 1$, and let us denote $\phi(x_i)$ by f_i . We introduce the $n \times n$ Hankel matrices

$$H_n^{(r)} := \begin{pmatrix} f_r & \cdots & f_{r+n-1} \\ \vdots & \ddots & \vdots \\ f_{r+n-1} & \cdots & f_{r+2n-2} \end{pmatrix}$$

and $\lambda_j = e^{\phi_j \Delta}$, $j = 1, \dots, n$.

The λ_j are then retrieved as the generalized eigenvalues of the problem

$$H_n^{(1)} v_j = \lambda_j H_n^{(0)} v_j, \quad j = 1, \dots, n,$$

where the v_j are the generalized right eigenvectors. From the values λ_j , the complex numbers ϕ_j can be retrieved uniquely subject to the restriction that $|\text{Im}(\phi_j \Delta)| < \pi$. In order to satisfy this restriction, the sampling interval Δ is usually adapted to the range of the values $\text{Im}(\phi_j)$.

The α_j are computed from the interpolation conditions

$$\sum_{j=1}^n \alpha_j e^{\phi_j x_i} = f_i, \quad i = 0, \dots, 2n - 1, \quad (11)$$

either by solving the system in the least-squares sense or by solving a subset of n consecutive interpolation conditions. Note that

$$e^{\phi_j x_i} = \lambda_j^i$$

and that the coefficient matrix of (11) is therefore a Vandermonde matrix.

With $f_i = \phi(x_i)$ we now define

$$f(x) = \sum_{j=0}^{\infty} f_j x^j,$$

where $x_i = i\Delta$, $i \geq 0$. Since

$$f_i = \sum_{j=1}^n \alpha_j e^{\phi_j x_i} = \sum_{j=1}^n \alpha_j \lambda_j^i,$$

we can rewrite $f(x)$ as follows:

$$f(x) = \sum_{j=1}^n \frac{\alpha_j}{1 - x\lambda_j}. \quad (12)$$

So we see that $f(x)$ is itself a rational function of degree $n - 1$ in the numerator and n in the denominator, with poles $1/\lambda_j$. Hence, from Padé approximation theory we know (as is to be expected) that $r_{n-1,n}(x)$ reconstructs $f(x)$; in other words,

$$r_{n-1,n}(x) = f(x)$$

with

$$q(x) = \prod_{j=1}^n (1 - x\lambda_j).$$

The partial fraction decomposition (12) is the Laplace transform of the exponential model (10), which explains why this approach is known as the *Padé-Laplace method*.

This connection between approximation theory and harmonic analysis is clearly not accidental. More constructions from harmonic analysis, including wavelets

and Fourier series, also provide important insights into central problems in approximation theory. Other mathematical models in which the major features of a data set are represented using only a few terms are considered in the theory of COMPRESSED SENSING [VII.10].

3 Best Approximation

When the quality of the data does not justify the imposition of an exact match on the approximating function, or when the quantity of the data is simply overwhelming and depicts a trend rather than very precise measurements, interpolation techniques are of no use. It is better to find a linear combination of suitable basis functions that approximates the data in some best sense. We first discuss the existence and uniqueness of a best approximant and the discrete linear least-squares problem. How the bestness or nearness of the approximation is measured is then explained. Different measures lead to different approximants and are to be used in different contexts. We discuss the importance of orthogonal basis functions and describe the continuous linear least-squares problem and the minimax approximation. A discussion of a connection with Fourier series and the interpolation and approximation of periodic data concludes the section.

3.1 Existence and Uniqueness

First and foremost we discuss the existence and uniqueness of a best approximant p^* from a finite-dimensional subspace P to an element f from a normed linear space V . More specifically, we ask for which of the ℓ_1 -, ℓ_2 -, or ℓ_∞ -norms can we guarantee that either at least one or exactly one solution exists to the approximation problem of finding $p^* \in P$ such that

$$\|f - p^*\| \leq \|f - p\|, \quad p \in P.$$

The answer to the existence problem is affirmative for all three mentioned norms. To guarantee uniqueness of p^* , either the norm or the subspace P under consideration must satisfy additional conditions. And we must distinguish between discrete and continuous approximation and norms.

When V is *strictly convex*, in other words, when a sphere in V does not contain line segments, so that

$$\|x_1 - c\| = r = \|x_2 - c\| \Rightarrow$$

$$\|\lambda x_1 + (1 - \lambda)x_2 - c\| < r, \quad 0 < \lambda < 1,$$

then the best approximant p^* to f is unique. This applies, for instance, to the ℓ_2 - or Euclidean norm, in both the discrete and continuous cases.

In the discussion of the role of P with respect to the uniqueness of p^* , we deal with the continuous case first. When a basis $\{b_0(x), \dots, b_n(x)\}$ for P satisfies the *Haar condition*, meaning that every linear combination

$$q_n(x) = \lambda_0 b_0(x) + \dots + \lambda_n b_n(x)$$

has at most n zeros, then the continuous best ℓ_1 and best ℓ_∞ approximation problems also have a unique solution.

Let us now look at the discrete best approximation problem in somewhat more detail. We consider a large data set of values f_i that we want to approximate by a linear combination of some linearly independent basis functions $b_j(x)$:

$$\lambda_0 b_0(x_i) + \dots + \lambda_n b_n(x_i) = f_i, \quad i = 0, \dots, m > n. \quad (13)$$

This $(m+1) \times (n+1)$ linear system can be written compactly as

$$\left. \begin{aligned} A\lambda &= f, & \lambda &= \begin{bmatrix} \lambda_0 \\ \vdots \\ \lambda_n \end{bmatrix}, & f &= \begin{bmatrix} f_0 \\ \vdots \\ f_m \end{bmatrix}, \\ A &= (b_{j-1}(x_{i-1})) \in \mathbb{R}^{(m+1) \times (n+1)}. \end{aligned} \right\} \quad (14)$$

Unless the right-hand side f lies in the column space of A , the system cannot be solved exactly. The residual vector is given by

$$r = f - A\lambda \in \mathbb{R}^{m+1},$$

and the solution λ we are looking for is the one that solves the system best, in other words, the system that makes the magnitude (or norm) of the residual vector minimal. The least-squares problem corresponds to using the Euclidean norm or the ℓ_2 -norm $\|r\|_2 = (r_1^2 + \dots + r_m^2)^{1/2}$ to measure the residual vector, and the optimization problem translates to

$$(A^T A)\lambda = A^T f,$$

which is a square linear system of equations called the **NORMAL EQUATIONS** [IV.10 §7.1]. If the matrix A of the overdetermined linear system has maximal column rank, then the matrix $A^T A$ is nonsingular and the solution is unique.

When every $(n+1) \times (n+1)$ submatrix of the matrix A in (14) is nonsingular, then the discrete best ℓ_∞ approximation problem has a unique solution as well. An example showing the lack of uniqueness of the best

ℓ_1 approximation under the same condition is easy to find. Take

$$A = \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \quad f = \begin{pmatrix} 1 \\ 2 \end{pmatrix}$$

in (14). Then the minimum of $\|A\lambda - f\|_1$ with $n = 0$ and $b_0(x) = 1$ is the same for all $-2 \leq \lambda_0 \leq 1$.

In practice, instead of solving the normal equations, more numerically stable techniques based on **ORTHOGONAL TRANSFORMATIONS** [IV.10 §7.1] are applied directly to the overdetermined system (14). These transformations do not alter the Euclidean norm of the residual vector r and hence have no impact on the optimization criterion.

Let us now see whether the Euclidean norm is the correct norm to use.

3.2 Choice of Norm

If the optimal solution to the overdetermined linear system is the one that makes the norm $\|r\|$ of the residual minimal, then we must decide which norm to use to measure r . Although norms are in a sense equivalent, because they differ only by a scalar multiple depending only on the dimension, it makes quite a difference whether we minimize $\|r\|_1$, $\|r\|_2$, or $\|r\|_\infty$. Let us perform the following experiment.

Using a Gaussian random number generator with mean μ and standard deviation σ , we generate $m+1$ numbers f_i . The approximation problem we consider is the computation of an estimate for μ from the data points f_i , where σ expresses a tight or loose spread around μ . Compare this with a real-life situation where the data f_i are collected by performing some measurements of a magnitude μ , and σ represents the accuracy of the measuring tool used to obtain the f_i .

In the notation of (13), we want to fit the f_i by a multiple of the basis function $b_0(x) = 1$ because we are looking for the constant μ . The overdetermined linear system takes the form

$$\lambda_0 \cdot 1 = f_i, \quad i = 0, \dots, m.$$

It is clear that this linear system does not have an exact solution. The residual vector is definitely nonzero. We shall see that different criteria or norms can be used to express the closeness of the estimate λ_0 for μ to the data points f_i or, in other words, the magnitude of the residual vector r with components $f_i - \lambda_0$, and that the standard deviation σ will also play a role.

If the Euclidean norm is used, then the optimal estimate $\lambda_0^{(2)}$ is the mean of the m measurements f_i :

$$\lambda_0^{(2)} = \frac{1}{m+1} \sum_{i=0}^m f_i.$$

If we choose the ℓ_1 -norm $\|r\|_1 = \sum_{i=1}^m |r_i|$ as a way to measure distances, then the value $\lambda_0^{(1)}$ that renders the ℓ_1 -norm of the residual vector minimal is the median of the values f_i . Any change that makes the larger values extremely large or the smaller values extremely small therefore has no impact on $\lambda_0^{(1)}$, which is rather insensitive to outliers.

When choosing as distance function the ℓ_∞ -norm $\|r\|_\infty = \max_{i=1,\dots,m} |r_i|$, the optimal solution $\lambda_0^{(\infty)}$ to the problem is given by

$$\lambda_0^{(\infty)} = \frac{1}{2} \left(\min_{i=0,\dots,m} f_i + \max_{i=0,\dots,m} f_i \right).$$

This can also be understood intuitively. The value for λ_1 that makes $\|r\|_\infty$ minimal is the one that makes the largest deviation minimal, so it should be right in the middle between the extremes.

So the ℓ_∞ -norm criterion performs particularly well in the context of rather accurate data (in this experiment meaning small standard deviation σ) that suffer relatively small input errors (such as roundoff errors). When outliers or additional errors (such as from manual data input) are suspected, use of the ℓ_1 -norm is recommended. If the measurement errors are believed to be normally distributed with mean zero, then the ℓ_2 -norm is the usual choice. Approximation problems of this type are therefore called least-squares problems.

3.3 Orthogonal Basis Functions

In the same way that we prefer to draw a graph using an orthogonal set of axes (the smaller the angle between the axes, the more difficult it becomes to make a clear drawing), it is preferred to use a so-called orthogonal set of basis functions $b_j(x)$ in (13). Orthogonal basis functions $b_j(x)$ can tremendously improve the conditioning or sensitivity of the problem (14). They are also useful in continuous least-squares problems.

The notion of orthogonality in a function space parallels that of orthogonality in the vector space \mathbb{R}^k : for a positive weight function $w(x)$ defined on the interval $[a, b]$, we say that the functions f and g are w -orthogonal if

$$\langle f, g \rangle_w = \int_a^b f(x)g(x)w(x) dx = 0.$$

The function $w(x)$ can assign a larger weight to certain parts of the interval $[a, b]$. For instance, the function $w(x) = 1/\sqrt{1-x^2}$ on $[-1, 1]$ assigns more weight toward the endpoints of the interval.

For $w(x) = 1$ and $[a, b] = [-1, 1]$, a sequence of orthogonal polynomials $L_i(x)$ satisfying

$$\int_{-1}^1 L_j(x)L_k(x) dx = 0, \quad j \neq k,$$

is given by

$$\begin{aligned} L_0(x) &= 1, & L_1(x) &= x, \\ L_{i+1}(x) &= \frac{2i+1}{i+1} x L_i(x) - \frac{i}{i+1} L_{i-1}(x), & i &\geq 1. \end{aligned}$$

The polynomials $L_i(x)$ are called the *Legendre polynomials*. For $w(x) = 1/\sqrt{1-x^2}$ and $[a, b] = [-1, 1]$, a sequence of orthogonal polynomials $T_i(x)$ satisfying

$$\int_{-1}^1 T_j(x)T_k(x) \frac{1}{\sqrt{1-x^2}} dx = 0, \quad j \neq k,$$

is given by

$$\begin{aligned} T_0(x) &= 1, & T_1(x) &= x, \\ T_{i+1}(x) &= 2xT_i(x) - T_{i-1}(x), & i &\geq 1. \end{aligned}$$

The polynomials $T_i(x)$ are called the *Chebyshev polynomials* (of the first kind). They are also very useful in (continuous as well as discrete) least-squares problems, as discussed below.

When the polynomials are to be used on an interval $[a, b]$ different from $[-1, 1]$, the simple change of variable

$$x \rightarrow \frac{2}{b-a} \left(x - \frac{a+b}{2} \right)$$

transforms the interval $[a, b]$ to the interval $[-1, 1]$, on which the orthogonal polynomials are defined.

Orthogonal polynomials also satisfy the Haar condition, so every linear combination

$$q_n(x) = a_0 p_0(x) + \cdots + a_n p_n(x)$$

of the orthogonal polynomials $p_i(x)$ of degree $i = 0, \dots, n$ has at most n zeros. Therefore, orthogonal polynomials are also a suitable basis in which to express an interpolating function; the system of interpolation conditions

$$\sum_{j=0}^n a_j p_j(x_i) = f_i, \quad i = 0, \dots, n,$$

has a coefficient matrix that is guaranteed to be non-singular for mutually distinct points x_i .

The importance of orthogonal basis functions in interpolation and approximation cannot be overstated. Problems become numerically better conditioned and

formulas simplify. For instance, the Chebyshev polynomials $T_i(x)$ also satisfy the discrete orthogonality

$$\sum_{i=0}^n T_j(x_i)T_k(x_i) = (1 + \delta_{k0}) \frac{n+1}{2} \delta_{jk}, \\ j, k = 0, 1, \dots,$$

where δ_{ij} is the KRONECKER DELTA [I.2 §2, table 3] and

$$x_i = \cos\left(\frac{(2i+1)\pi}{2(n+1)}\right)$$

are the zeros of the Chebyshev polynomial T_{n+1} . When expressing the polynomial interpolant $p_n(x)$ in (1) of degree n in the Chebyshev basis,

$$p_n(x) = \sum_{j=0}^n a_j T_j(x),$$

an easy explicit formula for $p_n(x)$ interpolating the values f_i at the points x_i can be given:

$$p_n(x) = \frac{\sum_{i=0}^n f_i}{n+1} + \sum_{j=1}^n \left(\frac{2 \sum_{i=0}^n f_i T_j(x_i)}{n+1} \right) T_j(x).$$

Another elegant explicit formula, based on the continuous orthogonality property of the Chebyshev polynomials, is given in (16).

The practical utility of Chebyshev polynomials is illustrated by the open source Chebfun software system (see www.chebfun.org) for numerical computation with functions, which is built on piecewise-polynomial interpolation at the extrema of Chebyshev polynomials, or what is equivalent (via the FAST FOURIER TRANSFORM [II.10]), expansions in Chebyshev polynomials.

3.4 Chebyshev Series

Let us now choose the basis functions $b_j(x) = T_j(x)$ and look for the coefficients λ_j that make the ℓ_2 -norm of

$$f(x) - \sum_{j=0}^n \lambda_j T_j(x), \quad -1 \leq x \leq 1,$$

minimal for $f(x)$ defined on $[-1, 1]$, for simplicity. We are looking for the polynomial $p_n(x)$ of degree n that is closest to $f(x)$, where we measure the distance between the functions using the inner product

$$\|f - p_n\|_2^2 = \langle f - p_n, f - p_n \rangle \\ = \int_{-1}^1 \frac{(f - p_n)^2(x)}{\sqrt{1-x^2}} dx. \quad (15)$$

This is a continuous least-squares problem because the norm of a function is minimized instead of the norm

of a finite-dimensional vector. Since

$$\begin{aligned} \left\| f - \sum_{j=0}^n \lambda_j T_j \right\|_2^2 &= \left\langle f - \sum_{j=0}^n \lambda_j T_j, f - \sum_{j=0}^n \lambda_j T_j \right\rangle \\ &= \|f\|_2^2 - \sum_{j=0}^n \langle f, T_j \rangle \|T_j\|_2^2 \\ &\quad + \sum_{j=0}^n (\langle f, T_j \rangle \|T_j\|_2 - \lambda_j \|T_j\|_2)^2, \end{aligned}$$

in which only the last sum of squares depends on λ_j , the minimum is attained for the so-called Chebyshev coefficients

$$\lambda_j = \langle f, T_j \rangle / \langle T_j, T_j \rangle. \quad (16)$$

The partial sum of degree n of the Chebyshev series development of a function,

$$f(x) = \sum_{j=0}^{\infty} \frac{\langle f, T_j \rangle}{\langle T_j, T_j \rangle} T_j(x),$$

is therefore the best polynomial approximation of degree n to $f(x)$ in the ℓ_2 sense. Since

$$\left| f(x) - \sum_{j=0}^n \frac{\langle f, T_j \rangle}{\langle T_j, T_j \rangle} T_j(x) \right| \leq \sum_{j=n+1}^{\infty} \left| \frac{\langle f, T_j \rangle}{\langle T_j, T_j \rangle} \right|,$$

this error can be made arbitrarily small when the series of Chebyshev coefficients converges absolutely, a condition that is automatically satisfied for functions that are continuously differentiable in $[-1, 1]$.

The above technique can be generalized to any weight function and its associated family of orthogonal polynomials: when switching the weight function, the norm criterion (15) changes and the orthogonal basis is changed.

The Chebyshev series partial sums are good overall approximations to a function $f(x)$ defined on the interval $[-1, 1]$ (or $[a, b]$ after a suitable change of variable). To illustrate this, in figure 6 we compare, for the function $f(x) = \arctan(x)$, the error plots of the Chebyshev series partial sum of degree 9 with the Taylor series partial sum of the same degree. Its Chebyshev series and Taylor series developments are, respectively, given by

$$\begin{aligned} \arctan(x) &= \sum_{i=0}^{\infty} (-1)^i \frac{2(\sqrt{2}-1)^{2i+1}}{2i+1} T_{2i+1}(x), \\ \arctan(x) &= \sum_{i=0}^{\infty} (-1)^i \frac{1}{2i+1} x^{2i+1}. \end{aligned}$$

Although explicit formulas for the Taylor series expansion of most elementary and special functions are known, the same is not true for Chebyshev series expansions. For most functions, the coefficients (16)

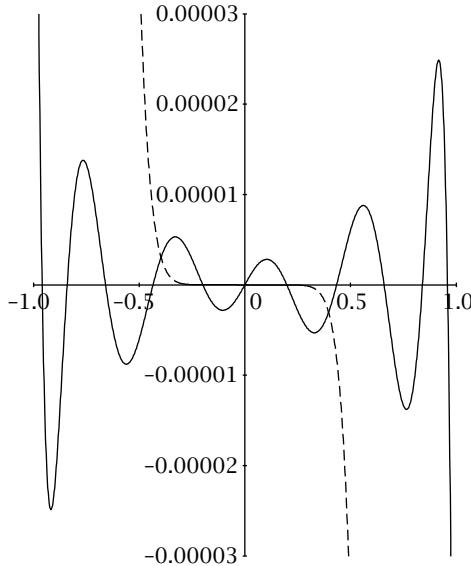

Figure 6 Error plots of Chebyshev (solid line) and Taylor (dashed line) partial sums of degree 9 for $\arctan(x)$.

have to be computed numerically because no analytic expression for (16) can be given.

3.5 The Minimax Approximation

Instead of minimizing the ℓ_2 -distance (15) between a function $f(x) \in C([a, b])$ and a polynomial model for $f(x)$, we can consider the problem of minimizing the ℓ_∞ -distance. Every continuous function $f(x)$ defined on a closed interval $[a, b]$ has a unique so-called *minimax polynomial approximant* of degree n . This means that there exists a unique polynomial $p_n = p_n^*$ of degree $\partial p_n \leq n$ that minimizes

$$\|f - p_n\|_\infty = \max_{x \in [a, b]} \left| f(x) - \sum_{j=0}^n \lambda_j x^j \right|. \quad (17)$$

More generally, if the set of basis functions $\{b_0(x), \dots, b_n(x)\}$ satisfies the Haar condition, then there exists a unique approximant

$$q_n^*(x) = \lambda_0^* b_0(x) + \dots + \lambda_n^* b_n(x)$$

that minimizes

$$\|f - q_n\|_\infty = \max_{x \in [a, b]} \left| f(x) - \sum_{j=0}^n \lambda_j b_j(x) \right|.$$

The minimum is attained and is not an infimum. When $b_j(x) = x^j$, the polynomial $p_n^*(x)$ is computed using the Remez algorithm, which is based on its characterization given by the alternation property of the function

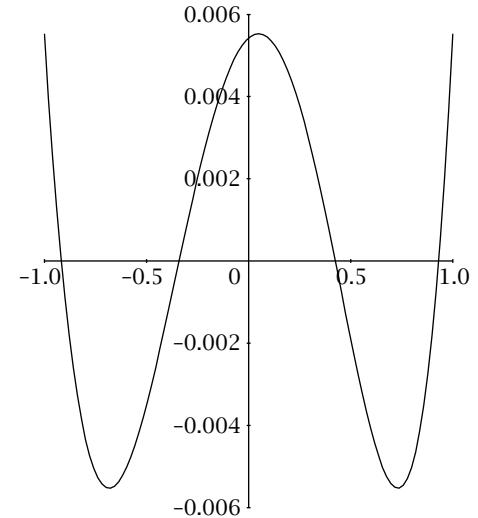

Figure 7 Error plot of $e^x - p_3^*(x)$.

$(f - p_n^*)(x); p_n^*$ is the best polynomial approximant of degree n if the error $\|f - p_n^*\|_\infty$ is attained by the function $f - p_n^*$ in at least $n + 2$ points y_0, \dots, y_{n+1} in the interval $[a, b]$ and this with alternating sign, meaning that

$$\exists y_0 > y_1 > \dots > y_{n+1} \in [a, b]:$$

$$(f - p_n^*)(y_i) = s(-1)^i \|f - p_n^*\|_\infty, \\ s = \pm 1, i = 0, \dots, n + 1.$$

The Remez algorithm is an iterative procedure, and the polynomial $p_n^*(x)$ is obtained as the limit. The above characterization is also called the *equioscillation property*. We illustrate it in figure 7, where we plot the error $e^x - p_3^*(x)$ on $[-1, 1]$. Compare this figure with figures 8 and 9, in which the error oscillates but does not equioscillate.

How much better the (nonlinear) minimax approximation is, compared with a linear approximation procedure of degree n such as polynomial interpolation, Chebyshev approximation, and the like, is expressed by the norm $\|P_n\|_\infty = \sup_{\|f\|_\infty \leq 1} \|P_n(f)\|_\infty$ of the linear operator P_n that associates with a function its particular linear approximant. Since $P_n(p_n^*) = p_n^*$, we have

$$\begin{aligned} \|f - P_n(f)\|_\infty &= \|f - p_n^* + p_n^* - P_n(f)\|_\infty \\ &= \|f - p_n^* + P_n(p_n^* - f)\|_\infty \\ &\leq (1 + \|P_n\|_\infty) \|f - p_n^*\|_\infty. \end{aligned}$$

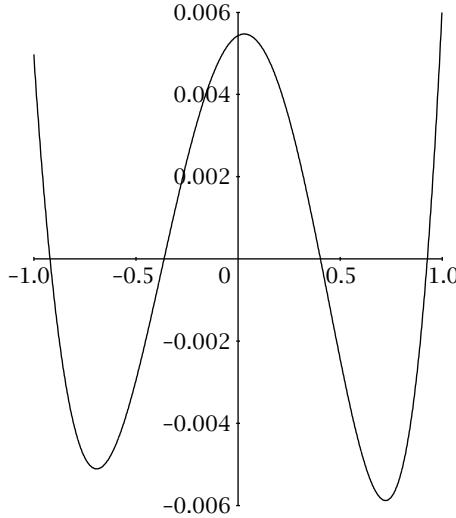

Figure 8 Error plot of the Chebyshev partial sum of degree 3 for e^x .

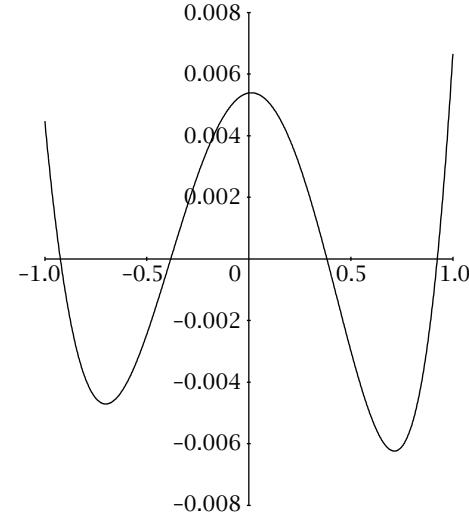

Figure 9 Error plot of the polynomial interpolant of degree 3 in the Chebyshev zeros for e^x .

The value $\|P_n\|_\infty$ is called the *Lebesgue constant*. When dealing with polynomial interpolation, $\|P_n\|_\infty = L_n$, with L_n given by (3).

The quality of the continuous best ℓ_2 approximant (such as that in figure 8) is expressed by

$$\|P_n\|_\infty = \frac{1}{\pi} \int_0^\pi \left| \frac{\sin((n + \frac{1}{2})\theta)}{\sin(\frac{1}{2}\theta)} \right| d\theta,$$

which again grows only logarithmically with n . Continuous ℓ_2 polynomial approximation and Lagrange interpolation in the Chebyshev zeros (such as in figure 9) can therefore be considered near-best polynomial approximants.

3.6 Fourier Series

Let us return to a discrete approximation problem. Our interest is now in data exhibiting some periodic behavior, such as the description of rotation-invariant geometric figures or the sampling of a sound waveform. A suitable set of orthogonal basis functions is the set

$$\left. \begin{aligned} & 1, \cos(x), \cos(2x), \dots, \cos(nx), \\ & \sin(x), \sin(2x), \dots, \sin(nx) \end{aligned} \right\} \quad (18)$$

as long as the distinct data points x_i with $i = 0, \dots, m$ are evenly spaced on an interval of length 2π because then, for any two basis functions $b_j(x)$ and $b_k(x)$ from

(18), we have

$$\begin{aligned} \langle b_j, b_k \rangle &= \sum_{i=0}^m b_j(x_i) b_k(x_i) = \frac{m+1}{2} \delta_{jk}, \quad j \neq 0, \\ \langle b_0, b_k \rangle &= \sum_{i=0}^m b_0(x_i) b_k(x_i) = (m+1) \delta_{0k}, \end{aligned}$$

where δ_{ij} is the Kronecker delta. For simplicity we assume that the real data f_0, \dots, f_m are given on $[0, 2\pi]$ at

$$x_0 = 0, \quad x_1 = \frac{2\pi}{m}, \quad x_2 = \frac{4\pi}{m}, \quad \dots, \quad x_m = \frac{2m\pi}{m+1}.$$

Because of the periodicity, the value at $x_{m+1} = 2\pi$ equals the value at x_0 and therefore it is not repeated. Let $m \geq 2n$ and consider the approximation

$$\frac{\lambda_0}{2} + \sum_{j=1}^n \lambda_{2j} \cos(jx) + \sum_{j=1}^n \lambda_{2j-1} \sin(jx).$$

The values

$$\lambda_{2j} = \frac{2}{m+1} \sum_{i=0}^m f_i \cos(jx_i), \quad j = 0, \dots, n,$$

$$\lambda_{2j-1} = \frac{2}{m+1} \sum_{i=0}^m f_i \sin(jx_i), \quad j = 1, \dots, n,$$

minimize the ℓ_2 -norm

$$\sum_{i=1}^m \left(\frac{\lambda_0}{2} + \sum_{j=1}^n \lambda_{2j} \cos(jx_i) + \sum_{j=1}^n \lambda_{2j-1} \sin(jx_i) - f_i \right)^2.$$

When $m = 2n$, the minimum is zero because the least-squares approximant becomes a trigonometric interpolant. Note that we have replaced λ_0 by $\frac{1}{2}\lambda_0$ because $\langle b_j, b_j \rangle$ is smaller by a factor of 2 when $j = 0$.

If we form a single complex quantity $A_j = \lambda_{2j} - i\lambda_{2j-1}$ for $j = 1, \dots, n$, where $i = \sqrt{-1}$, these summations can be computed using a discrete Fourier transform that maps the data f_i at the points x_i to the A_j :

$$A_j = \frac{1}{m+1} \sum_{i=0}^m f_i e^{-i2\pi ij/(m+1)}, \quad j = 0, \dots, n.$$

The functions in (18) also satisfy a continuous orthogonality property:

$$\begin{aligned} \int_0^{2\pi} \cos(jx) \cos(kx) dx &= \pi \delta_{jk}, \quad j \neq 0, \\ \int_0^{2\pi} \cos(jx) \cos(kx) dx &= \frac{\pi}{2} \delta_{jk}, \quad j = 0, \\ \int_0^{2\pi} \cos(jx) \sin(kx) dx &= 0, \\ \int_0^{2\pi} \sin(jx) \sin(kx) dx &= \pi \delta_{jk}. \end{aligned}$$

They can therefore be used for a Fourier series representation of a function $f(x)$:

$$\begin{aligned} f(x) &= \frac{\lambda_0}{2} + \sum_{j=1}^{\infty} \lambda_{2j} \cos(jx) + \sum_{j=1}^{\infty} \lambda_{2j-1} \sin(jx), \\ \lambda_{2j} &= \frac{\langle f(x), \cos(jx) \rangle}{\pi}, \quad j = 0, 1, \dots, \\ \lambda_{2j-1} &= \frac{\langle f(x), \sin(jx) \rangle}{\pi}, \quad j = 1, 2, \dots. \end{aligned}$$

The partial sum of trigonometric degree n of this series minimizes the ℓ_2 -norm

$$\begin{aligned} \int_0^{2\pi} \left(f(x) - \frac{\lambda_0}{2} - \sum_{j=1}^n \lambda_{2j} \cos(jx) \right. \\ \left. - \sum_{j=1}^n \lambda_{2j-1} \sin(jx) \right)^2 dx. \end{aligned}$$

4 Multivariate Interpolation and Approximation

The approximation of multivariate functions—continuous ones as well as discontinuous ones—is an active field of research due to its large variety of applications in the computational sciences and engineering.

A wide range of multivariate generalizations of the above interpolation and approximation problems to functions of several variables x, y, z, \dots have therefore been developed: polynomial and rational ones, discrete and continuous ones.

A fundamental issue in multivariate interpolation and approximation is the so-called CURSE OF DIMENSIONALITY [I.3 §2], meaning that, when the dimensionality increases, the number of different combinations of variables grows exponentially in the dimensionality. A polynomial of degree 3 in eight variables already has 165 terms! Another problem is that the polynomial basis of the multinomials does not satisfy the Haar condition and there is no easy generalization of this property to the multivariate case.

In order to counter both problems, the theory of radial basis functions has been developed.

Let us consider data f_i given at corresponding multidimensional vectors x_i , $i = 0, \dots, n$. The data vectors x_i do not have to form a grid but can be scattered. A *radial basis function* is a function whose value depends only on the distance from the origin or from another point, so its variable is $r = \|x\|_2$ or $r = \|x - c\|_2$. When centering a radial basis function $B(r)$ at each data point, there is a basis function $B(\|x - x_j\|_2)$ for each $j = 0, \dots, n$. The coefficients a_j in a radial basis function interpolant $\sum_{j=0}^n a_j B(\|x - x_j\|_2)$ are then computed from the linear system

$$\sum_{j=0}^n a_j B(\|x_i - x_j\|_2) = f_i, \quad i = 0, \dots, n.$$

Several commonly used types of radial basis functions $B(r)$ guarantee nonsingular systems of interpolation conditions, in other words, nonsingular matrices

$$\left(B(\|x_i - x_j\|_2) \right)_{i,j=0,\dots,n}.$$

We mention as examples the Gaussian, multiquadric, inverse multiquadric, and a member of the Matern family, respectively, given by

$$B(r) = e^{-(sr)^2},$$

$$B(r) = \sqrt{1 + (sr)^2},$$

$$B(r) = 1/\sqrt{1 + (sr)^2},$$

$$B(r) = (1 + sr)e^{-sr}.$$

The real parameter s is called a shape parameter. As can be seen in figure 10, different choices for s greatly influence the shape of $B(r)$. Smaller shape parameters correspond to a flatter or wider basis function. The choice

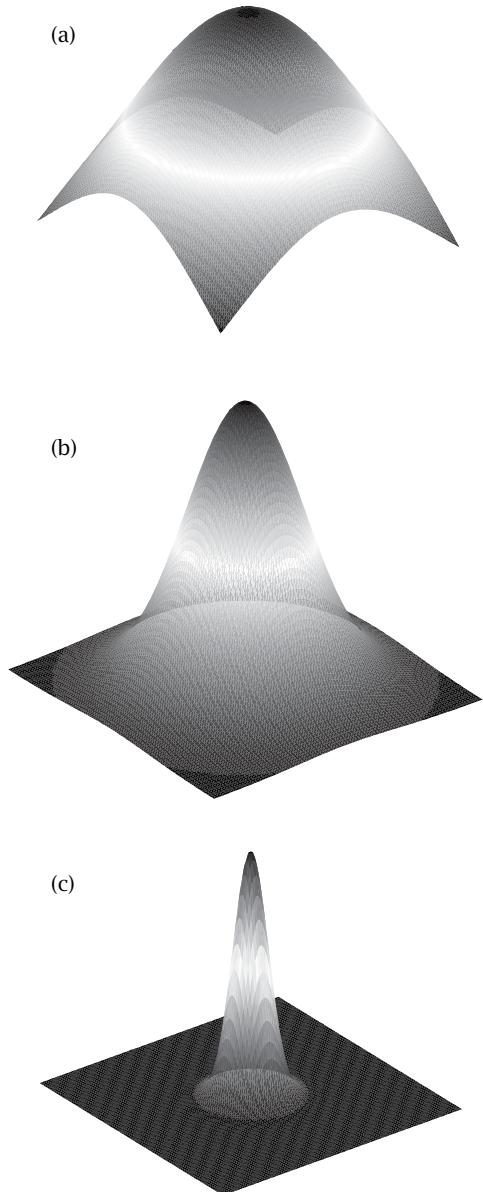

Figure 10 Gaussian basis function with (a) $s = 0.4$, (b) $s = 1$, and (c) $s = 3$.

of s has a significant impact on the accuracy of the approximation, and finding an optimal shape parameter is not an easy problem. Another concern is the numerical conditioning of the radial basis interpolation problem, especially when the shape parameter is small. The user often has to find the right trade-off between accuracy and conditioning.

The concept of radial basis function also allows one to work mesh free. In a mesh or grid of data points each point has a fixed number of neighbors, and this connectivity between neighbors is used to define mathematical operators such as the derivative and the divided difference. Multivariate mesh-free methods allow one to generalize these concepts and are especially useful when the mesh is difficult to maintain (e.g., in high-dimensional problems, when there is nonlinear behavior, discontinuities, singularities, etc.).

5 Future Research

Especially in multivariate approximation theory, many research questions remain unsolved: theory for the multivariate case is not nearly as well developed as it is for the univariate case. But researchers continue to push the boundaries in the one-variable case as well: what is the largest function class or the most general domain for which a result holds, for example? Many papers can be found on Jackson-type inequalities (approximation error bounds in terms of the function's smoothness), Bernstein-type inequalities (bounds on derivatives of polynomials), and convergence properties of particular approximations (polynomial, spline, rational, trigonometric), to name just a few fundamental topics. The development of orthogonal basis functions, on disconnected regions or in more variables, also deserves (and is getting) a lot of attention.

IV.10 Numerical Linear Algebra and Matrix Analysis

Nicholas J. Higham

Matrices are ubiquitous in applied mathematics. Ordinary differential equations (ODEs) and partial differential equations (PDEs) are solved numerically by finite-difference or finite-element methods, which lead to systems of linear equations or matrix eigenvalue problems. Nonlinear equations and optimization problems are typically solved using linear or quadratic models, which again lead to linear systems.

Solving linear systems of equations is an ancient task, undertaken by the Chinese around 1 C.E., but the study of matrices per se is relatively recent, originating with Arthur Cayley's 1858 "A memoir on the theory of matrices." Early research on matrices was largely theoretical, with much attention focused on the development of canonical forms, but in the twentieth century the practical value of matrices started to be appreciated. Heisenberg used matrix theory as a tool in the development of quantum mechanics in the 1920s. Early proponents of the systematic use of matrices in applied mathematics included Frazer, Duncan, and Collar, whose 1938 book *Elementary Matrices and Some Applications to Dynamics and Differential Equations* emphasized the important role of matrices in differential equations and mechanics. The continued growth of matrices in applications, together with the advent of mechanical and then digital computing devices, allowing ever larger problems to be solved, created the need for greater understanding of all aspects of matrices from theory to computation.

This article treats two closely related topics: matrix analysis, which is the theory of matrices with a focus on aspects relevant to other areas of mathematics, and numerical linear algebra (also called matrix computations), which is concerned with the construction and analysis of algorithms for solving matrix problems as well as related topics such as problem sensitivity and rounding error analysis.

Important themes that are discussed in this article include the matrix factorization paradigm, the use of unitary transformations for their numerical stability, exploitation of matrix structure (such as sparsity, symmetry, and definiteness), and the design of algorithms to exploit evolving computer architectures.

Throughout the article, uppercase letters are used for matrices and lowercase letters for vectors and scalars.

Matrices and vectors are assumed to be complex, unless otherwise stated, and $A^* = (\bar{a}_{ji})$ denotes the conjugate transpose of $A = (a_{ij})$. An unsubscripted norm $\|\cdot\|$ denotes a general vector norm and the corresponding subordinate matrix norm. Particular norms used here are the 2-norm $\|\cdot\|_2$ and the Frobenius norm $\|\cdot\|_F$. All of these norms are defined in THE LANGUAGE OF APPLIED MATHEMATICS [I.2 §§19.3, 20]. The notation " $i = 1:n$ " means that the integer variable i takes on the values $1, 2, \dots, n$.

1 Nonsingularity and Conditioning

Nonsingularity of a matrix is a key requirement in many problems, such as in the solution of n linear equations in n unknowns. For some classes of matrices, nonsingularity is guaranteed. A good example is the diagonally dominant matrices. The matrix $A \in \mathbb{C}^{n \times n}$ is *strictly diagonally dominant by rows* if

$$\sum_{j \neq i} |a_{ij}| < |a_{ii}|, \quad i = 1:n,$$

and *strictly diagonally dominant by columns* if A^* is strictly diagonally dominant by rows. Any matrix that is strictly diagonally dominant by rows or columns is nonsingular (a proof can be obtained by applying Gershgorin's theorem in section 5.1).

Since data is often subject to uncertainty, we wish to gauge the sensitivity of problems to perturbations, which is done using CONDITION NUMBERS [I.2 §22]. An appropriate condition number for the matrix inverse is

$$\lim_{\varepsilon \rightarrow 0} \sup_{\|\Delta A\| \leq \varepsilon \|A\|} \frac{\|(A + \Delta A)^{-1} - A^{-1}\|}{\varepsilon \|A^{-1}\|}.$$

This expression turns out to equal $\kappa(A) = \|A\| \|A^{-1}\|$, which is called the *condition number of A with respect to inversion*. This condition number occurs in many contexts. For example, suppose A is contaminated by errors and we perform a similarity transformation $X^{-1}(A + E)X = X^{-1}AX + F$. Then $\|F\| = \|X^{-1}EX\| \leq \kappa(X)\|E\|$ and this bound is attainable for some E . Hence the errors can be multiplied by a factor as large as $\kappa(X)$. We therefore prefer to carry out similarity and other transformations with matrices that are *well-conditioned*, that is, ones for which $\kappa(X)$ is close to its lower bound of 1. By contrast, a matrix for which κ is large is called *ill-conditioned*. For any unitary matrix X , $\kappa_2(X) = 1$, so in numerical linear algebra transformations by unitary or orthogonal matrices are preferred and usually lead to numerically stable algorithms.

In practice we often need an estimate of the matrix condition number $\kappa(A)$ but do not wish to go to the

expense of computing A^{-1} in order to obtain it. Fortunately, there are algorithms that can cheaply produce a reliable estimate of $\kappa(A)$ once a factorization of A has been computed.

Note that the determinant, $\det(A)$, is rarely computed in numerical linear algebra. Its magnitude gives no useful information about the conditioning of A , not least because of its extreme behavior under scaling: $\det(\alpha A) = \alpha^n \det(A)$.

2 Matrix Factorizations

The method of *Gaussian elimination* (GE) for solving a nonsingular linear system $Ax = b$ of n equations in n unknowns reduces the matrix A to upper triangular form and then solves for x by SUBSTITUTION [I.3 §7.1].

GE is typically described by writing down the equations $a_{ij}^{(k+1)} = a_{ij}^{(k)} - a_{ik}^{(k)} a_{kj}^{(k)} / a_{kk}^{(k)}$ (and similarly for b) that describe how the starting matrix $A = A^{(1)} = (a_{ij}^{(1)})$ changes on each of the $n - 1$ steps of the elimination in its progress toward upper triangular form U . Working at the element level in this way leads to a profusion of symbols, superscripts, and subscripts that tend to obscure the mathematical structure and hinder insights being drawn into the underlying process. One of the key developments in the last century was the recognition that it is much more profitable to work at the matrix level. Thus the basic equation above is written as $A^{(k+1)} = M_k A^{(k)}$, where M_k agrees with the identity matrix except below the diagonal in the k th column, where its (i, k) element is $m_{ik} = -a_{ik}^{(k)} / a_{kk}^{(k)}$, $i = k + 1 : n$. Recurring the matrix equation gives $U := A^{(n)} = M_{n-1} \cdots M_1 A$. Taking the M_k matrices over to the left-hand side leads, after some calculations, to the equation $A = LU$, where L is unit lower triangular, with (i, k) element m_{ik} . The prefix “unit” means that L has ones on the diagonal.

GE is therefore equivalent to factorizing the matrix A as the product of a lower triangular matrix and an upper triangular matrix—something that is not at all obvious from the element-level equations. Solving the linear system $Ax = b$ now reduces to the task of solving the two triangular systems $Ly = b$ and $Ux = y$.

Interpreting GE as LU factorization separates the computation of the factors from the solution of the triangular systems. It is then clear how to solve efficiently several systems $Ax_i = b_i$, $i = 1 : r$, with different right-hand sides but the same coefficient matrix A : compute the LU factors once and then reuse them to solve for each x_i in turn.

This matrix factorization¹ viewpoint dates from around the 1940s and has been extremely successful in matrix computations. In general, a factorization is a representation of a matrix as a product of “simpler” matrices. Factorization is a tool that can be used to solve a variety of problems, as we will see below.

Two particular benefits of factorizations are unity and modularity. GE, for example, can be organized in several different ways, corresponding to different orderings of the three nested loops that it comprises, as well as the use of different blockings of the matrix elements. Yet all of them compute the same LU factorization, carrying out the same mathematical operations in a different order. Without the unifying concept of a factorization, reasoning about these GE variants would be difficult.

Modularity refers to the way that a factorization breaks a problem down into separate tasks that can be analyzed or programmed independently. To carry out a rounding error analysis of GE, we can analyze the LU factorization and the solution of the triangular systems by substitution separately and then put the analyses together. The rounding error analysis of substitution can be reused in the many other contexts in which triangular systems arise.

An important example of the use of LU factorization is in *iterative refinement*. Suppose we have used GE to obtain a computed solution \hat{x} to $Ax = b$ in floating-point arithmetic. If we form $r = b - A\hat{x}$ and solve $Ae = r$, then in exact arithmetic $y = \hat{x} + e$ is the true solution. In computing e we can reuse the LU factors of A , so obtaining y from \hat{x} is inexpensive. In practice, the computation of r , e , and y is subject to rounding errors so the computed \hat{y} is not equal to x . But under suitable assumptions \hat{y} will be an improved approximation and we can iterate this refinement process. Iterative refinement is particularly effective if r can be computed using extra precision.

Two other key factorizations are the following.

- *Cholesky factorization*: for Hermitian positive-definite $A \in \mathbb{C}^{n \times n}$, $A = R^*R$, where R is upper triangular with positive diagonal elements, and this factorization is unique.
- *QR factorization*: for $A \in \mathbb{C}^{m \times n}$ with $m \geq n$, $A = QR$, where $Q \in \mathbb{C}^{m \times m}$ is unitary ($Q^*Q = I_m$) and $R \in \mathbb{C}^{m \times n}$ is upper trapezoidal, that is, $R = \begin{bmatrix} R_1 \\ 0 \end{bmatrix}$ with $R_1 \in \mathbb{C}^{n \times n}$ upper triangular.

1. Or decomposition—the two terms are essentially synonymous.

These two factorizations are related: if $A \in \mathbb{C}^{m \times n}$ with $m \geq n$ has full rank and $A = QR$ is a QR factorization, in which without loss of generality we can assume that R has positive diagonal, then $A^*A = R^*R$, so R is the Cholesky factor of A^*A .

The Cholesky factorization can be computed by what is essentially a symmetric and scaled version of GE. The QR factorization can be computed in three main ways, one of which is the classical Gram-Schmidt orthogonalization. The most widely used method constructs Q as a product of *Householder reflectors*, which are unitary matrices of the form $H = I - 2v v^*/(v^*v)$, where v is a nonzero vector. Note that H is a rank-1 perturbation of the identity, and since it is Hermitian and unitary, it is its own inverse; that is, it is *involutory*. The third approach builds Q as a product of *Givens rotations*, each of which is a 2×2 matrix $\begin{bmatrix} c & s \\ -s & c \end{bmatrix}$ embedded into two rows and columns of an $m \times m$ identity matrix, where (in the real case) $c^2 + s^2 = 1$.

The Cholesky factorization helps us to make the most of the very desirable property of positive-definiteness. For example, suppose A is Hermitian positive-definite and we wish to evaluate the scalar $\alpha = x^* A^{-1} x$. We can rewrite it as $x^*(R^*R)^{-1}x = (x^*R^{-1})(R^{-*}x) = z^*z$, where $z = R^{-*}x$. So once the Cholesky factorization has been computed we need just one triangular solve to compute α , and of course there is no need to explicitly invert the matrix A .

A matrix factorization might involve a larger number of factors: $A = N_1 N_2 \cdots N_k$, say. It is immediate that $A^T = N_k^T N_{k-1}^T \cdots N_1^T$. This factorization of the transpose may have deep consequences in a particular application. For example, the discrete Fourier transform is the matrix-vector product $y = F_n x$, where the $n \times n$ matrix F_n has (p, q) element $\exp(-2\pi i(p-1)(q-1)/n)$; F_n is a complex, symmetric matrix. The FAST FOURIER TRANSFORM [II.10] (FFT) is a way of evaluating y in $O(n \log_2 n)$ operations, as opposed to the $O(n^2)$ operations that are required by a standard matrix-vector multiplication. Many variants of the FFT have been proposed since the original 1965 paper by Cooley and Tukey. It turns out that different FFT variants correspond to different factorizations of F_n with $k = \log_2 n$ sparse factors. Some of these methods correspond simply to transposing the factorization in another method (recall that $F_n^T = F_n$), though this was not realized when the methods were developed. Transposition also plays an important role in AUTOMATIC DIFFERENTIATION [VI.7]; the so-called reverse or

adjoint mode can be obtained by transposing a matrix factorization representation of the forward mode.

The factorizations described in this section are in “plain vanilla” form, but all have variants that incorporate pivoting. Pivoting refers to row or column interchanges carried out at each step of the factorization as it is computed, introduced either to ensure that the factorization succeeds and is numerically stable or to produce a factorization with certain desirable properties usually associated with rank deficiency. For GE, *partial pivoting* is normally used: at the start of the k th stage of the elimination, an element $a_{rk}^{(k)}$ of largest modulus in the k th column below the diagonal is brought into the (k, k) (pivot) position by interchanging rows k and r . Partial pivoting avoids dividing by zero (if $a_{kk}^{(k)} = 0$ after the interchange then the pivot column is zero below the diagonal and the elimination step can be skipped). More importantly, partial pivoting ensures numerical stability (see section 8). The overall effect of GE with partial pivoting is to produce an LU factorization $PA = LU$, where P is a permutation matrix.

Pivoted variants of Cholesky factorization and QR factorization take the form $P^T AP = R^*R$ and $AP = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$, where P is a permutation matrix and R satisfies the inequalities

$$|r_{kk}|^2 \geq \sum_{i=k}^j |r_{ij}|^2, \quad j = k+1:n, \quad k = 1:n.$$

If A is rank deficient then R has the form $R = \begin{bmatrix} R_{11} & R_{12} \\ 0 & 0 \end{bmatrix}$ with R_{11} nonsingular, and the rank of A is the dimension of R_{11} . Equally importantly, when A is nearly rank deficient this tends to be revealed by a small trailing diagonal block of R .

A factorization of great importance in a wide variety of applications is the SINGULAR VALUE DECOMPOSITION [II.32] (SVD) of $A \in \mathbb{C}^{m \times n}$:

$$A = U\Sigma V^*, \quad \Sigma = \text{diag}(\sigma_1, \sigma_2, \dots, \sigma_p) \in \mathbb{R}^{m \times n}, \quad (1)$$

where $p = \min(m, n)$, $U \in \mathbb{C}^{m \times m}$ and $V \in \mathbb{C}^{n \times n}$ are unitary, and the *singular values* σ_i satisfy $\sigma_1 \geq \sigma_2 \geq \dots \geq \sigma_p \geq 0$. For a square A ($m = n$), the 2-norm condition number is given by $\kappa_2(A) = \sigma_1/\sigma_n$.

The *polar decomposition* of $A \in \mathbb{C}^{m \times n}$ with $m \geq n$ is a factorization $A = UH$ in which $U \in \mathbb{C}^{m \times n}$ has orthonormal columns and $H \in \mathbb{C}^{n \times n}$ is Hermitian positive-semidefinite. The matrix H is unique and is given by $(A^*A)^{1/2}$, where the exponent $1/2$ denotes the PRINCIPAL SQUARE ROOT [II.14], while U is unique if A has full rank. The polar decomposition generalizes to matrices the polar representation $z = r e^{i\theta}$ of a complex

number. The Hermitian polar factor H is also known as the *matrix absolute value*, $|A|$, and is much studied in matrix analysis and functional analysis.

One reason for the importance of the polar decomposition is that it provides an optimal way to orthogonalize a matrix; a result of Fan and Hoffman (1955) says that U is the nearest matrix with orthonormal columns to A in any unitarily invariant norm (a unitarily invariant norm is one with the property that $\|UAV\| = \|A\|$ for any unitary U and V ; the 2-norm and the Frobenius norm are particular examples). In various applications a matrix $A \in \mathbb{R}^{n \times n}$ that should be orthogonal drifts from orthogonality because of rounding or other errors; replacing it by the orthogonal polar factor U is then a good strategy.

The polar decomposition also solves the *orthogonal Procrustes problem*, for $A, B \in \mathbb{C}^{m \times n}$,

$$\min \{ \|A - BQ\|_F : Q \in \mathbb{C}^{n \times n}, Q^*Q = I \},$$

for which any solution Q is a unitary polar factor of B^*A . This problem comes from factor analysis and multidimensional scaling in statistics, where the aim is to see whether two data sets A and B are the same up to an orthogonal transformation.

Either of the SVD and the polar decomposition can be derived, or computed, from the other. Historically, the SVD came first (Beltrami, in 1873), with the polar decomposition three decades behind (Autonne, in 1902).

3 Distance to Singularity and Low-Rank Perturbations

The question commonly arises of whether a given perturbation of a nonsingular matrix A preserves nonsingularity. In a sense, this question is trivial. Recalling that a square matrix is nonsingular when all its eigenvalues are nonzero, and that the product of two matrices is nonsingular unless one of them is singular, from $A + \Delta A = A(I + A^{-1}\Delta A)$ we see that $A + \Delta A$ is nonsingular as long as $A^{-1}\Delta A$ has no eigenvalue equal to -1 . However, this is not an easy condition to check, and in practice we may not know ΔA but only a bound for its norm. Since any norm of a matrix exceeds the modulus of every eigenvalue, a sufficient condition for $A + \Delta A$ to be nonsingular is that $\|A^{-1}\Delta A\| < 1$, which is certainly true if $\|A^{-1}\| \|\Delta A\| < 1$. This condition can be rewritten as the inequality $\|\Delta A\|/\|A\| < \kappa(A)^{-1}$, where $\kappa(A) = \|A\| \|A^{-1}\| \geq 1$ is the condition number introduced in section 1. It turns out that we can always find a perturbation ΔA such that $A + \Delta A$ is singular

and $\|\Delta A\|/\|A\| = \kappa(A)^{-1}$. It follows that the *relative distance to singularity*

$$d(A) = \min \{ \|\Delta A\|/\|A\| : A + \Delta A \text{ is singular} \} \quad (2)$$

is given by $d(A) = \kappa(A)^{-1}$. This reciprocal relation between problem conditioning and the distance to a singular problem (one with an infinite condition number) is common to a variety of problems in linear algebra and control theory, as shown by James Demmel in the 1980s.

We may want a more refined test for whether $A + \Delta A$ is nonsingular. To obtain one we will need to make some assumptions about the perturbation. Suppose that ΔA has rank 1: $\Delta A = xy^*$ for some vectors x and y . From the analysis above we know that $A + \Delta A$ will be nonsingular if $A^{-1}\Delta A = A^{-1}xy^*$ has no eigenvalue equal to -1 . Using the fact that the nonzero eigenvalues of AB are the same as those of BA for any conformable matrices A and B , we see that the nonzero eigenvalues of $(A^{-1}x)y^*$ are the same as those of $y^*A^{-1}x$. Hence $A + xy^*$ is nonsingular as long as $y^*A^{-1}x \neq -1$.

Now that we know when $A + xy^*$ is nonsingular, we might ask if there is an explicit formula for the inverse. Since $A + xy^* = A(I + A^{-1}xy^*)$, we can take $A = I$ without loss of generality. So we are looking for the inverse of $B = I + xy^*$. One way to find it is to guess that $B^{-1} = I + \theta xy^*$ for some scalar θ and equate the product with B to I , to obtain $\theta(1 + y^*x) + 1 = 0$. Thus $(I + xy^*)^{-1} = I - xy^*/(1 + y^*x)$. The corresponding formula for $(A + xy^*)^{-1}$ is

$$(A + xy^*)^{-1} = A^{-1} - A^{-1}xy^*A^{-1}/(1 + y^*A^{-1}x),$$

which is known as the *Sherman-Morrison formula*. This formula and its generalizations originated in the 1940s and have been rediscovered many times. The corresponding formula for a rank- p perturbation is the *Sherman-Morrison-Woodbury formula*: for $U, V \in \mathbb{C}^{n \times p}$,

$$(A + UV^*)^{-1} = A^{-1} - A^{-1}U(I + V^*A^{-1}U)^{-1}V^*A^{-1}.$$

Important applications of these formulas are in optimization, where rank-1 or rank-2 updates are made to Hessian approximations in QUASI-NEWTON METHODS [IV.11 §4.2] and to basis matrices in the SIMPLEX METHOD [IV.11 §3.1]. More generally, the task of updating the solution to a problem after a coefficient matrix has undergone a low-rank change, or has had a row or column added or removed, arises in many applications, including SIGNAL PROCESSING [IV.35], where new data is continually being received and old data is discarded.

The minimal distance in the definition (2) of the distance to singularity $d(A)$ can be shown to be attained for a rank-1 matrix ΔA . Rank-1 matrices often feature in the solutions of matrix optimization problems.

4 Computational Cost

In order to compare competing methods and predict their practical efficiency, we need to know their computational cost. Traditionally, computational cost has been measured by counting the number of scalar arithmetic operations and retaining only the highest-order terms in the total. For example, using GE we can solve a system of n linear equations in n unknowns with $n^3/3 + O(n^2)$ additions, $n^3/3 + O(n^2)$ multiplications, and $O(n)$ divisions. This is typically summarized as $2n^3/3$ flops, where a *flop* denotes any of the scalar operations $+, -, *, /$. Most standard problems involving $n \times n$ matrices can be solved with a cost of order n^3 flops or less, so the interest is in the exponent (1, 2, or 3) and the constant of the dominant term. However, the costs of moving data around a computer's hierarchical memory and the costs of communicating between different processors on a multiprocessor system can be equally important. Simply counting flops does not therefore necessarily give a good guide to performance in practice.

Seemingly trivial problems can offer interesting challenges as regards minimizing arithmetic costs. For matrices A , B , and C of any dimensions such that the product ABC is defined, how should we compute the product? The associative law for matrix multiplication tells us that $(AB)C = A(BC)$, but this mathematical equivalence is not a computational one. To see why, note that for three vectors $a, b, c \in \mathbb{R}^n$ we can write

$$\underbrace{(ab^*)}_{n \times n} c = a \underbrace{(b^*c)}_{1 \times 1}.$$

Evaluation of the left-hand side requires $O(n^2)$ flops, as there is an outer product ab^* and then a matrix-vector product to evaluate, while evaluation of the right-hand side requires just $O(n)$ flops, as it involves only vector operations: an inner product and a vector scaling. One should always be alert for opportunities to use the associative law to save computational effort.

5 Eigenvalue Problems

The eigenvalue problem $Ax = \lambda x$ for a square matrix $A \in \mathbb{C}^{n \times n}$, which seeks an eigenvalue $\lambda \in \mathbb{C}$ and an eigenvector $x \neq 0$, arises in many forms. Depending on

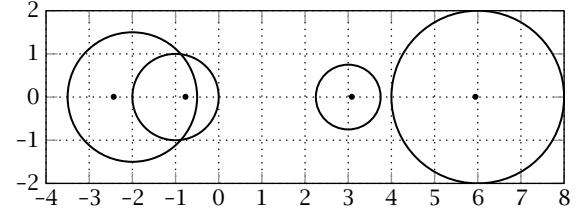

Figure 1 Gershgorin disks for the matrix in (3); the eigenvalues are marked as solid dots.

the application we may want all the eigenvalues or just a subset, such as the ten that have the largest real part, and eigenvectors may or may not be required as well. Whether the problem is Hermitian or non-Hermitian changes its character greatly. In particular, while a Hermitian matrix has real eigenvalues and a linearly independent set of n eigenvectors that can be taken to be orthonormal, the eigenvalues of a non-Hermitian matrix can be anywhere in the complex plane and there may not be a set of eigenvectors that spans \mathbb{C}^n .

5.1 Bounds and Localization

One of the first questions to ask is whether we can find a finite region containing the eigenvalues. The answer is yes because $Ax = \lambda x$ implies $|\lambda| \|x\| = \|Ax\| \leq \|A\| \|x\|$, and hence $|\lambda| \leq \|A\|$. So all the eigenvalues lie in a disk of radius $\|A\|$ about the origin. More refined bounds are provided by Gershgorin's theorem.

Theorem 1 (Gershgorin's theorem, 1931). *The eigenvalues of $A \in \mathbb{C}^{n \times n}$ lie in the union of the n disks in the complex plane*

$$D_i = \left\{ z \in \mathbb{C}: |z - a_{ii}| \leq \sum_{j \neq i} |a_{ij}| \right\}, \quad i = 1:n.$$

An extension of the theorem says that if k disks form a connected region that is isolated from the other disks then there are precisely k eigenvalues in this region. The Gershgorin disks for the matrix

$$\begin{bmatrix} -1 & 1/3 & 1/3 & 1/3 \\ 3/2 & -2 & 0 & 0 \\ 1/2 & 0 & 3 & 1/4 \\ 1 & 0 & -1 & 6 \end{bmatrix} \tag{3}$$

are shown in figure 1. We can conclude that there is one eigenvalue in the disk centered at 3, one in the disk centered at 6, and two in the union of the other two disks.

Gershgorin's theorem is most useful for matrices that are close to diagonal, such as those eventually produced by the Jacobi iterative method for eigenvalues of Hermitian matrices. Improved estimates can be sought by applying Gershgorin's theorem to a matrix $D^{-1}AD$ similar to A , with the diagonal matrix D chosen in an attempt to isolate and shrink the disks. Many variants of Gershgorin's theorem exist with disks replaced by other shapes.

The spectral radius $\rho(A)$ (the largest absolute value of any eigenvalue of A) satisfies $\rho(A) \leq \|A\|$, as shown above, but this inequality can be arbitrarily weak, as the matrix $\begin{bmatrix} 1 & \theta \\ 0 & 1 \end{bmatrix}$ shows for $|\theta| \gg 1$. It is natural to ask whether there are any sharper relations between the spectral radius and norms. One answer is the equality

$$\rho(A) = \lim_{k \rightarrow \infty} \|A^k\|^{1/k}. \quad (4)$$

Another is the result that given any $\varepsilon > 0$ there is a norm such that $\|A\| \leq \rho(A) + \varepsilon$; however, the norm depends on A . This result can be used to give a proof of the fact, discussed in the article on the JORDAN CANONICAL FORM [II.22], that the powers of A converge to zero if $\rho(A) < 1$.

The *field of values*, also known as the *numerical range*, is a tool that can be used for localization and many other purposes. It is defined for $A \in \mathbb{C}^{n \times n}$ by

$$F(A) = \left\{ \frac{z^* A z}{z^* z} : 0 \neq z \in \mathbb{C}^n \right\}.$$

The set $F(A)$ is compact and convex (a nontrivial property proved by Toeplitz and Hausdorff), and it contains all the eigenvalues of A . For normal matrices it is the CONVEX HULL [II.8] of the eigenvalues. The *normal matrices* A are those for which $AA^* = A^*A$, and they include the Hermitian, the skew-Hermitian, and the unitary matrices. For a Hermitian matrix, $F(A)$ is a segment of the real axis, while for a skew-Hermitian matrix it is a segment of the imaginary axis. Figure 2 illustrates two fields of values, the second of which is the convex hull of the eigenvalues because a CIRCULANT MATRIX [I.2 §18] is normal.

5.2 Eigenvalue Sensitivity

If A is perturbed, how much do its eigenvalues change? This question is easy to answer for a simple eigenvalue λ —one that has ALGEBRAIC MULTIPLICITY [II.22] 1. We need the notion of a *left eigenvector* of A corresponding to λ , which is a nonzero vector y such that $y^* A = \lambda y^*$. If λ is simple with right and left eigenvectors x and y , respectively, then there is an eigenvalue $\lambda + \Delta\lambda$ of

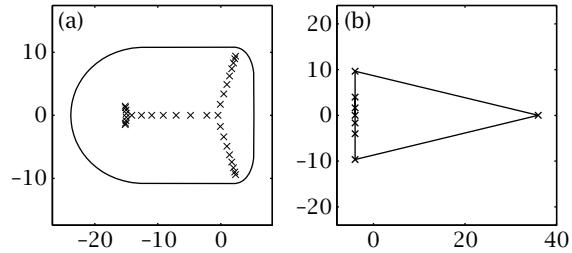

Figure 2 Fields of values for (a) a pentadiagonal Toeplitz matrix and (b) a circulant matrix, both of dimension 32. The eigenvalues are denoted by crosses.

$A + \Delta A$ such that $\Delta\lambda = y^* \Delta A x / (y^* x) + O(\|\Delta A\|^2)$ and so

$$|\Delta\lambda| \leq \frac{\|y\|_2 \|x\|_2}{|y^* x|} \|\Delta A\| + O(\|\Delta A\|^2).$$

The term $\|y\|_2 \|x\|_2 / |y^* x|$ can be shown to be an (absolute) condition number for λ . It is at least 1 and tends to infinity as y and x approach orthogonality (which can never exactly be achieved for simple λ), so λ can be very ill-conditioned. However, if A is Hermitian then we can take $y = x$ and the bound simplifies to $|\Delta\lambda| \leq \|\Delta A\| + O(\|\Delta A\|^2)$, so all the eigenvalues of a Hermitian matrix are perfectly conditioned.

Much research has been done to obtain eigenvalue perturbation bounds under both weaker and stronger assumptions about the problem. Suppose we drop the requirement that λ is simple. Consider the matrix and perturbation

$$A = \begin{bmatrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 0 & 0 & 0 \end{bmatrix}, \quad \Delta A = \begin{bmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ \varepsilon & 0 & 0 \end{bmatrix}.$$

The eigenvalues of A are all zero, and those of $A + \Delta A$ are the third roots of ε . The change in the eigenvalue is proportional not to ε but to a fractional power of ε . In general, the sensitivity of an eigenvalue depends on the JORDAN STRUCTURE [II.22] for that eigenvalue.

5.3 Companion Matrices and the Characteristic Polynomial

The eigenvalues of a matrix A are the roots of its CHARACTERISTIC POLYNOMIAL [I.2 §20], $\det(\lambda I - A)$. Conversely, associated with the polynomial

$$p(\lambda) = \lambda^n - a_{n-1}\lambda^{n-1} - \cdots - a_0$$

is the companion matrix

$$C = \begin{bmatrix} a_{n-1} & a_{n-2} & \cdots & \cdots & a_0 \\ 1 & 0 & \cdots & \cdots & 0 \\ 0 & 1 & \ddots & & 0 \\ \vdots & & \ddots & 0 & \vdots \\ 0 & \cdots & \cdots & 1 & 0 \end{bmatrix},$$

and the eigenvalues of C are the roots of p , as noted in METHODS OF SOLUTION [I.3 §7.2].

This relation means that the roots of a polynomial can be found by computing the eigenvalues of an $n \times n$ matrix, and this approach is used by some computer codes, for example the `roots` function of MATLAB. While standard eigenvalue algorithms do not exploit the structure of C , this approach has proved competitive with specialist polynomial root-finding algorithms. Another use for the relation is to obtain bounds for roots of polynomials from bounds for matrix eigenvalues, and vice versa.

Companion matrices have many interesting properties. For example, any NONDEROGATORY [II.22] $n \times n$ matrix is similar to a companion matrix. Companion matrices have therefore featured strongly in matrix analysis and also in control theory. However, similarity transformations to companion form are little used in practice because of problems with ill-conditioning and numerical instability.

Returning to the characteristic polynomial, $p(\lambda) = \det(\lambda I - A) = \lambda^n - a_{n-1}\lambda^{n-1} - \cdots - a_0$, we know that $p(\lambda_i) = 0$ for every eigenvalue λ_i of A . The *Cayley-Hamilton theorem* says that $p(A) = A^n - a_{n-1}A^{n-1} - \cdots - a_0I = 0$ (which cannot be obtained simply by putting “ $\lambda = A$ ” in the previous expression!). Hence the n th power of A and inductively all higher powers are expressible as a linear combination of I, A, \dots, A^{n-1} . Moreover, if A is nonsingular then from $A^{-1}p(A) = 0$ it follows that A^{-1} can also be written as a polynomial in A of degree at most $n - 1$. These relations are not useful for practical computation because the coefficients a_i can vary tremendously in magnitude, and it is not possible to compute them to high relative accuracy.

5.4 Eigenvalue Inequalities for Hermitian Matrices

The eigenvalues of Hermitian matrices $A \in \mathbb{C}^{n \times n}$, which in this section we order $\lambda_n \leq \cdots \leq \lambda_1$, satisfy many beautiful inequalities. Among the most important are those in the *Courant-Fischer theorem* (1905), which states that every eigenvalue is the solution of a

min-max problem over a suitable subspace S of \mathbb{C}^n :

$$\lambda_i = \min_{\dim(S)=n-i+1} \max_{0 \neq x \in S} \frac{x^* Ax}{x^* x}.$$

Special cases are $\lambda_n = \min_{x \neq 0} x^* Ax / (x^* x)$ and $\lambda_1 = \max_{x \neq 0} x^* Ax / (x^* x)$.

Taking x to be a unit vector e_i in the previous formula for λ_1 gives $\lambda_1 \geq a_{ii}$ for all i . This inequality is just the first in a sequence of inequalities relating sums of eigenvalues to sums of diagonal elements, obtained by Schur in 1923:

$$\sum_{i=1}^k \lambda_i \geq \sum_{i=1}^k \tilde{a}_{ii}, \quad k = 1:n, \quad (5)$$

where $\{\tilde{a}_{ii}\}$ is the set of diagonal elements of A arranged in decreasing order: $\tilde{a}_{11} \geq \cdots \geq \tilde{a}_{nn}$. There is equality for $k = n$, since both sides equal $\text{trace}(A)$. These inequalities say that the vector $[\lambda_1, \dots, \lambda_n]$ of eigenvalues *majorizes* the vector $[\tilde{a}_{11}, \dots, \tilde{a}_{nn}]$ of diagonal elements.

In general there is no useful formula for the eigenvalues of a sum $A + B$ of Hermitian matrices. However, the Courant-Fischer theorem yields the upper and lower bounds

$$\lambda_k(A) + \lambda_n(B) \leq \lambda_k(A + B) \leq \lambda_k(A) + \lambda_1(B),$$

from which it follows that $|\lambda_k(A + B) - \lambda_k(A)| \leq \max(|\lambda_n(B)|, |\lambda_1(B)|) = \|B\|_2$. The latter inequality again shows that the eigenvalues of a Hermitian matrix are well-conditioned under perturbation.

The *Cauchy interlace theorem* has a different flavor. It relates the eigenvalues of successive leading principal submatrices $A_k = A(1:k, 1:k)$ by

$$\begin{aligned} \lambda_{k+1}(A_{k+1}) &\leq \lambda_k(A_k) \leq \lambda_k(A_{k+1}) \\ &\leq \cdots \leq \lambda_2(A_{k+1}) \leq \lambda_1(A_k) \leq \lambda_1(A_{k+1}) \end{aligned}$$

for $k = 1:n - 1$, showing that the eigenvalues of A_k interlace those of A_{k+1} .

In 1962 Alfred Horn made a conjecture that a certain set of linear inequalities involving real numbers α_i, β_i , and γ_i , $i = 1:n$, is necessary and sufficient for the existence of $n \times n$ Hermitian matrices A, B , and C with eigenvalues the α_i, β_i , and γ_i , respectively, such that $C = A + B$. The conjecture was open for many years but was finally proved to be true in papers published by Klyachko in 1998 and by Knutson and Tao in 1999, which exploited deep connections with algebraic geometry, representations of Lie groups, and quantum cohomology.

5.5 Solving the Non-Hermitian Eigenproblem

The simplest method for computing eigenvalues, the *power method*, computes just one: the largest in modulus. It comprises repeated multiplication of a starting vector x by A . Since the resulting sequence is liable to overflow or underflow in floating-point arithmetic, one normalizes the vector after each iteration. Therefore one step of the power method has the form $x \leftarrow Ax$, $x \leftarrow v^{-1}x$, where $v = x_j$ with $|x_j| = \max_i |x_i|$. If A has a unique eigenvalue λ of largest modulus and the starting vector has a component in the direction of the corresponding eigenvector, then v converges to λ and x converges to the corresponding eigenvector. The power method is most often applied to $(A - \mu I)^{-1}$, where μ is an approximation to an eigenvalue of interest. In this form it is known as *inverse iteration* and convergence is to the eigenvalue closest to μ . We now turn to methods that compute all the eigenvalues.

Since similarities $X^{-1}AX$ preserve the eigenvalues and change the eigenvectors in a controlled way, carrying out a sequence of similarity transformations to reduce A to a simpler form is a natural way to tackle the eigenproblem. Some early methods used nonunitary X , but such transformations are now avoided because of numerical instability when X is ill-conditioned. Since the 1960s the focus has been on using unitary similarities to compute the *Schur decomposition* $A = QTQ^*$, where Q is unitary and T is upper triangular. The diagonal entries of T are the eigenvalues of A , and they can be made to appear in any order by appropriate choice of Q . The first k columns of Q span an INARIANT SUBSPACE [I.2 §20] corresponding to the eigenvalues t_{11}, \dots, t_{kk} . Eigenvectors can be obtained by solving triangular systems involving T .

For some matrices the Schur factor T is diagonal; these are precisely the normal matrices defined in section 5.1. The *real Schur decomposition* contains only real matrices when A is real: $A = QRQ^T$, where Q is orthogonal and R is real upper quasitriangular, which means that R is upper triangular except for 2×2 blocks on the diagonal corresponding to complex conjugate eigenvalues.

The standard algorithm for solving the non-Hermitian eigenproblem is the *QR algorithm*, which was proposed independently by John Francis and Vera Kublanovskaya in 1961. The matrix $A \in \mathbb{C}^{n \times n}$ is first unitarily reduced to upper Hessenberg form $H = U^*AU$ ($h_{ij} = 0$ for $i > j + 1$), with U a product of Householder matrices. The QR iteration constructs a

sequence of upper Hessenberg matrices beginning with $H_1 = H$ defined by $H_k - \mu_k I =: Q_k R_k$ (QR factorization, computed using Givens rotations), $H_{k+1} := R_k Q_k + \mu_k I$, where the μ_k are shifts chosen to accelerate the convergence of H_k to upper triangular form. It is easy to check that $H_{k+1} = Q_k^* H_k Q_k$, so the QR iteration carries out a sequence of unitary similarity transformations.

Why the QR iteration works is not obvious but can be elegantly explained by analyzing the subspaces spanned by the columns of Q_k . To produce a practical and efficient algorithm various refinements of the iteration are needed, which include

- deflation, whereby when an element on the first subdiagonal of H_k becomes small, that element is set to zero and the problem is split into two smaller problems that are solved independently,
- a double shift technique for real A that allows two QR steps with complex conjugate shifts to be carried out entirely in real arithmetic and gives convergence to the real Schur form, and
- a multishift technique for including m different shifts in a single QR iteration.

A proof of convergence is lacking for all current shift strategies. Implementations introduce a random shift when convergence appears to be stagnating. The QR algorithm works very well in practice and continues to be the method of choice for the non-Hermitian eigenproblem.

5.6 Solving the Hermitian Eigenproblem

The eigenvalue problem for Hermitian matrices is easier to solve than that for non-Hermitian matrices, and the range of available numerical methods is much wider.

To solve the complete Hermitian eigenproblem we need to compute the *spectral decomposition* $A = QDQ^*$, where $D = \text{diag}(\lambda_i)$ contains the eigenvalues and the columns of the unitary matrix Q are the corresponding eigenvectors. Many methods begin by unitary reduction to tridiagonal form $T = U^*AU$, where $t_{ij} = 0$ for $|i - j| > 1$ and the unitary matrix U is constructed as a product of Householder matrices. The eigenvalue problem for T is much simpler, though still nontrivial. The most widely used method is the QR algorithm, which has the same form as in the non-Hermitian case but with the upper Hessenberg H_k replaced by the Hermitian tridiagonal T_k and the shifts chosen to accelerate the convergence of T_k to diagonal form. The

Hermitian QR algorithm with appropriate shifts has been proved to converge at a cubic rate.

Another method for solving the Hermitian tridiagonal eigenproblem is the *divide and conquer method*. This method decouples T in the form

$$T = \begin{bmatrix} T_{11} & 0 \\ 0 & T_{22} \end{bmatrix} + \alpha v v^*,$$

where only the trailing diagonal element of T_{11} and the leading diagonal element of T_{22} differ from the corresponding elements of T and hence the vector v has only two nonzero elements. The eigensystems of T_{11} and T_{22} are found by applying the method recursively, yielding $T_{11} = Q_1 \Lambda_1 Q_1^*$ and $T_{22} = Q_2 \Lambda_2 Q_2^*$. Then

$$\begin{aligned} T &= \begin{bmatrix} Q_1 \Lambda_1 Q_1^* & 0 \\ 0 & Q_2 \Lambda_2 Q_2^* \end{bmatrix} + \alpha v v^* \\ &= \text{diag}(Q_1, Q_2)(\text{diag}(\Lambda_1, \Lambda_2) + \alpha \tilde{v} \tilde{v}^*) \text{diag}(Q_1, Q_2)^*, \end{aligned}$$

where $\tilde{v} = \text{diag}(Q_1, Q_2)^* v$. The eigensystem of a rank-1 perturbed diagonal matrix $D + \rho z z^*$ can be found by solving the *secular equation* obtained by equating the characteristic polynomial to zero:

$$f(\lambda) = 1 + \rho \sum_{j=1}^n \frac{|z_j|^2}{d_{jj} - \lambda} = 0.$$

Putting the pieces together yields the overall eigendecomposition.

Other methods are suitable for computing just a portion of the spectrum. Suppose we want to compute the k th smallest eigenvalue of T and that we can somehow compute the integer $N(x)$ equal to the number of eigenvalues of T that are less than or equal to x . Then we can apply the *BISECTION METHOD* [I.4 §2] to $N(x)$ to find the point where $N(x)$ jumps from $k-1$ to k . We can compute $N(x)$ by making use of the following result about the *inertia* of a Hermitian matrix, defined by $\text{inertia}(A) = (\nu, \zeta, \pi)$, where ν is the number of negative eigenvalues, ζ is the number of zero eigenvalues, and π is the number of positive eigenvalues.

Theorem 2 (Sylvester's inertia theorem). *If A is Hermitian and M is nonsingular, then $\text{inertia}(A) = \text{inertia}(M^* A M)$.*

Sylvester's inertia theorem says that the number of negative, zero, and positive eigenvalues does not change under *congruence transformations*. By using GE we can factorize² $T - xI = LDL^*$, where D is diagonal and L is unit lower bidiagonal (a bidiagonal matrix

is one that is both triangular and tridiagonal). Then $\text{inertia}(T - xI) = \text{inertia}(D)$, so the number of negative or zero diagonal elements of D equals the number of eigenvalues of $T - xI$ less than or equal to 0, which is the number of eigenvalues of T less than or equal to x , that is, $N(x)$. The LDL^* factors of a tridiagonal matrix can be computed in $O(n)$ flops, so this bisection process is efficient. An alternative approach can be built by using properties of *Sturm sequences*, which are sequences comprising the characteristic polynomials of leading principal submatrices of $T - \lambda I$.

5.7 Computing the SVD

For a rectangular matrix $A \in \mathbb{C}^{m \times n}$ the eigenvalues of the Hermitian matrix $\begin{bmatrix} 0 & A \\ A^* & 0 \end{bmatrix}$ of dimension $m+n$ are plus and minus the nonzero singular values of A along with $m+n-2 \min(m, n)$ zeros. Hence the SVD can be computed via the eigendecomposition of this larger matrix. However, this would be inefficient, and instead one uses algorithms that work directly on A and are analogues of the algorithms for Hermitian matrices. The standard approach is to reduce A to bidiagonal form B by Householder transformations applied on the left and the right and then to apply an adaptation of the QR algorithm that works on the bidiagonal factor (and implicitly applies the QR algorithm to the tridiagonal matrix $B^* B$).

5.8 Generalized Eigenproblems

The *generalized eigenvalue problem* (GEP) $Ax = \lambda Bx$, with $A, B \in \mathbb{C}^{n \times n}$, can be converted into a standard eigenvalue problem if B (say) is nonsingular: $B^{-1}Ax = \lambda x$. However, such a transformation is inadvisable numerically unless B is very well-conditioned. If A and B have a common null vector z , the problem takes on a different character because then $(A - \lambda B)z = 0$ for any λ ; such a problem is called *singular*. We will assume that the problem is *regular*, so that $\det(A - \lambda B) \neq 0$. The linear polynomial $A - \lambda B$ is sometimes called a *pencil*.

It is convenient to write $\lambda = \alpha/\beta$, where α and β are not both zero, and rephrase the problem in the more symmetric form $\beta Ax = \alpha Bx$. If x is a nonzero vector such that $Bx = 0$, then, since the problem is assumed to be regular, $Ax \neq 0$ and so $\beta = 0$. This means that $\lambda = \infty$ is an eigenvalue. Infinite eigenvalues may seem a strange concept, but in fact they are no different in most respects to finite eigenvalues.

An important special case is the *definite generalized eigenvalue problem*, in which A and B are Hermitian

2. The factorization may not exist, but if it does not we can simply perturb T slightly and try again without any loss of numerical stability.

and B (say) is positive-definite. If $B = R^*R$ is a Cholesky factorization, then $Ax = \lambda Bx$ can be rewritten as $R^{-*}AR^{-1} \cdot Rx = \lambda Rx$, which is a standard eigenproblem for the Hermitian matrix $C = R^{-*}AR^{-1}$. This argument shows that the eigenvalues of a definite problem are all real. Definite generalized eigenvalue problems arise in many physical situations where an energy-minimization principle is at work, such as in problems in engineering and physics.

A generalization of the QR algorithm called the *QZ algorithm* computes a generalization to two matrices of the Schur decomposition: $Q^*AZ = T$, $Q^*BZ = S$, where Q and Z are unitary and T and S are upper triangular. The generalized Schur decomposition yields the eigenvalues as the ratios t_{ii}/s_{ii} and enables eigenvectors to be computed by substitution.

The *quadratic eigenvalue problem* (QEP) $Q(\lambda)x = (\lambda^2 A_2 + \lambda A_1 + A_0)x = 0$, where $A_i \in \mathbb{C}^{n \times n}$, $i = 0:2$, arises most commonly in the dynamic analysis of structures when the finite-element method is used to discretize the original PDE into a system of second-order ODEs $A_2\ddot{q}(t) + A_1\dot{q}(t) + A_0q(t) = f(t)$. Here, the A_i are usually Hermitian (though A_1 is skew-Hermitian in gyroscopic systems) and positive (semi)definite. Analogously to the GEP, the QEP is said to be regular if $\det(Q(\lambda)) \neq 0$. The quadratic problem differs fundamentally from the linear GEP because a regular problem has $2n$ eigenvalues, which are the roots of $\det(Q(\lambda)) = 0$, but at most n linearly independent eigenvectors, and a vector may be an eigenvector for two different eigenvalues. For example, the QEP with

$$Q(\lambda) = \lambda^2 I + \lambda \begin{bmatrix} -1 & -6 \\ 2 & -9 \end{bmatrix} + \begin{bmatrix} 0 & 12 \\ -2 & 14 \end{bmatrix}$$

has eigenvalues 1, 2, 3, and 4, with eigenvectors $\begin{bmatrix} 1 \\ 0 \end{bmatrix}$, $\begin{bmatrix} 0 \\ 1 \end{bmatrix}$, $\begin{bmatrix} 1 \\ 1 \end{bmatrix}$, and $\begin{bmatrix} 1 \\ -1 \end{bmatrix}$, respectively. Moreover, there is no Schur form for three or more matrices; that is, we cannot in general find unitary matrices U and V such that U^*A_iV is triangular for $i = 0:2$.

Associated with the QEP is the matrix $Q(X) = A_2X^2 + A_1X + A_0$, with $X \in \mathbb{C}^{n \times n}$. From the relation

$$\begin{aligned} Q(\lambda) - Q(X) &= A_2(\lambda^2 I - X^2) + A_1(\lambda I - X) \\ &= (\lambda A_2 + A_2X + A_1)(\lambda I - X), \end{aligned}$$

it is clear that if we can find a matrix X such that $Q(X) = 0$, known as a *solvent*, then we have reduced the QEP to finding the eigenvalues of X and solving one $n \times n$ GEP. For the 2×2 Q above there are five solvents, one of which is $\begin{bmatrix} 3 & 0 \\ 1 & 2 \end{bmatrix}$. The existence and enumeration of solvents is nontrivial and leads into the theory

of *matrix polynomials*. In general, matrix polynomials are matrices of the form $\sum_{i=0}^k \lambda^i A_i$ whose elements are polynomials in a complex variable; an older term for such matrices is *λ -matrices*.

The standard approach for numerical solution of the QEP mimics the conversion of the scalar polynomial root problem into a matrix eigenproblem described in section 5.3. From the relation

$$\begin{aligned} L(\lambda)z &\equiv \left(\begin{bmatrix} A_1 & A_0 \\ I & 0 \end{bmatrix} + \lambda \begin{bmatrix} A_2 & 0 \\ 0 & -I \end{bmatrix} \right) \begin{bmatrix} \lambda x \\ x \end{bmatrix} \\ &= \begin{bmatrix} Q(\lambda)x \\ 0 \end{bmatrix}, \end{aligned}$$

we see that the eigenvalues of the quadratic Q are the eigenvalues of the $2n \times 2n$ linear polynomial $L(\lambda)$. This is an example of an exact linearization process—thanks to the hidden λ in the eigenvector! The eigenvalues of L can be found using the QZ algorithm. The eigenvectors of L have the form $z = \begin{bmatrix} \lambda x \\ x \end{bmatrix}$, where x is an eigenvector of Q , and so x can be obtained from either the first n (if $\lambda \neq 0$) or the last n components of z .

6 Sparse Linear Systems

For linear systems coming from discretization of differential equations it is common that A is *banded*, that is, the nonzero elements lie in a band about the main diagonal. An extreme case is a *tridiagonal matrix*, of which the classic example is the second-difference matrix, illustrated for $n = 4$ by

$$A = \begin{bmatrix} -2 & 1 & 0 & 0 \\ 1 & -2 & 1 & 0 \\ 0 & 1 & -2 & 1 \\ 0 & 0 & 1 & -2 \end{bmatrix}, \quad A^{-1} = -\frac{1}{5} \begin{bmatrix} 4 & 3 & 2 & 1 \\ 3 & 6 & 4 & 2 \\ 2 & 4 & 6 & 3 \\ 1 & 2 & 3 & 4 \end{bmatrix}.$$

This matrix corresponds to a centered FINITE-DIFFERENCE APPROXIMATION [II.11] to a second derivative: $f''(x) \approx (f(x+h) - 2f(x) + f(x-h))/h^2$. Note that A^{-1} is a full matrix. For banded matrices, GE produces banded LU factors and its computational cost is proportional to n times the square of the bandwidth.

A matrix is *sparse* if advantage can be taken of the zero entries because of either their number or their distribution. A banded matrix is a special case of a sparse matrix. Sparse matrices are stored on a computer not as a square array but in a special format that records only the nonzeros and their location in the matrix. This can be done with three vectors: one to store the nonzero entries and the other two to define the row and column indices of the elements in the first vector.

Sparse matrices help to explain the tenet: *never solve a linear system $Ax = b$ by computing $x = A^{-1} \times b$* . The reasons for eschewing A^{-1} are threefold.

- Computing A^{-1} requires three times as many flops as solving $Ax = b$ by GE with partial pivoting.
- GE with partial pivoting is backward stable for solving $Ax = b$ (see section 8) but solution via A^{-1} is not.
- If A is sparse, A^{-1} is generally dense and so requires much more storage than GE with partial pivoting.

When GE is applied to a sparse matrix, *fill-in* occurs when the row operations cause a zero entry to become nonzero during the elimination. To minimize the storage and the computational cost, fill-in must be avoided as much as possible. This can be done by employing row and column interchanges to choose a suitable pivot from the active submatrix. The first such strategy was introduced by Markowitz in 1957. At the k th stage, with $c_j^{(k)}$ denoting the number of nonzeros in rows k to n of column j and $r_i^{(k)}$ the number of nonzeros in columns k to n of row i , the Markowitz strategy finds the pair (r, s) that minimizes $(r_i^{(k)} - 1)(c_j^{(k)} - 1)$ over all nonzero potential pivots $a_{ij}^{(k)}$ and then takes $a_{rs}^{(k)}$ as the pivot. The quantity being minimized is a bound on the fill-in. In practice, the potential pivots must be restricted to those not too much smaller in magnitude than the partial pivot in order to preserve numerical stability. The result of GE with Markowitz pivoting is a factorization $PAQ = LU$, where P and Q are permutation matrices.

The analogue of the Markowitz strategy for Hermitian positive-definite matrices chooses a diagonal entry $a_{ii}^{(k)}$ as the pivot, where $r_i^{(k)}$ is minimal. This is the *minimum-degree algorithm*, which has been very successful in practice. Figure 3 shows in the first row a sparse and banded symmetric positive-definite matrix A of dimension 225 followed to the right by its Cholesky factor. The Cholesky factor has many more nonzeros than A . The second row shows the matrix PAP^T produced by an approximate minimum-degree ordering (produced by the MATLAB `symamd` function) and its Cholesky factor. We can see that the permutations have destroyed the band structure but have greatly reduced the fill-in, producing a much sparser Cholesky factor.

As an alternative to GE for solving sparse linear systems one can apply iterative methods, described in section 9; for sufficiently large problems these are the only feasible methods.

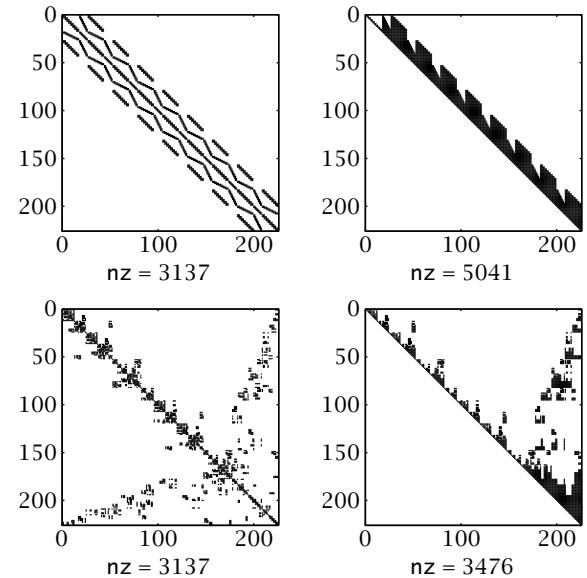

Figure 3 Sparsity plots of a symmetric positive-definite matrix (left) and its Cholesky factor (right) for original matrix (first row) and reordered matrix (second row). nz is the number of nonzeros.

7 Overdetermined and Underdetermined Systems

Linear systems $Ax = b$ with a rectangular matrix $A \in \mathbb{C}^{m \times n}$ are very common. They break into two categories: *overdetermined systems*, with more equations than unknowns ($m > n$), and *underdetermined systems*, with fewer equations than unknowns ($m < n$). Since in general there is no solution when $m > n$ and there are many solutions when $m < n$, extra conditions must be imposed for the problems to be well defined. These usually involve norms, and different choices of norms are possible. We will restrict our discussion mainly to the 2-norm, which is the most important case, but other choices are also of practical interest.

7.1 The Linear Least-Squares Problem

When $m > n$ the residual $r = b - Ax$ cannot in general be made zero, so we try to minimize its norm. The most common choice of norm is the 2-norm, which gives the *linear least-squares problem*

$$\min_{x \in \mathbb{C}^n} \|b - Ax\|_2. \quad (6)$$

This choice can be motivated by statistical considerations (the Gauss–Markov theorem) or by the fact that the square of the 2-norm is differentiable, which makes

the problem explicitly solvable. Indeed, by setting the gradient of $\|b - Ax\|_2^2$ to zero we obtain the *normal equations* $A^*Ax = A^*b$, which any solution of the least-squares problem must satisfy. If A has full rank then A^*A is positive-definite and so there is a unique solution, which can be computed by solving the normal equations using Cholesky factorization. For reasons of numerical stability it is preferable to use a QR factorization: if $A = Q \begin{bmatrix} R \\ 0 \end{bmatrix}$ then the normal equations reduce to the triangular system $R_1x = c$, where c is the first n components of Q^*b .

When A is rank deficient there are many least-squares solutions, which vary widely in norm. A natural choice is one of minimal 2-norm, and in fact there is a unique minimal 2-norm solution, x_{LS} , given by

$$x_{\text{LS}} = \sum_{i=1}^r (u_i^* b / \sigma_i) v_i,$$

where

$$A = U\Sigma V^*, \quad U = [u_1, \dots, u_m], \quad V = [v_1, \dots, v_n], \quad (7)$$

is an SVD and $r = \text{rank}(A)$. The use of this formula in practice is not straightforward because a matrix stored in floating-point arithmetic will rarely have any zero singular values. Therefore r must be chosen by designating which singular values can be regarded as negligible, and this choice should take account of the accuracy with which the elements of A are known.

Another choice of least-squares solution in the rank-deficient case is a *basic solution*: one with at most r nonzeros. Such a solution can be computed via the QR factorization with column pivoting.

7.2 Underdetermined Systems

When $m < n$ and A has full rank, there are infinitely many solutions to $Ax = b$ and again it is natural to seek one of minimal 2-norm. There is a unique such solution $x_{\text{LS}} = A^*(AA^*)^{-1}b$, and it is best computed via a QR factorization, this time of A^* . A basic solution, with m nonzeros, can alternatively be computed. As a simple example, consider the problem “find two numbers whose sum is 5,” that is, solve $[1 \ 1] \begin{bmatrix} x_1 \\ x_2 \end{bmatrix} = 5$. A basic solution is $[5 \ 0]^T$, while the minimal 2-norm solution is $[5/2 \ 5/2]^T$. Minimal 1-norm solutions to underdetermined systems are important in COMPRESSED SENSING [VII.10].

7.3 Pseudoinverse

The analysis in the previous two subsections can be unified in a very elegant way by making use of the

Moore–Penrose pseudoinverse A^+ of $A \in \mathbb{C}^{m \times n}$, which is defined as the unique $X \in \mathbb{C}^{n \times m}$ satisfying the Moore–Penrose conditions

$$\begin{aligned} AXA &= A, & XAX &= X, \\ (AX)^* &= AX, & (XA)^* &= XA. \end{aligned}$$

(It is certainly not obvious that these equations have a unique solution.) In the case where A is square and nonsingular, it is easily seen that A^+ is just A^{-1} . Moreover, if $\text{rank}(A) = n$ then $A^+ = (A^*A)^{-1}A^*$, while if $\text{rank}(A) = m$ then $A^+ = A^*(AA^*)^{-1}$. In terms of the SVD (7),

$$A^+ = V \text{diag}(\sigma_1^{-1}, \dots, \sigma_r^{-1}, 0, \dots, 0) U^*,$$

where $r = \text{rank}(A)$. The formula $x_{\text{LS}} = A^+b$ holds for all m and n , so the pseudoinverse yields the minimal 2-norm solution to both the least-squares (overdetermined) problem $Ax = b$ and an underdetermined system $Ax = b$. The pseudoinverse has many interesting properties, including $(A^+)^+ = A$, but it is not always true that $(AB)^+ = B^+A^+$.

Although the pseudoinverse is a very useful theoretical tool, it is rarely necessary to compute it explicitly (just as for its special case the matrix inverse).

The pseudoinverse is just one of many ways of generalizing the notion of inverse to rectangular matrices, but it is the right one for minimum 2-norm solutions to linear systems. Other generalized inverses can be obtained by requiring only a subset of the four Moore–Penrose conditions to hold.

8 Numerical Considerations

Prior to the introduction of the first digital computers in the 1940s, numerical computations were carried out by humans, sometimes with the aid of mechanical calculators. The human involvement in a sequence of calculations meant that potentially dangerous events such as dividing by a tiny number or subtracting two numbers that agree to almost all their significant digits could be observed, their effect monitored, and possible corrective action taken—such as temporarily increasing the precision of the calculations. On the very early computers intermediate results were observed on a cathode ray tube monitor, but this became impossible as problem sizes increased (along with available computing power). Fears were raised in the 1940s that algorithms such as GE would suffer exponential growth of errors as the problem dimension increased, due to the rapidly increasing number of arithmetic operations, each having its associated ROUNDING ERROR [II.13].

These fears were particularly concerning given that the error growth might be unseen and unsuspected.

The subject of *rounding error analysis* grew out of the need to understand the effect of rounding errors on algorithms. The person who did the most to develop the subject was James Wilkinson, whose influential papers and 1961 and 1965 books showed how BACKWARD ERROR ANALYSIS [I.2 §23] can be used to obtain deep insights into numerical stability. We will discuss just two particular examples.

Wilkinson showed that when a nonsingular linear system $Ax = b$ is solved by GE in floating-point arithmetic the computed solution \hat{x} satisfies

$$(A + \Delta A)\hat{x} = b, \quad \|\Delta A\|_\infty \leq p(n)\rho_n u \|A\|_\infty.$$

Here, $p(n)$ is a cubic polynomial, the *growth factor*

$$\rho_n = \frac{\max_{i,j,k} |a_{ij}^{(k)}|}{\max_{i,j} |a_{ij}|} \geq 1$$

measures the growth of elements during the elimination, and u is the UNIT ROUNDOFF [II.13]. This is a *backward stability result*: it says that the computed solution \hat{x} is the exact solution of a perturbed system. Ideally, we would like $\|\Delta A\|_\infty \leq u \|A\|_\infty$, which reflects the uncertainty caused by converting the elements of A to floating-point numbers. The polynomial term $p(n)$ is pessimistic and might be more realistically replaced by its square root. The danger term is the growth factor ρ_n , and the conclusion from Wilkinson's analysis is that a pivoting strategy should aim to keep ρ_n small. If no pivoting is done, ρ_n can be arbitrarily large (e.g., for $A = [\begin{smallmatrix} \varepsilon & 1 \\ 1 & 1 \end{smallmatrix}]$ with $0 < \varepsilon \ll 1$, $\rho_n \approx 1/\varepsilon$). For partial pivoting, however, it can be shown that $\rho_n \leq 2^{n-1}$ and that this bound is attainable. In practice, ρ_n is almost always of modest size for partial pivoting ($\rho_n \leq 50$, say); why this should be so remains one of the great mysteries of numerical analysis!

One of the benefits of Wilkinson's backward error analysis is that it enables us to identify classes of matrices for which pivoting is not necessary, that is, for which the LU factorization $A = LU$ exists and ρ_n is nicely bounded. One such class is the matrices that are diagonally dominant by either rows or columns, for which $\rho_n \leq 2$.

The potential instability of GE can be attributed to the fact that A is premultiplied by a sequence of nonunitary transformations, any of which can be ill-conditioned. Many algorithms, including Householder QR factorization and the QR algorithm for eigenvalues, use exclusively unitary transformations. Such algorithms are

usually (but not always) backward stable, essentially because unitary transformations do not magnify errors: $\|UAV\| = \|A\|$ for any unitary U and V for the 2-norm and the Frobenius norm. As an example, the QR algorithm applied to $A \in \mathbb{C}^{n \times n}$ produces a computed upper triangular matrix \hat{T} such that

$$\tilde{Q}^*(A + \Delta A)\tilde{Q} = \hat{T}, \quad \|\Delta A\|_F \leq p(n)u \|A\|_F,$$

where \tilde{Q} is some exactly unitary matrix and $p(n)$ is a cubic polynomial. The computed Schur factor \hat{Q} is not necessarily close to \tilde{Q} —which in turn is not necessarily close to the exact Q !—but it is close to being orthogonal: $\|\hat{Q}^*\hat{Q} - I\|_F \leq p(n)u$. This distinction between the different Q matrices is an indication of the subtleties of backward error analysis. For some problems it is not clear exactly what form of backward error result it is possible to prove while obtaining useful bounds. However, the purpose of a backward error analysis is always the same: either to show that an algorithm behaves in a numerically stable way or to shed light on how it might fail to do so and to indicate what quantities should be monitored in order to identify potential instability.

9 Iterative Methods

In numerical linear algebra, methods can broadly be divided into two classes: direct and iterative. Direct methods, such as GE, solve a problem in a fixed number of arithmetic operations or a variable number that in practice is fairly constant, as for the QR algorithm for eigenvalues. Iterative methods are infinite processes that must be truncated at some point when the approximation they provide is “good enough.” Usually, iterative methods do not transform the matrix in question and access it only through matrix–vector products; this makes them particularly attractive for large, sparse matrices, where applying a direct method may not be practical.

We have already seen in section 5.5 a simple iterative method for the eigenvalue problem: the power method. The *stationary iterative methods* are an important class of iterative methods for solving a nonsingular linear system $Ax = b$. These methods are best described in terms of a *splitting*

$$A = M - N,$$

with M nonsingular. The system $Ax = b$ can be rewritten $Mx = Nx + b$, which suggests constructing a sequence $\{x^{(k)}\}$ from a given starting vector $x^{(0)}$ via

$$Mx^{(k+1)} = Nx^{(k)} + b. \tag{8}$$

Different choices of M and N yield different methods. The aim is to choose M in such a way that it is inexpensive to solve (8) while M is a good enough approximation to A that convergence is fast. It is easy to analyze convergence. Denote by $e^{(k)} = x^{(k)} - x$ the error in the k th iterate. Subtracting $Mx = Nx + b$ from (8) gives $M(x^{(k+1)} - x) = N(x^{(k)} - x)$, so

$$e^{(k+1)} = M^{-1}Ne^{(k)} = \dots = (M^{-1}N)^{k+1}e^{(0)}. \quad (9)$$

If $\rho(M^{-1}N) < 1$ then $(M^{-1}N)^k \rightarrow 0$ as $k \rightarrow \infty$ (see JORDAN CANONICAL FORM [II.22]) and so $x^{(k)}$ converges to x at a linear rate. In practice, for convergence in a reasonable number of iterations we need $\rho(M^{-1}N)$ to be sufficiently less than 1 and the powers of $M^{-1}N$ should not grow too large initially before eventually decaying; in other words, $M^{-1}N$ must not be too nonnormal.

Three standard choices of splitting are as follows, where $D = \text{diag}(A)$ and L and U denote the strictly lower and strictly upper triangular parts of A , respectively.

- $M = D, N = -(L + U)$: *Jacobi iteration* (illustrated in METHODS OF SOLUTION [I.3 §6]).
- $M = D + L, N = -U$: *Gauss-Seidel iteration*.
- $M = (1/\omega)D + L, N = ((1 - \omega)/\omega)D - U$, where $\omega \in (0, 2)$ is a relaxation parameter: *successive overrelaxation (SOR) iteration*.

Sufficient conditions for convergence are that A is strictly diagonally dominant by rows for the Jacobi iteration and that A is symmetric positive-definite for the Gauss-Seidel iteration. How to choose ω so that $\rho(M^{-1}N|_{\omega})$ is minimized for the SOR iteration was elucidated in the landmark 1950 Ph.D. thesis of David Young.

The Google PAGERANK ALGORITHM [VI.9], which underlies Google's ordering of search results, can be interpreted as an application of the Jacobi iteration to a certain linear system involving the ADJACENCY MATRIX [II.16] of the graph corresponding to the whole World Wide Web. However, the most common use of stationary iterative methods is as preconditioners within other iterative methods.

The aim of *preconditioning* is to convert a given linear system $Ax = b$ into one that can be solved more cheaply by a particular iterative method. The basic idea is to use a nonsingular matrix W to transform the system to $(W^{-1}A)x = W^{-1}b$ in such a way that (a) the preconditioned system can be solved in fewer iterations than the original system and (b) matrix-vector multiplications with $W^{-1}A$ (which require the solution of a

linear system with coefficient matrix W) are not significantly more expensive than matrix-vector multiplications with A . In general, this is a difficult or impossible task, but in many applications the matrix A has structure that can be exploited. For example, many elliptic PDE problems lead to a positive-definite matrix A of the form

$$A = \begin{bmatrix} M_1 & F \\ F^T & M_2 \end{bmatrix},$$

where $M_1z = d_1$ and $M_2z = d_2$ are easy to solve. In this case it is natural to take $W = \text{diag}(M_1, M_2)$ as the preconditioner. When A is Hermitian positive-definite the preconditioned system is written in a way that preserves the structure. For example, for the Jacobi preconditioner, $D = \text{diag}(A)$, the preconditioned system would be written $D^{-1/2}AD^{-1/2}\tilde{x} = \tilde{b}$, where $\tilde{x} = D^{1/2}x$ and $\tilde{b} = D^{-1/2}b$. Here, the matrix $D^{-1/2}AD^{-1/2}$ has unit diagonal and off-diagonal elements lying between -1 and 1 .

The most powerful iterative methods for linear systems $Ax = b$ are the Krylov methods. In these methods each iterate $x^{(k)}$ is chosen from the shifted subspace $x^{(0)} + \mathcal{K}_k(A, r^{(0)})$, where

$$\mathcal{K}_k(A, r^{(0)}) = \text{span}\{r^{(0)}, Ar^{(0)}, \dots, A^{k-1}r^{(0)}\}$$

is a KRYLOV SUBSPACE [II.23] of dimension k , with $r^{(k)} = b - Ax^{(k)}$. Different strategies for choosing approximations from within the Krylov subspaces yield different methods. For example, the *conjugate gradient method* (CG, for Hermitian positive-definite A) and the *full orthogonalization method* (FOM, for general A) make the residual $r^{(k)}$ orthogonal to the Krylov subspace $\mathcal{K}_k(A, r^{(0)})$, while the *minimal residual method* (MINRES, for Hermitian A) and the *generalized minimal residual method* (GMRES, for general A) minimize the 2-norm of the residual over all vectors in the Krylov subspace. How to compute the vectors defined in these ways is nontrivial. It turns out that CG can be implemented with a recurrence requiring just one matrix-vector multiplication and three inner products per iteration, and MINRES is just a little more expensive. GMRES, being applicable to non-Hermitian matrices, is significantly more expensive, and it is also much harder to analyze its convergence behavior. For general matrices there are alternatives to GMRES that employ short recurrences. We mention just *BICGSTAB*, which has the distinction that the 1992 paper by Henk van der Vorst that introduced it was the most-cited paper in mathematics in the 1990s.

Theoretically, Krylov methods converge in at most n iterations for a system of dimension n . However, in practical computation rounding errors intervene and the methods behave as truly iterative methods not having finite termination. Since n is potentially huge, a Krylov method would not be used unless a good approximate solution was obtained in many fewer than n iterations, and preconditioning plays a crucial role here. Available error bounds for a method help to guide the choice of preconditioner, but care is needed in interpreting the bounds. To illustrate this, consider the CG method for $Ax = b$, where A is Hermitian positive-definite. In the A -norm, $\|z\|_A = (z^*Az)^{1/2}$, the error on the k th step satisfies

$$\|x - x^{(k)}\|_A \leq 2\|x - x^{(0)}\|_A \left(\frac{\kappa_2(A)^{1/2} - 1}{\kappa_2(A)^{1/2} + 1} \right)^k,$$

where $\kappa_2(A) = \|A\|_2\|A^{-1}\|_2$. If we can precondition A so that its 2-norm condition number is very close to 1, then fast convergence is guaranteed. However, another result says that if A has k distinct eigenvalues then CG converges in at most k iterations. A better approach might therefore be to choose the preconditioner so that the eigenvalues of the preconditioned matrix are clustered into a small number of groups.

Another important class of iterative methods is MULTIGRID METHODS [IV.13 §3], which work on a hierarchy of grids that come from a discretization of an underlying PDE (geometric multigrid) or are constructed artificially from a given matrix (algebraic multigrid).

An important practical issue is how to terminate an iteration. Popular approaches are to stop when the residual $r^{(k)} = b - Ax^{(k)}$ (suitably scaled) is small or when an estimate of the error $x - x^{(k)}$ is small. Complicating factors include the fact that the preconditioner can change the norm and a possible desire to match the error in the iterations with the discretization error in the PDE from which the linear system might have come (as there is no point solving the system to greater accuracy than the data warrants). Research in recent years has led to good understanding of these issues.

The ideas of Krylov methods and preconditioners can be applied to problems other than linear systems. A popular Krylov method for solving the least-squares problem (6) is LSQR, which is mathematically equivalent to applying CG to the normal equations. In large-scale eigenvalue problems only a few eigenpairs are usually required. A number of methods project the original matrix onto a Krylov subspace and then solve

a smaller eigenvalue problem. These include the *Lanczos method* for Hermitian matrices and the *Arnoldi method* for general matrices. Also of much current research interest are *rational Krylov methods* based on RATIONAL GENERALIZATIONS OF KRYLOV SUBSPACES [II.23].

10 Nonnormality and Pseudospectra

Normal matrices $A \in \mathbb{C}^{n \times n}$ (defined in section 5.1) have the property that they are unitarily diagonalizable: $A = QDQ^*$ for some unitary Q and diagonal $D = \text{diag}(\lambda_i)$ containing the eigenvalues on its diagonal. In many respects normal matrices have very predictable behavior. For example, $\|A^k\|_2 = \rho(A)^k$ and $\|e^{tA}\|_2 = e^{\alpha(tA)}$, where the *spectral abscissa* $\alpha(tA)$ is the largest real part of any eigenvalue of tA . However, matrices that arise in practice are often very nonnormal. The adjective “very” can be quantified in various ways, of which one is the Frobenius norm of the strictly upper triangular part of the upper triangular matrix T in the Schur decomposition $A = QTQ^*$. For example, the matrix $\begin{bmatrix} t_{11} & \theta \\ 0 & t_{22} \end{bmatrix}$ is nonnormal for $\theta \neq 0$ and grows increasingly nonnormal as $|\theta|$ increases.

Consider the moderately nonnormal matrix

$$A = \begin{bmatrix} -0.97 & 25 \\ 0 & -0.3 \end{bmatrix}. \quad (10)$$

While the powers of A ultimately decay to zero, since $\rho(A) = 0.97 < 1$, we see from figure 4 that initially they increase in norm. Likewise, since $\alpha(A) = -0.3 < 0$ the norm $\|e^{tA}\|_2$ tends to zero as $t \rightarrow \infty$, but figure 4 shows that there is an initial hump in the plot. In stationary iterations the hump caused by a nonnormal iteration matrix $M^{-1}N$ can delay convergence, as is clear from (9). In finite-precision arithmetic it can even happen that, for a sufficiently large hump, rounding errors cause the norms of the powers to plateau at the hump level and never actually converge to zero.

How can we predict the shape of the curves in figure 4? Let us concentrate on $\|A^k\|_2$. Initially it grows like $\|A\|_2^k$ and ultimately it decays like $\rho(A)^k$, the decay rate following from (4). The height of the hump is related to pseudospectra, which have been popularized by Nick Trefethen.

The ε -pseudospectrum of $A \in \mathbb{C}^{n \times n}$ is defined, for a given $\varepsilon > 0$, to be the set

$$\Lambda_\varepsilon(A) = \{z \in \mathbb{C} : z \text{ is an eigenvalue of } A + E \text{ for some } E \text{ with } \|E\|_2 < \varepsilon\}, \quad (11)$$

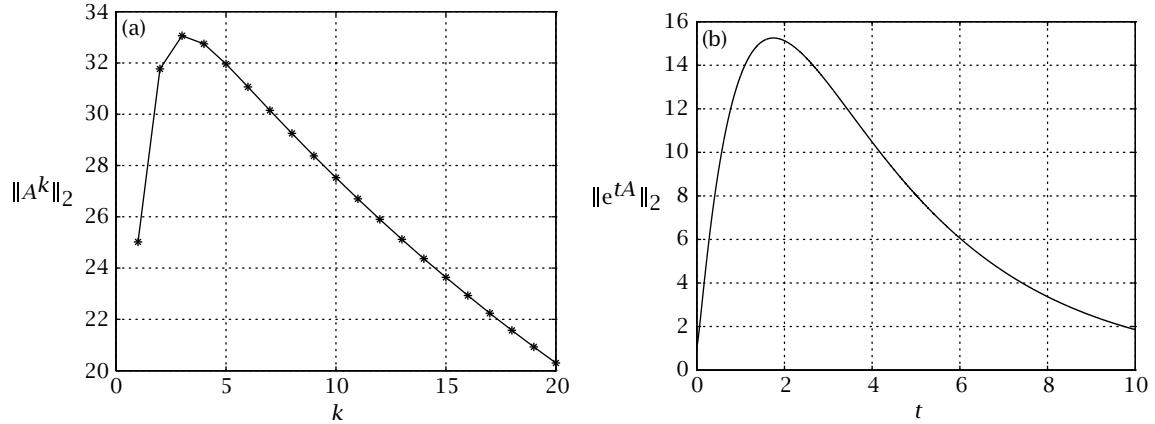

Figure 4 2-norms of (a) powers and (b) exponentials of 2×2 matrix A in (10).

and it can also be represented, in terms of the *resolvent* $(zI - A)^{-1}$, as

$$\Lambda_\varepsilon(A) = \{z \in \mathbb{C}: \|(zI - A)^{-1}\|_2 > \varepsilon^{-1}\}.$$

The 0.001-pseudospectrum, for example, tells us the uncertainty in the eigenvalues of A if the elements are known only to three decimal places. Pseudospectra provide much insight into the effects of nonnormality of matrices and (with an appropriate extension of the definition) linear operators. For nonnormal matrices the pseudospectra are much bigger than a perturbation of the spectrum by ε . It can be shown that for any $\varepsilon > 0$,

$$\sup_{k \geq 0} \|A^k\| \geq \frac{\rho_\varepsilon(A) - 1}{\varepsilon}, \quad \|A^k\| \leq \frac{\rho_\varepsilon(A)^{k+1}}{\varepsilon},$$

where the *pseudospectral radius* $\rho_\varepsilon(A) = \max\{|\lambda| : \lambda \in \Lambda_\varepsilon(A)\}$. For A in (10) and $\varepsilon = 10^{-2}$, these inequalities give an upper bound of 230 for $\|A^3\|$ and a lower bound of 23 for $\sup_{k \geq 0} \|A^k\|$, and figure 5 plots the corresponding ε -pseudospectrum.

11 Structured Matrices

In a wide variety of applications the matrices have a special structure. The matrix elements might form a pattern, as for TOEPLITZ OR HAMILTONIAN MATRICES [I.2 §18], the matrix may satisfy a nonlinear equation such as $A^* \Sigma A = \Sigma$, where $\Sigma = \text{diag}(\pm 1)$, which yields the *pseudo-unitary matrices* A , or the submatrices may satisfy certain rank conditions (as for *quasiseparable matrices*). We discuss here two of the oldest and most-studied classes of structured matrices, both

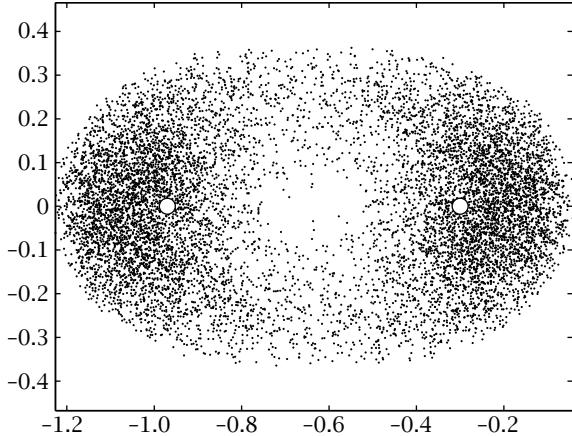

Figure 5 Approximation to 10^{-2} -pseudospectrum of A in (10) comprising eigenvalues of 5000 randomly perturbed matrices $A + E$ in (11). The eigenvalues of A are marked by white circles.

of which were historically important in the analysis of iterative methods for linear systems arising from the discretization of differential equations.

11.1 Nonnegative Matrices

A *nonnegative matrix* is a real matrix all of whose entries are nonnegative. A number of important classes of matrices are subsets of the nonnegative matrices. These include adjacency matrices, STOCHASTIC MATRICES [II.25], and Leslie matrices (used in population modeling). Nonnegative matrices have a large body of theory, which originates with Perron in 1907 and Frobenius in 1908.

To state the celebrated Perron–Frobenius theorem we need the definition that $A \in \mathbb{R}^{n \times n}$ with $n \geq 2$ is *reducible* if there is a permutation matrix P such that

$$P^T AP = \begin{bmatrix} A_{11} & A_{12} \\ 0 & A_{22} \end{bmatrix},$$

where A_{11} and A_{22} are square, nonempty submatrices, and it is *irreducible* if it is not reducible. A matrix with positive entries is trivially irreducible. A useful characterization is that A is irreducible if and only if the directed graph associated with A (which has n vertices, with an edge connecting the i th vertex to the j th vertex if $a_{ij} \neq 0$) is STRONGLY CONNECTED [II.16].

Theorem 3 (Perron–Frobenius). If $A \in \mathbb{R}^{n \times n}$ is non-negative and irreducible then

- (1) $\rho(A) > 0$,
- (2) $\rho(A)$ is an eigenvalue of A ,
- (3) there is a positive vector x such that $Ax = \rho(A)x$,
- (4) $\rho(A)$ is an eigenvalue of algebraic multiplicity 1.

To illustrate the theorem consider the following two irreducible matrices and their eigenvalues:

$$A = \begin{bmatrix} 8 & 1 & 6 \\ 3 & 5 & 7 \\ 4 & 9 & 2 \end{bmatrix}, \quad \Lambda(A) = \{15, \pm 2\sqrt{6}\},$$

$$B = \begin{bmatrix} 0 & 0 & 6 \\ \frac{1}{2} & 0 & 0 \\ 0 & \frac{1}{3} & 0 \end{bmatrix}, \quad \Lambda(B) = \{1, \frac{1}{2}(-1 \pm \sqrt{3}i)\}.$$

The Perron–Frobenius theorem correctly tells us that $\rho(A) = 15$ is a distinct eigenvalue of A and that it has a corresponding positive eigenvector, which is known as the *Perron vector*. The Perron vector of A is the vector of all ones, as A forms a magic square and $\rho(A)$ is the magic sum! The Perron vector of B , which is both a Leslie matrix and a companion matrix, is $[6 \ 3 \ 1]^T$. There is one notable difference between A and B : for A , $\rho(A)$ exceeds the other eigenvalues in modulus, but all three eigenvalues of B have modulus 1. In fact, Perron's original version of Theorem 3 says that if A has all positive elements then $\rho(A)$ is not only an eigenvalue of A but is larger in modulus than every other eigenvalue. Note that $B^3 = I$, which provides another way to see that the eigenvalues of B all have modulus 1.

We saw in section 9 that the spectral radius plays an important role in the convergence of stationary iterative methods, through $\rho(M^{-1}N)$, where $A = M - N$ is a splitting. In comparing different splittings we can use

the result that for $A, B \in \mathbb{R}^{n \times n}$, with $|A|$ denoting the matrix $(|a_{ij}|)$,

$$|a_{ij}| \leq b_{ij} \quad \forall i, j \quad \Rightarrow \quad \rho(A) \leq \rho(|A|) \leq \rho(B).$$

11.2 *M*-Matrices

$A \in \mathbb{R}^{n \times n}$ is an *M-matrix* if it can be written in the form $A = sI - B$, where B is nonnegative and $s > \rho(B)$. *M*-matrices arise in many applications, a classic one being Leontief's input-output models in economics.

The special sign pattern of an *M-matrix*—positive diagonal elements and nonpositive off-diagonal elements—combines with the spectral radius condition to give many interesting characterizations and properties. For example, a nonsingular matrix A with nonpositive off-diagonal elements is an *M-matrix* if and only if A^{-1} is nonnegative. Another characterization, which makes connections with section 1, is that A is an *M-matrix* if and only if A has positive diagonal entries and AD is diagonally dominant by rows for some nonsingular diagonal matrix D .

An important source of *M-matrices* is discretizations of differential equations, and the archetypal example is the second-difference matrix, described at the start of section 6, which is an *M-matrix* multiplied by -1 . For this application it is an important result that when A is an *M-matrix* the Jacobi and Gauss–Seidel iterations for $Ax = b$ both converge for any starting vector—a result that is part of the more general theory of regular splittings.

Another important property of *M-matrices* is immediate from the definition: the eigenvalues all lie in the open right half-plane. This means that *M-matrices* are special cases of positive stable matrices, which in turn are of great interest due to the fact that the stability of various mathematical processes is equivalent to positive (or negative) stability of an associated matrix.

The class of matrices whose inverses are *M-matrices* is also much studied. To indicate why, we state a result about matrix roots. It is known that if A is an *M-matrix* then $A^{1/2}$ is also an *M-matrix*. But if A is stochastic (that is, it is nonnegative and has unit row sums), $A^{1/2}$ may not be stochastic. However, if A is both stochastic and the inverse of an *M-matrix*, then $A^{1/p}$ is stochastic for all positive integers p .

12 Matrix Inequalities

There is a large body of work on matrix inequalities, ranging from classical nineteenth-century and

early twentieth-century inequalities (some of which are described in section 5.4) to more recent contributions, which are often motivated by applications, notably in statistics, physics, and control theory. In this section we describe just a few examples, chosen for their interest or practical usefulness.

An important class of inequalities on Hermitian matrices is expressed using the *Löwner (partial) ordering* in which, for Hermitian X and Y , $X \geq Y$ denotes that $X - Y$ is positive-semidefinite while $X > Y$ denotes that $X - Y$ is positive-definite. Many inequalities between real numbers generalize to Hermitian matrices in this ordering. For example, if A, B, C are Hermitian and A commutes with B and C , then

$$A \geq 0, \quad B \leq C \quad \Rightarrow \quad AB \leq AC.$$

A function f is *matrix monotone* if it preserves the order, that is, $A \leq B$ implies $f(A) \leq f(B)$, where $f(A)$ denotes a FUNCTION OF A MATRIX [II.14]. Much is known about this class of functions, including that $t^{1/2}$ and $\log t$ are matrix monotone but t^2 is not.

Many matrix inequalities involve norms. One example is

$$\| |A| - |B| \|_F \leq \sqrt{2} \|A - B\|_F,$$

where $A, B \in \mathbb{C}^{m \times n}$ and $|\cdot|$ is the matrix absolute value defined in section 2. This inequality can be regarded as a perturbation result that shows the matrix absolute value to be very well-conditioned.

An example of an inequality that finds use in the analysis of convergence of methods in nonlinear optimization is the *Kantorovich inequality*, which for Hermitian positive-definite A with eigenvalues $\lambda_n \leq \dots \leq \lambda_1$ and $x \neq 0$ is

$$\frac{(x^* Ax)(x^* A^{-1} x)}{(x^* x)^2} \leq \frac{(\lambda_1 + \lambda_n)^2}{4\lambda_1 \lambda_n}.$$

This inequality is attained for some x , and the left-hand side is always at least 1.

Many inequalities are available that generalize scalar inequalities for means. For example, the arithmetic-geometric mean inequality $(ab)^{1/2} \leq \frac{1}{2}(a + b)$ for positive scalars has an analogue for Hermitian positive-definite A and B in the inequality $A \# B \leq \frac{1}{2}(A + B)$, where $A \# B$ is the geometric mean defined as the unique Hermitian positive-definite solution to $XA^{-1}X = B$. The geometric mean also satisfies the extremal property

$$A \# B = \max \left\{ X : X = X^*, \begin{bmatrix} A & X \\ X & B \end{bmatrix} \geq 0 \right\},$$

which hints at *matrix completion problems*, in which the aim is to choose missing elements of a matrix in order

to achieve some goal, which could be to satisfy a particular matrix property or, as here, to maximize an objective function. Another mean for Hermitian positive-definite matrices (and applicable more generally) is the *log-Euclidean mean*, $\exp(\frac{1}{2}(\log A + \log B))$, where \log is the PRINCIPAL LOGARITHM [II.14], which is used in image registration, for example.

Finally, we mention an inequality for the matrix exponential. Although there is no simple relation between e^{A+B} and $e^A e^B$ in general, for Hermitian A and B the inequality $\text{trace}(e^{A+B}) \leq \text{trace}(e^A e^B)$ was proved independently by S. Golden and J. Thompson in 1965. Originally of interest in statistical mechanics, the Golden-Thompson inequality has more recently found use in RANDOM-MATRIX THEORY [IV.24]. Again for Hermitian A and B , the related inequalities $\|e^{A+B}\| \leq \|e^{A/2} e^B e^{A/2}\| \leq \|e^A e^B\|$ hold for any unitarily invariant norm.

13 Library Software

From the early days of digital computing the benefits of providing library subroutines for carrying out basic operations such as the addition of vectors and the formation of vector inner products was recognized. Over the ensuing years many matrix computation research codes were published, including in the linear algebra volume of the *Handbook for Automatic Computation* (1971) and in the *Collected Algorithms of the ACM*. Starting in the 1970s the concept of standardized subprograms was developed in the form of the Basic Linear Algebra Subprograms (BLAS), which are specifications for vector (level 1), matrix-vector (level 2), and matrix-matrix (level 3) operations. The BLAS have been widely adopted, and highly optimized implementations are available for most machines. The freely available LAPACK library of Fortran codes represents the current state of the art for solving dense linear equations, least-squares problems, and eigenvalue and singular value problems. Many modern programming packages and environments build on LAPACK.

It is interesting to note that the TOP500 list (www.top500.org) ranks the world's fastest computers by their speed (measured in flops per second) in solving a random linear system $Ax = b$ by GE. This benchmark has its origins in the 1970s LINPACK project, a precursor to LAPACK, in which the performance of contemporary machines was compared by running the LINPACK GE code on a 100×100 system.

14 Outlook

Matrix analysis and numerical linear algebra remain very active areas of research. Many problems in applied mathematics and scientific computing require the solution of a matrix problem at some stage, so there is always a demand for better understanding of matrix problems and faster and more accurate algorithms for their solution. As the overarching applications evolve, new problem variants are generated, often involving new assumptions on the data, different requirements on the solution, or new metrics for measuring the success of an algorithm. A further driver of research is computer hardware. With the advent of processors with many cores, the use of accelerators such as graphics processing units, and the harnessing of vast numbers of processors for parallel computing, the standard algorithms in numerical linear algebra are having to be reorganized and possibly even replaced, so we are likely to see significant changes in the coming years.

IV.11 Continuous Optimization (Nonlinear and Linear Programming)

Stephen J. Wright

1 Overview

At the core of any optimization problem is a mathematical model of a system. This model could be constructed according to physical, economic, behavioral, or statistical principles, and it describes relationships between variables that define the state of the system; it may also place restrictions on the states, in the form of constraints on the variables. The model also includes an objective function that measures the desirability of a given set of variables. The optimization problem is to find the set of variables that achieves the best possible value of the objective function, among all those values that satisfy the given constraints.

1.1 Examples

Optimization problems are ubiquitous, as we illustrate with some examples.

- (1) A firm wishes to maximize its profit, given constraints on availability of resources (equipment, labor, raw materials), production costs, and forecast demand.
- (2) In order to forecast weather, we first need to solve a problem to identify the state of the atmosphere a few hours ago. This is done by finding the state that is most consistent with recent meteorological observations (temperature, wind speed, humidity, etc.) taken at a variety of locations and times. The model contains differential equations that describe evolution of the atmosphere, statistical elements that describe prior knowledge of the atmospheric state, and an objective function that measures the consistency between the atmospheric state and the observations.
- (3) Computer systems for recognizing handwritten digits contain models that read the written character, in the form of a pixelated image, and output their best guess as to the digit that is represented in the image. These models can be “trained” by presenting them with a (typically large) set of images containing known digits. An optimization problem is solved to adjust the parameters in the model so that the error count on the training set is minimized. If the training set is representative of the images that the system will see in future,

this optimized model can be trusted to perform reliable digit recognition.

(4) Given a product that is produced in a number of cities and consumed in other cities, we wish to find the least expensive way to transport the product from supply locations to demand locations. Here, the model consists of a graph that describes the transportation network, capacity constraints, and the cost of transporting one unit of the product between two adjacent locations in the network.

(5) Given a set of possible investments along with the means, variances, and correlations of their expected returns, an investor wishes to allocate his or her funds in a way that balances the expected mean return of the portfolio with its variance, in a way that fits his or her appetite for risk.

These examples capture some of the wide variety of applications currently seen in the field. As they suggest, the mathematical models that underlie optimization problems vary widely in size, complexity, and structure. They may contain simple algebraic relationships, systems of ordinary or partial differential equations, models derived from Bayesian statistics, and “black-box” models whose internal details are not accessible and can be accessed only by supplying inputs and observing outputs.

1.2 Continuous Optimization

In continuous optimization, the variables in the model are nominally allowed to take on a continuous range of values, usually real numbers. This feature distinguishes continuous optimization from discrete or combinatorial optimization, in which the variables may be binary (restricted to the values 0 and 1), integer (for which only integer values are allowed), or more abstract objects drawn from sets with finitely many elements. (DISCRETE OPTIMIZATION [IV.38] is the subject of another article in this volume.)

The algorithms used to solve continuous optimization problems typically generate a sequence of values of the variables, known as *iterates*, that converge to a solution of the problem. In deciding how to step from one iterate to the next, the algorithm makes use of knowledge gained at previous iterates, and information about the model at the current iterate, possibly including information about its sensitivity to perturbations in the variables. The continuous nature of the problem allows sensitivities to be defined in terms of first

and second derivatives of the functions that define the models.

1.3 Standard Paradigms

Research in continuous optimization tends to be organized into several paradigms, each of which makes certain assumptions about the properties of the objective function, variables, and constraints. To define these paradigms, we group the variables into a real vector x with n components (that is, $x \in \mathbb{R}^n$) and define the general continuous optimization problem as follows:

$$\begin{aligned} \min_{x \in \mathbb{R}^n} f(x) & \quad (1a) \\ \text{subject to } c_i(x) = 0, \quad i \in \mathcal{E}, & \quad (1b) \\ c_i(x) \geq 0, \quad i \in \mathcal{I}, & \quad (1c) \end{aligned}$$

where the objective f and the constraints c_i , $i \in \mathcal{E} \cup \mathcal{I}$, are real-valued functions on \mathbb{R}^n . To this formulation is sometimes added a geometric constraint

$$x \in \Omega, \quad (2)$$

where $\Omega \subset \mathbb{R}^n$ is a closed convex set. (Any nonconvexity in the feasible set is conventionally captured by the algebraic constraints (1b) and (1c) rather than the geometric constraint (2).) All functions in (1) are assumed to at least be continuous. A point x that satisfies all the constraints is said to be *feasible*.

There is considerable flexibility in the way that a given optimization problem can be formulated; the choice of formulation has a strong bearing on the effectiveness with which the problem can be solved. One common reformulation technique is to replace an inequality constraint by an equality constraint plus a bound by introducing a new “slack” variable:

$$c_i(x) \leq 0 \Leftrightarrow c_i(x) + s_i = 0, \quad s_i \geq 0.$$

Referring to the general form (1), we distinguish several popular paradigms.

- In *linear programming*, the objective function and the constraints are affine functions of x ; that is, they have the form $a^T x + b$ for some $a \in \mathbb{R}^n$ and $b \in \mathbb{R}$.
- In *quadratic programming*, we have

$$f(x) = \frac{1}{2} x^T Q x + c^T x + d$$

for some $n \times n$ symmetric matrix Q , vector $c \in \mathbb{R}^n$, and scalar $d \in \mathbb{R}$, while all constraints c_i are linear. When Q is positive-semidefinite, we have a *convex quadratic program*.

- In *convex programming*, the objective f and the negated inequality constraint functions $-c_i$, $i \in \mathcal{I}$, are convex functions, while the equality constraints c_i , $i \in \mathcal{E}$, are affine functions. (These assumptions, along with the convexity and closedness of Ω in the case when (2) is included in the formulation, imply that the set of feasible points is closed and convex.)
- *Conic optimization* problems have the form (1), (2), where the set Ω is assumed to be a closed, convex cone that is pointed (that is, it contains no straight line), while the objective f and equality constraints c_i , $i \in \mathcal{E}$, are assumed to be affine. There are no inequalities; that is, $\mathcal{I} = \emptyset$.
- In *unconstrained optimization*, there are not any constraints (1b), (1c), and (2), while the objective f is usually assumed to be smooth, with at least continuous first derivatives. *Nonsmooth optimization* allows f to have discontinuous first derivatives, but it is often assumed that f has some other structure that can be exploited by the algorithms.
- In *nonlinear programming*, the functions f and c_i , $i \in \mathcal{E} \cup \mathcal{I}$, are generally nonlinear but smooth, at least having continuous first partial derivatives on the region of interest.

An important special class of conic optimization problems is *semidefinite programming*, in which the vector x of unknowns contains the elements of a symmetric $m \times m$ matrix X that is required to be positive-semidefinite. It is natural and useful to write this problem in terms of the matrix X as follows:

$$\min_{X \in S\mathbb{R}^{m \times m}} C \bullet X \quad (3a)$$

$$\text{subject to } A_i \bullet X = b_i, \quad i = 1, 2, \dots, p, \quad (3b)$$

$$X \succeq 0. \quad (3c)$$

Here, $S\mathbb{R}^{m \times m}$ denotes the set of symmetric $m \times m$ matrices, the matrices C and A_i , $i = 1, 2, \dots, p$, all belong to $S\mathbb{R}^{m \times m}$, and the operator \bullet is defined on pairs of matrices in $S\mathbb{R}^{m \times m}$ as follows:

$$X \bullet Z = \sum_{i=1}^m \sum_{j=1}^m x_{ij} z_{ij} = \text{trace}(XZ).$$

The constraint (3c) instantiates the geometric constraint (2).

Terminology

“Mathematical programming” is a historical term that encompasses optimization and closely related areas such as complementarity problems. Its origins date to

the 1940s, with the development of the simplex method of George Dantzig, the first effective method for linear programming (7). The term “programming” originally referred to the formalized, systematic mathematical procedure by which problems can be solved. Only later did “programming” become roughly synonymous with “computer programming,” causing some confusion that optimization researchers have often been called on to explain. The more modern term “optimization” is generally preferred, although the term “programming” is still attached (probably forever) to such problems as linear programming and integer programming.

1.4 Scope of Research

Research in optimization encompasses

- study of the mathematical properties of the problems themselves;
- development, testing, and analysis of algorithms for solving particular classes of problems (such as one of the paradigms described above); and
- development of models and algorithms for specific application areas.

We give a brief description of each of these aspects.

One topic of fundamental interest is the characterization of solution sets: are there verifiable conditions that we can check to determine whether a given point is a solution to the optimization problem? Given the uncertainty that is present in many practical settings, we may also be interested in the sensitivity of the solution to perturbations in the data or in the objective and constraint functions. Ill-conditioned problems are those in which the solution can change significantly when the data or functions change slightly. Another important fundamental concept is *duality*. Often, the data and functions that define an optimization problem can be rearranged to produce a new “dual” problem that is related to the original problem in interesting ways. The concept of duality can also be of great practical importance in designing more efficient formulations and algorithms.

The study of algorithms for optimization problems blends theory and practice. The design of algorithms that work well on practical problems requires a good deal of intuition and testing. Most algorithms in use today have a solid theoretical basis, but the theory often allows wide latitude in the choice of certain parameters, and algorithms are often “engineered” to

find suitable values for these parameters and to incorporate other heuristics. Analysis of algorithms tackles such issues as whether the iterates can be guaranteed to converge to a solution (or some other point of interest); whether there is an upper bound on the number of iterations needed, as a function of the size or complexity of the problem; and the rate of convergence, particularly after the iterates enter a certain neighborhood of the solution. Algorithmic analysis is typically worst-case in nature. It gives important indications about how the algorithm will behave in practice, but it does not tell the whole story. Famously, the simplex method (described in section 3.1) is known to perform badly in the worst case—its running time may be exponential in the problem size—yet its performance on most practical problems is impressively good.

Development of software that implements efficient algorithms is another important activity. High-quality codes are available both commercially and in the public domain. Modeling tools—high-level languages that serve as a front end to algorithmic software packages—have become more popular in recent years. They relieve users of much of the burden of transforming their practical problem to a set of functions (the objective and constraint functions in (1)), allowing the model to be expressed in intuitive terms, related more directly to the application.

With the growth in the size and complexity of practical optimization problems, issues of modeling, formulation, and customized algorithm design have become more prominent. A particular application can be formulated as an optimization problem in many different ways, and different formulations can lead to very different solver performance. Experience and testing is often required to identify the most effective formulation.

Many modern applications cannot be solved effectively with packaged software for one of the standard paradigms of section 1.3. It is necessary to assemble a customized algorithm, drawing on a variety of algorithmic elements from the optimization toolbox and also on tools from other disciplines in scientific computing. This approach allows the particular structure or context of the problem to be exploited. Examples of special context include the following.

- Low-accuracy solutions may suffice for some problems.
- Algorithms that require less data movement—or sampling from a large data set, or the ability to handle streaming data—may be essential in other settings.

- Algorithms that produce (possibly suboptimal) solutions in real time may be essential in such contexts as industrial control.

1.5 Connections

Continuous optimization is a highly interconnected discipline, having close relationships with other areas of mathematics, with scientific computing, and with numerous application areas. It also has close connections to discrete optimization, which often requires continuous optimization problems to be solved as subproblems or relaxations.

In mathematics, continuous optimization relies heavily on various forms of mathematical analysis, especially real analysis and functional analysis. Certain types of analysis have been developed in close association with the discipline of optimization, including convex analysis, nonsmooth analysis, and variational analysis. The theory of computational complexity also plays a role in the study of algorithms. Game theory is particularly relevant when we examine duality and optimality conditions for optimization problems. Control theory is also relevant: for framing problems involving dynamical models and as an important source of applications for optimization. Statistics provides vital tools for stochastic optimization and for optimization in machine learning, in which the model is available only through sampling from a data set.

Continuous optimization also intersects with many areas in numerical analysis and scientific computing. Numerical linear algebra is vitally important, since many optimization algorithms generate a sequence of linear approximations, and these must be solved with linear algebra tools. Differential equation solvers are important counterparts to optimization in applications such as data assimilation and distributed parameter identification, which involve optimization of ordinary differential equation and partial differential equation models. The ubiquity of multicore architectures and the wide availability of cluster computing have given new prominence to parallel algorithms in some areas (such as machine learning), requiring the use of software tools for parallel computing.

Finally, we mention some of the many connections between optimization and the application areas within which it has become deeply embedded. Machine learning uses optimization algorithms extensively to perform classification and learning tasks. The challenges posed by machine learning applications (e.g., large

data sets) have driven recent developments in stochastic optimization and large-scale unconstrained optimization. Compressed sensing, in which sparse signals are recovered from randomized encodings, also relies heavily on optimization formulations and specialized algorithms. Engineering control is a rich source of challenging optimization problems at many scales, frequently involving dynamic models of plant processes. In these and many other areas, practitioners have made important contributions to all aspects of continuous optimization.

2 Basic Principles

We mention here some basic theory that underpins continuous optimization and that serves as a starting point for the algorithms outlined in later sections.

Possibly the most fundamental issues are how we define a solution to a problem and how we recognize a given point as a solution. The answers become more complicated as we expand the classes of functions allowed in the formulation. The type of solution most amenable to analysis is a *local solution*. The point x^* is a local solution of (1) if x^* is feasible and if there is an open neighborhood \mathcal{N} of x^* such that $f(x) \geq f(x^*)$ for all feasible points $x \in \mathcal{N}$. Furthermore, x^* is a *strict local solution* if $f(x) > f(x^*)$ for all feasible $x \in \mathcal{N}$ with $x \neq x^*$. A *global solution* is a point x^* such that $f(x) \geq f(x^*)$ for all feasible x .

As we see below, we can use the derivatives of the objective and constraint functions to construct testable conditions that verify that x^* is a local solution under certain assumptions. It is difficult to verify global optimality, even when the objective and constraint functions are smooth, because of the difficulty of gaining a global perspective on these functions. However, in *convex optimization*, where the objective f is a convex function and the set of feasible points is also convex, all local solutions are global solutions. (Convex optimization includes linear programming and conic optimization as special cases.)

Global optimization techniques have also been devised for certain classes of nonconvex problems. It is possible to prove results about the performance of such methods when the function f satisfies additional properties (such as Lipschitz continuity, with known Lipschitz constant) and the feasible region is bounded. One class of methods for solving the global optimization problem uses a process of subdividing the feasible region and using information about f to obtain a

lower bound on the objective in that region, leading to a branch-and-bound algorithm akin to methods used in integer programming.

We now turn to characterizations of local solutions for problems defined by smooth functions, assuming for simplicity that f and c_i , $i \in \mathcal{I} \cup \mathcal{I}$, have continuous second partial derivatives. We use $\nabla f(x)$ to denote the gradient of f (the vector $[\partial f / \partial x_i]_{i=1}^n$ of first partial derivatives) and $\nabla^2 f(x)$ to denote the Hessian of f (the $n \times n$ matrix $[\partial^2 f / \partial x_i \partial x_j]_{i,j=1}^n$ of second partial derivatives). An important tool, both in the characterization of solutions for smooth problems and in the design of algorithms, is *Taylor's theorem*. This result can be used to estimate the value of f by using its derivative information at a nearby point. For example, we have

$$f(x + p) = f(x) + \nabla f(x)^T p + o(\|p\|), \quad (4a)$$

$$\begin{aligned} f(x + p) &= f(x) + \nabla f(x)^T p \\ &\quad + \frac{1}{2} p^T \nabla^2 f(x) p + o(\|p\|^2), \end{aligned} \quad (4b)$$

where the notation $o(t)$ indicates a quantity that goes to zero faster than t . These formulas can be used to construct low-order approximations to (1) that are valid in the neighborhood of a current iterate x and can thus be used to identify a possibly improved iterate $x + p$.

For unconstrained optimization of a smooth function f , we have the following necessary condition.

If x^* is a local solution of $\min_x f(x)$, then $\nabla f(x^*) = 0$.

Note that this is only a *necessary* condition; it is possible to have $\nabla f(x) = 0$ without x being a minimizer. (An example is the scalar function $f(x) = x^3$, which has no minimizer but which has $\nabla f(0) = 0$.) To complement this result, we have the following sufficient condition.

If x^* is a point such that $\nabla f(x^*) = 0$ with $\nabla^2 f(x^*)$ positive-definite, then x^* is a strict local solution of $\min_x f(x)$.

Turning to constrained optimization—the general form (1), with smooth functions—characterization of local solutions becomes somewhat more complex. A central role is played by the *Lagrangian* function, defined as follows:

$$\mathcal{L}(x, \lambda) = f(x) - \sum_{i \in \mathcal{I} \cup \mathcal{I}} \lambda_i c_i(x). \quad (5)$$

This is a linear combination of objective and constraint functions, where the weights λ_i are called *Lagrange multipliers*. The following set of conditions, known as the *Karush-Kuhn-Tucker conditions* or *KKT conditions*

after their inventors, are closely related to local optimality of x^* for the problem (1): there exist $\lambda_i^*, i \in \mathcal{E} \cup \mathcal{I}$, such that

$$\nabla_x \mathcal{L}(x^*, \lambda^*) = 0, \quad (6a)$$

$$c_i(x^*) = 0, \quad i \in \mathcal{E}, \quad (6b)$$

$$c_i(x^*) \geq 0, \quad i \in \mathcal{I}, \quad (6c)$$

$$\lambda_i^* \geq 0, \quad i \in \mathcal{I}, \quad (6d)$$

$$\lambda_i^* c_i(x^*) = 0, \quad i \in \mathcal{I}. \quad (6e)$$

Condition (6e) is a *complementarity condition* that indicates complementarity between each inequality constraint value $c_i(x^*)$ and its Lagrange multiplier λ_i^* ; for each i , at least one of these two quantities must be zero. Roughly speaking, the Lagrange multipliers measure the sensitivity of the optimal objective value $f(x^*)$ to perturbations in the constraints c_i . When x^* is a local solution of (1), the KKT conditions will hold, provided an additional condition called a *constraint qualification* is satisfied. The constraint qualification requires the true geometry of the feasible set near x^* to be captured by linear approximations to the constraint functions around x^* .

When the functions in (1) are nonsmooth, it becomes harder to define optimality conditions, as even the concept of derivative becomes more complicated. We consider the simplest problem of this type: the unconstrained problem $\min_x f(x)$, where f is a convex (possibly nonsmooth) function. The *subdifferential* of f at a point x is defined from the collection of supporting hyperplanes to f at x :

$$\partial f(x) := \{v : f(z) \geq f(x) + v^T(z - x) \text{ for all } z \text{ in the domain of } f\}.$$

For example, the function $f(x) = \|x\|_1 = \sum_{i=1}^n |x_i|$ is nonsmooth, with subdifferential consisting of the vectors v such that

$$v_i = +1 \quad \text{if } x_i > 0,$$

$$v_i \in [-1, 1] \quad \text{if } x_i = 0,$$

$$v_i = -1 \quad \text{if } x_i < 0.$$

When f is smooth at x in addition to being convex, we have $\partial f(x) = \{\nabla f(x)\}$. A necessary and sufficient condition for x^* to be a solution of $\min_x f(x)$ is that $0 \in \partial f(x^*)$.

3 Linear Programming

Consider the problem

$$\min_x c^T x \quad \text{subject to } Ax = b, x \geq 0, \quad (7)$$

where $x \in \mathbb{R}^n$ as before, $b \in \mathbb{R}^m$ is the right-hand side, and $A \in \mathbb{R}^{m \times n}$ is the constraint matrix. Any optimization problem with an affine objective function and affine constraints can, after some elementary transformations, be written in this standard form. As illustrated by the example in figure 1, the feasible region for the problem (7) is polyhedral, and the contours of the objective function are lines.

There are three possible outcomes for a linear program.

- (a) The problem is *infeasible*; that is, there is no point x that satisfies $Ax = b$ and $x \geq 0$.
- (b) The problem is *unbounded*; that is, there is a sequence of feasible points x^k such that $c^T x^k \downarrow -\infty$.
- (c) The problem has a solution; that is, there is a feasible point x^* such that $c^T x^* \leq c^T x$ for all feasible x .

When a solution exists (case (c)), it may not be uniquely defined. However, we can note that the set of solutions itself forms a polyhedron and that at least one solution lies at a *vertex* of this polyhedron, that is, at a point that does not lie in the interior of a line joining any other two points in the polyhedron.

By rearranging the data in (7), we obtain another linear program called the *dual*:

$$\max_{\lambda, s} b^T \lambda \quad \text{subject to } A^T \lambda + s = c, s \geq 0. \quad (8)$$

(In discussions of duality, the original problem (7) is called the *primal* problem.) The primal and dual problems are related by a powerful *duality theory* that has important practical implications. *Weak duality* states that, if x is a feasible point for (7) and (λ, s) is a feasible point for (8), then the primal objective is greater than or equal to the dual objective. This statement is easily proved in a single line:

$$c^T x = (A^T \lambda + s)^T x \geq \lambda^T A x = \lambda^T b.$$

The other fundamental duality result—*strong duality*—states that there are three possible outcomes for the pair of problems (7) and (8):

- (a) one of the two problems is infeasible and the other is unbounded;
- (b) both problems are infeasible; or
- (c) (7) has a solution x^* and (8) has a solution (λ^*, s^*) with objective functions equal (that is, $c^T x^* = b^T \lambda^*$).

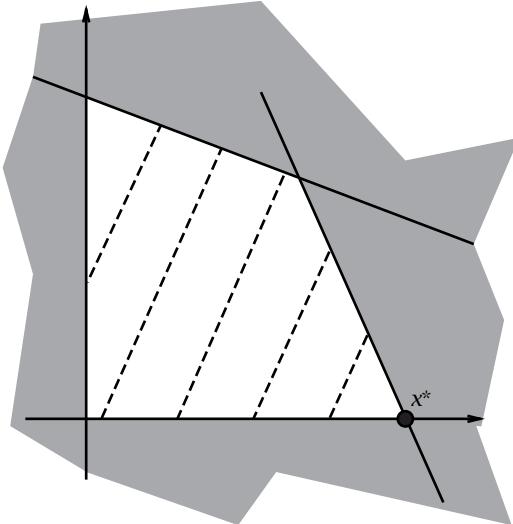

Figure 1 Feasible region (unshaded), objective function contours (dashed lines), and optimal vertex x^* for a linear program in two variables.

Specializing (6) to the case of linear programming, we see that the primal and dual problems share a common set of KKT conditions:

$$Ax = b, \quad A^T \lambda + s = c, \quad (9a)$$

$$x \geq 0, \quad s \geq 0, \quad (9b)$$

$$x_i s_i = 0, \quad i = 1, 2, \dots, n. \quad (9c)$$

If (x^*, λ^*, s^*) is any vector triple that satisfies these conditions, x^* is a solution of (7) and (λ^*, s^*) is a solution of (8).

We now discuss the two most important classes of algorithms for linear programming.

3.1 The Simplex Method

The simplex method, devised by George Dantzig in the 1940s, remains a fundamental approach of practical and theoretical importance in linear programming. Geometrically speaking, the simplex method moves from vertex to neighboring vertex of the feasible set, decreasing the objective function with each move and terminating when it cannot find a neighboring vertex with a lower objective value. The method is implemented by maintaining a *basis*: a subset of m out of the n components of x that are allowed to be nonzero at the current iteration. The values of these basic components of x are determined uniquely by the m linear constraints $Ax = b$. Each step of the simplex method starts by choosing a nonbasic variable to enter the basis. This

variable is allowed to increase away from zero, a process that, because of the requirement to maintain feasibility of the linear constraints $Ax = b$, causes the values of the existing basic variables to change. The entering variable is allowed to increase to the point where one of the basic variables reaches zero, upon which it leaves the basis, and the iteration is complete.

Efficient implementation of the simplex method depends both on good “pricing” strategies (to choose which nonbasic variable should enter the basis) and on efficient linear algebra (to update the values of the basic variables as the entering variable increases away from zero). Both topics have seen continued development over the years, and highly effective software is available, both commercially and in the public domain. Specialized, highly efficient versions of the simplex method exist for some special cases of linear programming, such as those arising from transportation or routing over networks.

The simplex method is an example of an active-set method: a subset of the inequality constraints (which are the bounds $x \geq 0$) is held to be *active* at each iteration. In the simplex method, the active set consists of the nonbasic variables, those indices i for which $x_i = 0$. This active set changes only slightly from one iteration to the next; in fact, the simplex method changes just a single component of the active (nonbasic) set at each iteration.

The theoretical properties of the simplex method remain a source of fascination because, despite its practical efficiency, its worst-case behavior is poor. In an article from 1972, Klee and Minty famously showed that the number of steps may be exponential in the dimension of the problem. There have been various attempts to understand the “average-case” behavior, in which the number of iterations required is roughly linear in the problem dimensions, that is, the numbers of variables and constraints. The “smoothed analysis” of Spielman and Teng shows that any linear program for which the simplex method behaves badly can be modified, with small perturbations, to become a problem that requires only polynomially many iterations.

An algorithm with polynomial complexity (in the worst case) was announced in 1979: Khachiyan’s ellipsoid algorithm. Though of great theoretical interest, it was not a practical alternative to simplex. The interior-point revolution began with Karmarkar’s algorithm (in 1984); this is also a polynomial-time approach, but it has much better computational properties than the ellipsoid approach. It motivated a new class of

algorithms—primal-dual interior-point methods—that not only had attractive theoretical properties but were also truly competitive with the simplex method on practical problems. We describe these next.

3.2 Interior-Point Methods

As their name suggests, primal-dual interior-point methods generate a sequence of iterates (x^k, λ^k, s^k) , $k = 1, 2, \dots$, in both primal and dual variables, in which x^k and s^k contain all positive numbers (that is, they are strictly feasible with respect to the constraints $x \geq 0$ and $s \geq 0$ in (9b)). Steps between iterates are obtained by applying Newton's method to a perturbed form of the condition (9c) in which the right-hand side 0 is replaced by a positive quantity $\mu_k > 0$, which is gradually decreased to zero as $k \rightarrow \infty$. The Newton equations for each step $(\Delta x^k, \Delta \lambda^k, \Delta s^k)$ are obtained from a linearization of these perturbed KKT conditions: specifically,

$$\begin{bmatrix} 0 & A^T & I \\ A & 0 & 0 \\ S & 0 & X \end{bmatrix} \begin{bmatrix} \Delta x^k \\ \Delta \lambda^k \\ \Delta s^k \end{bmatrix} = - \begin{bmatrix} A^T \lambda^k + s^k - c \\ Ax^k - b \\ X^k S^k e - \mu_k \mathbf{1} \end{bmatrix},$$

where X^k is the diagonal matrix whose diagonal elements come from x^k , S^k is defined similarly, and $\mathbf{1}$ is the vector of length n whose elements are all 1. The new iteration is obtained by setting

$$\begin{aligned} (x^{k+1}, \lambda^{k+1}, s^{k+1}) \\ = (x^k + \alpha_k \Delta x^k, \lambda^k + \beta_k \Delta \lambda^k, s^k + \beta_k \Delta s^k), \end{aligned}$$

where α_k and β_k are step lengths in the range $[0, 1]$ chosen so as to ensure that $x^{k+1} > 0$ and $s^{k+1} > 0$, among other goals. Convergence, with polynomial complexity, can be demonstrated under appropriate schemes for choosing μ_k and the step lengths α_k and β_k . Clever schemes for choosing these parameters and for enhancing the search directions using “second-order corrections” lead to good practical behavior.

Primal-dual interior-point methods have the additional virtue that they are easily extendible to convex quadratic programming and monotone linear complementarity problems, with only minor changes to the algorithm and the convergence theory. As we see in section 6.3, they can also be extended to general nonlinear programming, though the modifications in this case are more substantial and the convergence guarantees are weaker.

4 Unconstrained Optimization

Consider the problem of simply minimizing a function without constraints:

$$\min_x f(x),$$

where f has at least continuous first derivatives. This problem is important in its own right. It also appears as a subproblem in many methods for constrained optimization, and it serves to illustrate several algorithmic techniques that can also be applied to the constrained case.

4.1 First-Order Methods

The Taylor approximation (4a) shows that f decreases most rapidly in the direction of the negative gradient vector $-\nabla f(x)$. Steepest-descent methods move in this direction, each iteration having the form

$$x^{k+1} = x^k - \alpha_k \nabla f(x^k),$$

for some positive step length α_k . A suitable value of α_k can be found by performing (approximately) a one-dimensional search along the direction $-\nabla f(x^k)$, thus guaranteeing a decrease in f at every iteration. When further information about f is available, it may be possible to choose α_k to guarantee descent in f without doing a line search. A nonstandard approach, which first appeared in a 1988 paper by Barzilai and Borwein, chooses α_k according to a formula that allows f to increase (sometimes dramatically) on some iterations, while often achieving better long-term behavior than standard steepest-descent approaches.

For the case of convex f , there has been renewed focus on accelerated first-order methods that still require only the calculation of a gradient ∇f at each step but that have more attractive convergence rates than steepest descent, both in theory and in practice. The common aspect of these methods is a “momentum” device, in which the step from x^k to x^{k+1} is based not just on the latest gradient $\nabla f(x^k)$ but also on the step from the previous iterate x^{k-1} to the current iterate x^k . In *heavy-ball* and *conjugate gradient* methods, the steps have the form

$$x^{k+1} = x^k - \alpha_k \nabla f(x^k) + \beta_k (x^k - x^{k-1})$$

for positive parameters α_k and β_k , which are chosen in a variety of ways. Accelerated methods that have been proposed more recently also make use of momentum together with the latest gradient $\nabla f(x^k)$, but combine these factors in different ways. Some methods separate the steepest-descent steps from the momentum steps,

alternating between these two types of steps to produce two interleaved sequences of iterates, rather than the single sequence $\{x^k\}$.

For convex f , first-order methods are characterized in some cases by linear convergence (with the error in x^k decreasing to zero in a geometric sequence) or sublinear convergence (with the error decreasing to zero but not geometrically, typically at a rate of $1/k$ or $1/k^2$, where k is the iteration number).

4.2 Superlinear Methods

When second derivatives of f are available, we can use the second-order Taylor approximation (4 b) to motivate *Newton's method*, a fundamental algorithm in both optimization and nonlinear equations. When $\nabla^2 f$ is positive-definite at the current iterate x^k , we can define the step p^k to be the minimizer of the right-hand side of (4 b) (with the $o(\|p\|^2)$ term omitted), yielding the formula

$$p^k = -[\nabla^2 f(x^k)]^{-1} \nabla f(x^k). \quad (10)$$

The next iterate is defined by choosing a step length $\alpha_k > 0$ and setting $x^{k+1} = x^k + \alpha_k p^k$. This method is characterized by *quadratic* convergence, in which the error in x^{k+1} is bounded by a constant multiple of the *square* of the error in x^k , for all x^k sufficiently close to the solution x^* . (The number of digits of agreement between x^k and x^* doubles at each of the last few iterations.)

Enhancements of the basic approach based on (10) yield more robust and general implementations. For example, the Hessian matrix $\nabla^2 f(x^k)$ may be modified during the computation of p^k to ensure that it is a descent direction for f . Another important class of methods known as *quasi-Newton* methods avoids the calculation of second derivatives altogether, instead replacing $\nabla^2 f(x^k)$ in (10) by an approximation B_k that is constructed using first-derivative information. The possibility of such an approximation is a consequence of another form of Taylor's theorem, which posits the following relationship between two successive gradients:

$$\nabla f(x^{k+1}) - \nabla f(x^k) \approx \nabla^2 f(x^k)(x^{k+1} - x^k).$$

In updating the Hessian approximation to B_{k+1} after the step to x^{k+1} is taken, we ensure that B_{k+1} mimics this property of the true Hessian; that is, we enforce the condition

$$\nabla f(x^{k+1}) - \nabla f(x^k) \approx B_{k+1}(x^{k+1} - x^k).$$

We obtain a variety of quasi-Newton methods by imposing various other conditions on B_{k+1} : closeness to B_k in some metric, for example, and positive-semidefiniteness. *Limited-memory* quasi-Newton methods store B_k implicitly by means of the difference vectors between successive iterates and successive gradients at a limited number of prior iterations (typically between five and twenty).

4.3 Derivative-Free Methods

Methods that require the user to supply only function values f (and not gradients or Hessians) have been enormously popular for many years. More recently, they have attracted the attention of optimization researchers, who have tried to improve their performance, equip them with a convergence theory, and customize them to certain specific classes of problems, such as problems in which f is obtained from a simulation.

In the absence of gradient or Hessian values, it is sometimes feasible to use finite differencing to construct approximations to these higher-order quantities and then apply the methods described above. Another possible option is to use algorithmic differentiation to obtain derivatives directly from computer code and, once again, use them in the algorithms described above.

Methods that use only function values are usually best suited to problems of modest dimension n . *Model-based methods* use interpolation among function values at recently visited points to construct a model of the function f . This model is used to generate a new candidate, which is accepted as the next iterate if it yields a sufficient improvement in the function value over the best point found so far. The model is updated by changing the set of points on which the interpolation is based, replacing older points with higher values of f by newer points with lower function values. *Pattern-search methods* take candidate steps along a fixed set of directions, shrinking step lengths as needed to evaluate a new iterate with a lower function value. After a successful step, the step length may be increased, to speed future progress. Appropriate maintenance of the set of search directions is crucial to efficient implementation and valid convergence theory. Another derivative-free method is the enormously popular *simplex method* of Nelder and Mead from 1965. This method—unrelated to the method of the same name for linear programming—maintains a set of $n+1$ points that form the vertex of a simplex in \mathbb{R}^n . At each

iteration, it replaces one of these points with a new one, by expanding or contracting the simplex along promising directions or reflecting one of the vertices through its opposite face. Various attempts have been made in the years since to improve the performance of this method and to develop a convergence theory.

4.4 Stochastic Gradient Methods

Important problems have recently been identified for which evaluation of ∇f or even f is computationally expensive but where it is possible to obtain an unbiased estimate of ∇f cheaply. Such problems are common in data analysis, where f typically has the form

$$f(x) = \frac{1}{N} \sum_{i=1}^N f_i(x)$$

for large N , where each f_i depends on a single item in the data set. If i is selected at random from $\{1, 2, \dots, N\}$, the vector $g^k = \nabla f_i(x^k)$ is an unbiased estimate of $\nabla f(x^k)$. For convex f , methods that use this approximate gradient information have been a focus of work in the optimization and machine learning communities for some years, and efforts have recently intensified as their wide applicability has become evident. The basic iteration has the form $x^{k+1} = x^k - \alpha_k g^k$, where the choice of g^k may be based on additional information about f , such as lower and upper bounds on its curvature. (Line searches are not practical in this setting, as evaluation of f is assumed to be too expensive.) Additional devices such as averaging of the iterates x^k or the gradient estimates g^k enhance the properties of the method in some settings, such as when f is only weakly convex. Typical convergence analysis shows that the *expected* value of the error in x^k , or of the difference between the function value after k iterations and its optimal value, approaches zero at a sublinear rate, such as $O(1/k)$ or $O(1/\sqrt{k})$.

5 Conic Optimization

Conic optimization problems have the form

$$\min c^T x \quad \text{subject to } Ax = b, x \in \Omega,$$

where Ω is a closed, convex, pointed cone. They include linear programming (7) and semidefinite programming (3) as special cases. It is possible to design generic algorithms with good complexity properties for this problem class provided that we can identify a certain type of *barrier function* for Ω . A barrier function φ is convex with domain the interior of Ω , with $\varphi(x) \rightarrow \infty$ as x

approaches the boundary of Ω . The additional property required for an efficient algorithm is *self-concordancy*, which is the property that for any x in the domain of φ , and any $v \in \mathbb{R}^n$, we have that

$$|t'''(0)| \leq 2|t''(0)|^{3/2},$$

where $t(\alpha) := \varphi(x + \alpha v)$. Because the third derivatives are bounded in terms of the second derivatives, the function φ is well approximated (locally at least) by a quadratic, so we can derive complexity bounds on Newton's method applied to φ , with a suitable step-length scheme. We can use this barrier function to define an interior-point method in which each iterate x^k is obtained by finding an approximate minimizer of the following equality-constrained optimization problem:

$$\min_x c^T x + \mu_k \varphi(x) \quad \text{subject to } Ax = b,$$

where the positive parameter μ_k can be decreased gradually to zero as k increases, as in interior-point methods for linear programming. One or more steps of Newton's method can be used to find the approximate solution to this subproblem, starting from the previous iterate.

For linear programming, the cone $\Omega = \{x \mid x \geq 0\}$ admits a self-concordant barrier function $\varphi(x) = -\sum_{i=1}^n \log x_i$. In semidefinite programming, where Ω is the cone of positive-semidefinite matrices, we have $\varphi(X) = -\log \det X$.

In practice, the most successful interior-point methods for semidefinite programming are primal-dual methods rather than primal methods. These methods are (nontrivial) extensions of the linear programming approaches of section 3.2.

6 Nonlinear Programming

Next we turn to methods for nonlinear programming, in which the functions f and c_i in (1) are smooth nonlinear functions. A basic principle used in constructing algorithms for this problem is successive approximation of the nonlinear program by simpler problems, such as quadratic programming or unconstrained optimization, to which methods from the previous sections can be applied. Taylor's theorem is instrumental in constructing these approximations, using first- or second-order expansions of functions around the current iterate x^k and possibly also the current estimates of the Lagrange multipliers for the constraints (1 b) and (1 c). The optimality conditions described in section 2 also play a central role in algorithm design.

6.1 Gradient Projection

Gradient projection is an extension of the steepest-descent approach for unconstrained optimization in which steps are taken along the negative gradient direction but projected onto the feasible set. Considering the formulation

$$\min f(x) \text{ subject to } x \in \Omega,$$

the basic gradient projection step is

$$x^{k+1} = P_{\Omega}(x^k - \alpha_k \nabla f(x^k)),$$

where $P_{\Omega}(\cdot)$ denotes projection onto the closed convex constraint set Ω . This approach may be practical if the projection can be computed inexpensively, as is the case when Ω is a “box” defined by bounds on the variables. It is possible to enhance the gradient method by using second-order information in a selective way (simple projection of the Newton step does not work).

6.2 Sequential Quadratic Programming

In sequential quadratic programming we use Taylor's theorem to form the following approximation of (1) around the current point x^k :

$$\min_{d \in \mathbb{R}^n} \nabla f(x^k)^T d + \frac{1}{2} d^T H_k d \quad (11a)$$

$$\text{subject to } c_i(x^k) + \nabla c_i(x^k)^T d = 0, \quad i \in E, \quad (11b)$$

$$c_i(x^k) + \nabla c_i(x^k)^T d \geq 0, \quad i \in I, \quad (11c)$$

where H_k is a symmetric matrix. Denoting the solution of (11) by d^k , the next iterate is obtained by setting

$$x^{k+1} = x^k + \alpha_k d^k$$

for some step length $\alpha_k > 0$. The subproblem (11) is a quadratic program; it can be solved with methods of active-set or interior-point type. The matrix H_k may contain second-order information from both objective and constraint functions; an “ideal” value is the Hessian of the Lagrangian function defined in (5), that is, $H_k = \nabla_{xx}^2 \mathcal{L}(x^k, \lambda^k)$, where λ^k are estimates of the Lagrange multipliers, obtained for example from the solution of the subproblem (11) at the previous iteration. When second derivatives are not readily available, H_k could be a quasi-Newton approximation to the Lagrangian Hessian, updated by formulas similar to those used in unconstrained optimization.

A line search can be performed to find a suitable value of α_k in the update step. An alternative approach to stabilizing sequential quadratic programming is to add a “trust region” to the subproblem (11), in the form of a constraint $\|d\|_{\infty} \leq \Delta_k$, for some $\Delta_k > 0$.

6.3 Interior-Point Methods

The interior-point methods for linear programming described in section 3.2 can be extended to nonlinear programming, and software based on such extensions has been highly successful. To avoid notational clutter, we consider a formulation of nonlinear programming containing nonnegativity constraints on x along with equality constraints:

$$\min f(x) \text{ subject to } c_j(x) = 0, \quad j \in E; \quad x \geq 0. \quad (12)$$

(This problem is no less general than (1); simple transformations can be used to express (1) in the form (12).) Following (6), and introducing an additional vector s in the style of (9), we can write the optimality conditions for this problem as

$$\nabla f(x) - \sum_{j \in E} \lambda \nabla c_j(x) - s = 0, \quad (13a)$$

$$c_j(x) = 0, \quad j \in E, \quad (13b)$$

$$x \geq 0, \quad s \geq 0, \quad (13c)$$

$$x_i s_i = 0, \quad i = 1, 2, \dots, n. \quad (13d)$$

As in linear programming, interior-point methods generate a sequence of iterates (x^k, λ^k, s^k) in which all components of x^k and s^k are strictly positive. The basic primal-dual step is obtained by applying Newton's method at (x^k, λ^k, s^k) to the nonlinear equations defined by (13a), (13b), and (13d), with the right-hand side in (13d) replaced by a positive parameter μ_k , which is reduced to zero gradually as the iterations progress. The basic approach can be enhanced in various ways: quasi-Newton approximations, line searches or trust regions, second-order corrections to the search direction, and so on.

6.4 Augmented Lagrangian Methods

An approach for solving (12) that was first proposed in the early 1970s is enjoying renewed popularity because of its successful use in new application areas. Originally known as the “method of multipliers,” it is founded on the augmented Lagrangian function

$$\mathcal{L}_A(x, \lambda; \mu) := f(x) + \sum_{j \in E} \lambda_j c_j(x) + \frac{1}{2\mu} \sum_{j \in E} c_j^2(x)$$

for some positive parameter μ . The method defines a sequence of primal-dual iterates (x^k, λ^k) for a given sequence of parameters $\{\mu_k\}$, where each iteration is defined as follows:

- obtain x^{k+1} by solving (approximately) the problem

$$\min_x \mathcal{L}_A(x, \lambda^k; \mu_k) \quad \text{subject to } x \geq 0; \quad (14)$$

- update Lagrange multipliers

$$\lambda_j^{k+1} = \lambda_j^k + c_j(x^k)/\mu_k, \quad j \in \mathcal{E};$$

- choose $\mu_{k+1} \in (0, \mu_k]$ by some heuristic.

The original problem with nonlinear constraints is replaced by a sequence of bound-constrained problems (14). Unlike in interior-point methods, it is not necessary to drive the parameters μ_k to zero to obtain satisfactory convergence. Although the motivation for this approach is perhaps not as clear as for other algorithms, it can be seen that, if the Lagrange multipliers λ^k happen to be optimal in (14), then the solution of the original nonlinear program (12) would also be optimal for this subproblem. Under favorable assumptions, and provided that the sequence $\{\mu_k\}$ is chosen judiciously, we find that the sequence (x^k, λ^k) converges to a point satisfying the optimality conditions (13).

Augmented Lagrangian methods were first proposed by Hestenes (in 1969) and Powell (in 1969). A 1982 book by Bertsekas was influential in later developments. The approach has proved particularly useful in “splitting” schemes, where the objective f is decomposed naturally into a sum of functions, each of which is assigned its own copy of the variable vector x . Equality of the different copies is enforced via equality constraints, and the augmented Lagrangian method is applied to the resulting equality-constrained problem. The appeal of this approach is that minimization with respect to each copy of x can be performed independently and these individual minimizations may be simpler to perform than minimization of the original function f . Moreover, the possibility arises of performing these minimizations simultaneously on a parallel computer.

6.5 Penalty Functions and Filters

Penalty functions combine the objective and constraint functions for a nonlinear program (1) into a single function, yielding an alternative problem whose solution is an approximate solution to the original constrained problem. The augmented Lagrangian function of section 6.4 can be viewed as a penalty function. Another important case is the ℓ_1 penalty function, which is defined as follows:

$$f(x) + \nu \sum_{i \in \mathcal{E}} |c_i(x)| + \nu \sum_{i \in \mathcal{I}} \max(-c_i(x), 0), \quad (15)$$

where $\nu > 0$ is a chosen *penalty parameter*. Note that each term in the summations is positive if and only if the corresponding constraint in (1) is violated. Under certain conditions, we have for ν sufficiently large that a local solution of (1) is an *exact* minimizer of (15). In other words, we can replace the constrained problem (1) by the unconstrained, but nonsmooth, problem of minimizing (15). One possible way to make use of this observation is to choose ν and minimize (15) directly, increasing ν as needed to ensure that the solutions of (15) and (1) coincide. More commonly, (15) is used as a *merit* function to evaluate the quality of proposed steps d^k generated by some other algorithm, such as sequential quadratic programming or an interior-point method. Such steps are accepted only if they produce a sufficient reduction in (15) or some other merit function.

An alternative device to decide whether proposed steps are acceptable is a *filter*, which dispenses with the penalty parameter ν in (15) and considers the objective function f and the constraint violations separately. Defining the violation measure by

$$h(x) = \sum_{i \in \mathcal{E}} |c_i(x)| + \sum_{i \in \mathcal{I}} \max(-c_i(x), 0),$$

the filter consists of a set of pairs $\{(f_\ell, h_\ell) : \ell \in F\}$ of objective and constraint values such that no pair dominates another: that is, we do not have $f_\ell \leq f_j$ and $h_\ell \leq h_j$ for any $\ell \in F$ and $j \in F$. An iterate x^k is acceptable provided that $(f(x^k), h(x^k))$ is not dominated by any point in the filter F . When accepted, the new pair is added to the filter, and any pairs that are dominated by it are removed. (This basic strategy is amended in several ways to improve its practical performance and to facilitate convergence analysis.)

7 Final Remarks

Our brief description of major problem classes in continuous optimization, and algorithms for solving them, has necessarily omitted several important topics. We mention several of these before closing.

Stochastic and *robust* optimization deal with problems in which there is uncertainty in the objective functions or constraints but where the uncertainty can be quantified and modeled. In these problems we may seek solutions that minimize the *expected value* of the uncertain objective or solutions that are guaranteed to satisfy the constraints with a certain specified probability. The stochastic gradient method of section 4.4 provides one tool for solving these problems, but there

are many other relevant techniques from optimization and statistics that can be brought to bear.

Equilibrium problems are not optimization problems, in that there is no objective to be minimized, but they use a range of algorithmic techniques that are closely related to optimization techniques. The basic formulation is as follows: given a function $F: \mathbb{R}^n \rightarrow \mathbb{R}^n$, find a vector $x \in \mathbb{R}^n$ such that

$$x \geq 0, \quad F(x) \geq 0, \quad x_i F_i(x) = 0, \quad i = 1, 2, \dots, n.$$

(Note that the KKT conditions in (6) have a similar form.) Equilibrium problems arise in economic applications and game theory. More recently, applications have been identified in contact problems in mechanical simulations.

Nonlinear equations, in which we seek a vector $x \in \mathbb{R}^n$ such that $F(x) = 0$ for some smooth function $F: \mathbb{R}^n \rightarrow \mathbb{R}^n$, arise throughout scientific computing. Newton's method, so fundamental in continuous optimization, is also key here. The Newton step is obtained by solving

$$\nabla F(x^k) d^k = -F(x^k)$$

(compare this with (10)), where $\nabla F(x) = [\partial F_i / \partial x_j]_{i,j=1}^n$ is the $n \times n$ Jacobian matrix.

IV.12 Numerical Solution of Ordinary Differential Equations

Ernst Hairer and Christian Lubich

1 Introduction: Euler Methods

Ordinary differential equations are ubiquitous in science and engineering: in geometry and mechanics from the first examples onward (Newton, Leibniz, Euler, Lagrange), in chemical reaction kinetics, molecular dynamics, electronic circuits, population dynamics,

and in many more application areas. They also arise, after semidiscretization in space, in the numerical treatment of time-dependent partial differential equations, which are even more impressively omnipresent in our technologically developed and financially controlled world.

The standard initial-value problem is to determine a vector-valued function $y: [t_0, T] \rightarrow \mathbb{R}^d$ with a given initial value $y(t_0) = y_0 \in \mathbb{R}^d$ such that the derivative $y'(t)$ depends on the current solution value $y(t)$ at every $t \in [t_0, T]$ in a prescribed way:

$$y'(t) = f(t, y(t)) \quad \text{for } t_0 \leq t \leq T, \quad y(t_0) = y_0.$$

Here, the given function f is defined on an open subset of $\mathbb{R} \times \mathbb{R}^d$ containing (t_0, y_0) and takes values in \mathbb{R}^d . If f is continuously differentiable, then there exists a unique solution at least locally on some open interval containing t_0 . In many applications, t represents time, and it will be convenient to refer to t as time in what follows.

In spite of the ingenious efforts of mathematicians throughout the eighteenth and nineteenth centuries, in most cases the solution of a differential equation cannot be given in closed form by functions that can be evaluated directly on a computer. This even applies to linear differential equations $y' = Ay$ with a square matrix A , for which $y(t) = e^{(t-t_0)A}y_0$, as computing the MATRIX EXPONENTIAL [II.14] is a notoriously tricky problem. One must therefore rely on numerical methods that are able to approximate the solution of a differential equation to any desired accuracy.

1.1 The Explicit Euler Method

The ancestor of all the advanced numerical methods in use today was proposed by Leonhard Euler in 1768. On writing down the first terms in the Taylor expansion of the solution at t_0 and using the prescribed initial value and the differential equation at $t = t_0$, it is noted that $y(t_0 + h) = y(t_0) + hy'(t_0) + \dots = y_0 + hf(t_0, y_0) + \dots$. Choosing a small step size $h > 0$ and neglecting the higher-order terms represented by the dots, an approximation y_1 to $y(t_1)$ at the later time $t_1 = t_0 + h$ is obtained by setting

$$y_1 = y_0 + hf(t_0, y_0).$$

The next idea is to take y_1 as the starting value for a further step, which then yields an approximation to the solution at $t_2 = t_1 + h$ as $y_2 = y_1 + hf(t_1, y_1)$. Continuing in this way, at the $(n+1)$ st step we take $y_n \approx y(t_n)$

as the starting value for computing an approximation at $t_{n+1} = t_n + h$ as

$$y_{n+1} = y_n + hf(t_n, y_n),$$

and after a sufficient number of steps, we reach the final time T . The computational cost of the method lies in the evaluations of the function f . The step size need not be the same in each step and could be replaced by h_n in the formula, so that $t_{n+1} = t_n + h_n$.

It is immediate that the quality of the approximation y_n depends on two aspects: the error made by truncating the Taylor expansion and the error introduced by continuing from approximate solution values. These two aspects are captured in the notions of *consistency* and *stability*, respectively, and are fundamental to all numerical methods for ordinary differential equations.

1.2 The Implicit Euler Method and Stiff Differential Equations

A minor-looking change in the method, already considered by Euler in 1768, makes a big difference; taking as the argument of f the new value instead of the previous one yields

$$y_{n+1} = y_n + hf(t_{n+1}, y_{n+1}),$$

from which y_{n+1} is now determined implicitly. In general, the new solution approximation needs to be computed iteratively, typically by a modified Newton method such as $y_{n+1}^{(k+1)} = y_{n+1}^{(k)} + \Delta y_{n+1}^{(k)}$, where the increment is computed by solving a linear system of equations

$$(I - hJ_n)\Delta y_{n+1}^{(k)} = -r_{n+1}^{(k)}$$

with an approximation J_n to the Jacobian matrix $\partial_y f(t_n, y_n)$ and the residual

$$r_{n+1}^{(k)} = y_{n+1}^{(k)} - y_n - hf(t_{n+1}, y_{n+1}^{(k)}).$$

The computational cost per step has increased dramatically; whereas the explicit Euler method requires a single function evaluation, we now need to compute the Jacobian and then solve a linear system and evaluate f on each Newton iteration.

Why it may nevertheless be preferable to perform the computation using the implicit rather than the explicit Euler method is evident for the scalar linear example, made famous by Germund Dahlquist in 1963,

$$y' = \lambda y,$$

where the coefficient λ is large and negative (or complex with large negative real part). Here the exact solution $y(t) = e^{(t-t_0)\lambda} y_0$ decays to zero as time increases, and

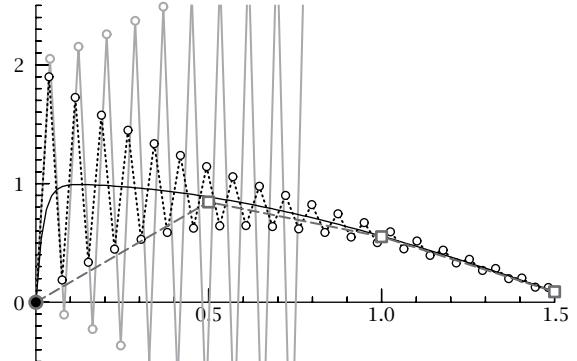

Figure 1 The exact solution (solid line), the implicit Euler solution ($h = 0.5$, dashed line), and two explicit Euler solutions ($h = 0.038$, dotted line; $h = 0.041$, gray line) for the problem $y' = -50(y - \cos t)$, $y(0) = 0$.

so does the numerical solution given by the implicit Euler method *for every step size $h > 0$* :

$$y_n^{\text{impl}} = (1 - h\lambda)^{-n} y_0.$$

In contrast, the explicit Euler method yields

$$y_n^{\text{expl}} = (1 + h\lambda)^n y_0,$$

which decays to zero for growing n only when h is so small that $|1 + h\lambda| < 1$. This imposes a severe step-size restriction when λ is a negative number of large absolute value (just think of $\lambda = -10^{10}$). For larger step sizes the numerical solution suffers an instability that is manifested in wild oscillations of increasing amplitude. The problem is that the explicit Euler method and the differential equation have completely different stability behaviors unless the step size is chosen extremely small (see figure 1).

Such behavior is not restricted to the simple scalar example considered above but extends to linear systems of differential equations in which the matrix has some eigenvalues with large negative real part and to classes of nonlinear differential equations with a Jacobian matrix $\partial_y f$ having this property. The explicit and implicit Euler methods also give rise to very different behaviors for nonlinear differential equations in which the function $f(t, y)$ has a large (local) Lipschitz constant L with respect to y , while for some inner product the inequality

$$\langle f(t, y) - f(t, z), y - z \rangle \leq \ell \|y - z\|^2$$

holds for all t and y, z with a moderate constant $\ell \ll L$ (called a one-sided Lipschitz constant).

Differential equations for which the numerical solution using the implicit Euler method is more efficient

than that using the explicit Euler method are called *stiff* differential equations. They include important applications in the description of processes with multiple timescales (e.g., fast and slow chemical reactions) and in spatial semidiscretizations of time-dependent partial differential equations. For example, for the heat equation, stable numerical solutions are obtained with the explicit Euler method only when temporal step sizes are bounded by the square of the spatial grid size, whereas the implicit Euler method is unconditionally stable.

1.3 The Symplectic Euler Method and Hamiltonian Systems

An important class of differential equations for which neither the explicit nor the implicit Euler method is appropriate is *Hamiltonian differential equations*,

$$p' = -\nabla_q H(p, q), \quad q' = +\nabla_p H(p, q),$$

which are fundamental to many branches of physics. Here, the real-valued Hamilton function H , defined on a domain of \mathbb{R}^{d+d} , represents the total energy, and $q(t) \in \mathbb{R}^d$ and $p(t) \in \mathbb{R}^d$ represent the positions and momenta, respectively, of a conservative system at time t . The total energy is conserved:

$$H(p(t), q(t)) = \text{const.}$$

along any solution $(p(t), q(t))$ of the Hamiltonian system. It turns out that a partitioned method obtained by applying the explicit Euler method to the position variables and the implicit Euler method to the momentum variables (or vice versa) behaves much better than either Euler method applied to the system as a whole. The *symplectic Euler method* reads

$$\begin{aligned} p_{n+1} &= p_n - h \nabla_q H(p_{n+1}, q_n), \\ q_{n+1} &= q_n + h \nabla_p H(p_{n+1}, q_n). \end{aligned}$$

For a separable Hamiltonian $H(p, q) = T(p) + V(q)$ the method is explicit.

Figure 2 illustrates the qualitative behavior of the three Euler methods applied to the differential equations of the mathematical pendulum,

$$p' = -\sin q, \quad q' = p,$$

which are Hamiltonian with $H(p, q) = \frac{1}{2}p^2 - \cos q$. The energy of the implicit Euler solution decreases, while that of the explicit Euler solution increases. The symplectic Euler method nearly conserves the energy over extremely long times.

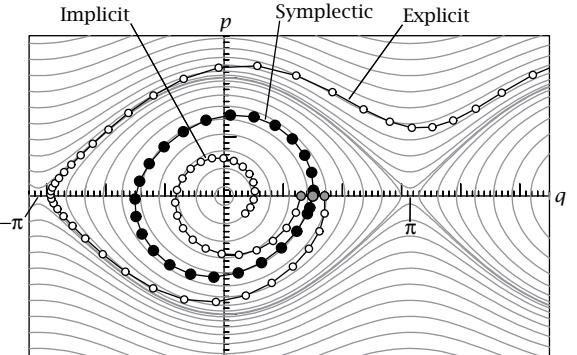

Figure 2 The pendulum equation: Euler polygons with step size $h = 0.3$; initial value $p(0) = 0$ and $q(0) = 1.7$ for the explicit Euler method, $q(0) = 1.5$ for the symplectic Euler method, and $q(0) = 1.3$ for the implicit Euler method. The solid lines are solution curves for the differential equations.

2 Basic Notions

In this section we describe some of the mechanisms that lead to the different behaviors of the various methods.

2.1 Local Error

For the explicit Euler method, the error after one step of the method starting from the exact solution, called the *local error*, is given as

$$d_{n+1} = (\gamma(t_n) + hf(t_n, \gamma(t_n))) - \gamma(t_n + h).$$

By estimating the remainder term in the Taylor expansion of $\gamma(t_n + h)$ at t_n , we can bound d_{n+1} by

$$\|d_{n+1}\| \leq Ch^2 \quad \text{with } C = \frac{1}{2} \max_{t_0 \leq t \leq T} \|\gamma''(t)\|,$$

provided that the solution is twice continuously differentiable, which is the case if f is continuously differentiable.

2.2 Error Propagation

Since the method advances in each step with the computed values γ_n instead of the exact solution values $\gamma(t_n)$, it is important to know how errors, once introduced, are propagated by the method. Consider explicit Euler steps starting from different starting values:

$$\begin{aligned} u_{n+1} &= u_n + hf(t_n, u_n), \\ v_{n+1} &= v_n + hf(t_n, v_n). \end{aligned}$$

When f is (locally) Lipschitz continuous with Lipschitz constant L , the difference is controlled by the *stability*

estimate

$$\|u_{n+1} - v_{n+1}\| \leq (1 + hL) \|u_n - v_n\|.$$

2.3 Lady Windermere's Fan

The above estimates can be combined to study the error accumulation, as illustrated by the fan of figure 3 (named by Gerhard Wanner in the 1980s after a play by Oscar Wilde). Each arrow from left to right represents a step of the numerical method, with different starting values. The fat vertical bars represent the local errors, whose propagation by the numerical method is controlled using the stability estimate repeatedly from step to step; the *global error*

$$e_n = y_n - y(t_n)$$

is the sum of the propagated local errors (represented as the distances between two adjacent arrowheads ending at t_n in figure 3). The contribution of the first local error d_1 to the global error e_n is bounded by $(1 + hL)^{n-1} \|d_1\|$, as is seen by applying the stability estimate $n - 1$ times following the numerical solutions starting from y_1 and $y(t_1)$. The contribution of the second local error d_2 is bounded by $(1 + hL)^{n-2} \|d_2\|$, and so on. Since the local errors are bounded by Ch^2 , the global error is thus bounded by

$$\begin{aligned} \|e_n\| &\leq \sum_{j=0}^{n-1} (1 + hL)^j Ch^2 \\ &= \frac{(1 + hL)^n - 1}{1 + hL - 1} Ch^2 \\ &\leq \frac{e^{nhL} - 1}{L} Ch. \end{aligned}$$

With $M = (e^{(T-t_0)L} - 1)C/L$, the global error satisfies

$$\|e_n\| \leq Mh \quad \text{for } t_n \leq T.$$

The numerical method thus converges to the exact solution as $h \rightarrow 0$ with nh fixed, but only at first order, that is, with an error bound proportional to h . We will later turn to higher-order numerical methods, with an error bound proportional to h^p with $p > 1$.

2.4 Stiff Differential Equations

The above error bound becomes meaningless for stiff problems, where L is large. The implicit Euler method admits an analogous error analysis in which only the one-sided Lipschitz constant ℓ appears in the stability estimate; provided that $h\ell < 1$,

$$\|u_{n+1} - v_{n+1}\| \leq \frac{1}{1 - h\ell} \|u_n - v_n\|$$

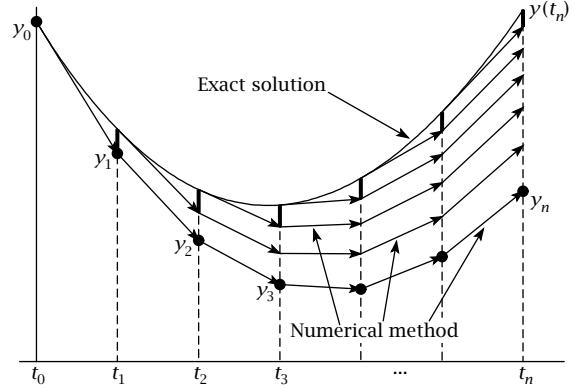

Figure 3 Lady Windermere's fan.

holds for the results of two Euler steps starting from u_n and v_n . For stiff problems with $\ell \ll L$ this is much more favorable than the stability estimate of the explicit Euler method in terms of L . It leads to an error bound $\|e_n\| \leq mh$, in which m is essentially of the same form as M above but with the Lipschitz constant L replaced by the one-sided Lipschitz constant ℓ .

The above arguments explain the convergence behavior of the explicit and implicit Euler methods and their fundamentally different behavior for large classes of stiff differential equations. They do not explain the favorable behavior of the symplectic Euler method for Hamiltonian systems. This requires another concept, backward analysis, which is treated next.

2.5 Backward Analysis

Much insight into numerical methods is obtained by interpreting the numerical result after a step as the (almost) exact solution of a *modified differential equation*. Properties of the numerical method can then be inferred from properties of a differential equation. For each of the Euler methods applied to $y' = f(y)$ an asymptotic expansion

$$\tilde{f}(\tilde{y}) = f(\tilde{y}) + hf_2(\tilde{y}) + h^2 f_3(\tilde{y}) + \dots$$

can be uniquely constructed recursively such that, up to arbitrarily high powers of h ,

$$y_1 = \tilde{y}(t_1),$$

where $\tilde{y}(t)$ is the solution of the modified differential equation $\tilde{y}' = \tilde{f}(\tilde{y})$ with initial value y_0 . The remarkable feature is that, when the symplectic Euler method is applied to a Hamiltonian system, the modified differential equation is again Hamiltonian. The modified

Hamilton function has an asymptotic expansion

$$\tilde{H} = H + hH_2 + h^2H_3 + \dots$$

The symplectic Euler method therefore conserves the modified energy \tilde{H} (up to arbitrarily high powers of h), which is close to the exact energy H . This conservation of the modified energy prevents the linearly growing drift in the energy that is present along numerical solutions of the explicit and implicit Euler methods. For these two methods the modified differential equation is no longer Hamiltonian.

3 Nonstiff Problems

3.1 Higher-Order Methods

A method is said to have *order* p if the local error (recall that this is the error after one step of the method starting from the exact solution) is bounded by Ch^{p+1} , where h is the step size and C depends only on bounds of derivatives of the solution $y(t)$ and of the function f . As for the Euler method in section 2.1, the order is determined by comparing the Taylor expansions of the exact solution and the numerical solution, which for a method of order p should agree up to and including the h^p term.

A drawback of the Euler methods is that they are only of order 1. There are different ways to increase the order: using additional, auxiliary function evaluations in passing from y_n to y_{n+1} (one-step methods); using previously computed solution values y_{n-1}, y_{n-2}, \dots and/or their function values (multistep methods); or using both (general linear methods). For nonstiff initial-value problems the most widely used methods are explicit Runge–Kutta methods of orders up to 8, in the class of one-step methods, and Adams-type multistep methods up to order 12. For very stringent accuracy requirements of 10 or 100 digits, high-order extrapolation methods or high-order Taylor series expansions of the solution (when higher derivatives of f are available with automatic differentiation software) are sometimes used.

3.2 Explicit Runge–Kutta Methods

Two ideas underlie Runge–Kutta methods. First, the integral in

$$y(t_0 + h) = y(t_0) + h \int_0^1 y'(t_0 + \theta h) d\theta,$$

with $y'(t) = f(t, y(t))$, is approximated by a quadrature formula with weights b_i and nodes c_i :

$$y_1 = y_0 + h \sum_{i=1}^s b_i Y'_i, \quad Y'_i = f(t_0 + c_i h, Y_i).$$

Second, the internal stage values $Y_i \approx y(t_0 + c_i h)$ are determined by another quadrature formula for the integral from 0 to c_i :

$$Y_i = y_0 + h \sum_{j=1}^s a_{ij} Y'_j, \quad i = 1, \dots, s,$$

with the *same* function values Y'_j as for y_1 . If the coefficients satisfy $a_{ij} = 0$ for $j \geq i$, then the above sum actually extends only from $j = 1$ to $i - 1$, and hence $Y_1, Y'_1, Y_2, Y'_2, \dots, Y_s, Y'_s$ can be computed explicitly one after the other. The methods are named after Carl Runge, who in 1895 proposed two- and three-stage methods of this type, and Wilhelm Kutta, who in 1901 proposed what is now known as the *classical Runge–Kutta method* of order 4, which extends the Simpson quadrature rule from integrals to differential equations:

		0		
		$\frac{1}{2}$	$\frac{1}{2}$	
		$\frac{1}{2}$	0	$\frac{1}{2}$
	a_{ij}	1	0	0
c_i		b_j	$\frac{1}{6}$	$\frac{2}{6}$

Using Lady Windermere's fan as in section 2, one finds that the global error $y_n - y(t_n)$ of a p th-order Runge–Kutta method over a bounded time interval is $\mathcal{O}(h^p)$.

The order conditions of general Runge–Kutta methods were elegantly derived by John Butcher in 1964 using a tree model for the derivatives of f and their concatenations by the chain rule, as they appear in the Taylor expansions of the exact solution and the numerical solution. This enabled the construction of methods of even higher order, among which excellently constructed methods of orders 5 and 8 by Dormand and Prince (from 1980) have found widespread use. These methods are equipped with lower-order error indicators from embedded formulas that use the same function evaluations. These error indicators are used for an adaptive selection of the step size that is intended to keep the local error close to a given error tolerance in each time step.

3.3 Extrapolation Methods

A systematic, if suboptimal, construction of explicit Runge-Kutta methods of arbitrarily high order is provided by *Richardson extrapolation* of the results of the explicit Euler method obtained with different step sizes. This technique makes use of an asymptotic expansion of the error,

$$y(t, h) - y(t) = e_1(t)h + e_2(t)h^2 + \dots,$$

where $y(t, h)$ is the explicit Euler approximation at t obtained with step size h . At $t = t_0 + H$, the error expansion coefficients up to order p can be eliminated by evaluating at $h = 0$ (*extrapolating*) the interpolation polynomial through the Euler values $y(t_0 + H, h_j)$ for $j = 1, \dots, p$ corresponding to different step sizes $h_j = H/j$. This gives a method of order p , which formally falls into the general class of Runge-Kutta methods. Instead of using the explicit Euler method as the basic method, it is preferable to use *Gragg's method* (from 1964), which uses the explicit midpoint rule

$$y_{n+1} = y_{n-1} + 2hf(t_n, y_n), \quad n \geq 1,$$

and an explicit Euler starting step to compute y_1 . This method has an error expansion in powers of h^2 (instead of h , above) at even n , and with the elimination of each error coefficient one therefore gains a power of h^2 . Extrapolation methods have built-in error indicators that can be used for order and step-size control.

3.4 Adams Methods

The methods introduced by astronomer John Couch Adams in 1855 were the first of high order that used only function evaluations, and in their current variable-order, variable-step-size implementations they are among the most efficient methods for general nonstiff initial-value problems.

When k function values $f_{n-j} = f(t_{n-j}, y_{n-j})$ ($j = 0, \dots, k-1$) have already been computed, the integrand in

$$y(t_{n+1}) = y(t_n) + h \int_0^1 f(t_n + \theta h, y(t_n + \theta h)) d\theta$$

is approximated by the interpolation polynomial $P(t)$ through (t_{n-j}, f_{n-j}) , $j = 0, \dots, k-1$, yielding the *explicit Adams method* of order k ,

$$y_{n+1} = y_n + h \int_0^1 P(t_n + \theta h) d\theta,$$

which, upon inserting the Newton interpolation formula, becomes (for constant step size h)

$$y_{n+1} = y_n + hf_n + h \sum_{i=1}^{k-1} \gamma_i \nabla^i f_n,$$

with the backward differences $\nabla f_n = f_n - f_{n-1}$, $\nabla^i f_n = \nabla^{i-1} f_n - \nabla^{i-1} f_{n-1}$, and with coefficients $(\gamma_i) = (\frac{1}{2}, \frac{5}{12}, \frac{3}{8}, \frac{251}{720}, \dots)$. The method thus corrects the explicit Euler method by adding differences of previous function values.

Especially for higher orders, the accuracy of the approximation suffers from the fact that the interpolation polynomial is used outside the interval of interpolation. This is avoided if the (as yet) unknown value (t_{n+1}, f_{n+1}) is added to the interpolation points. Let $P^*(t)$ denote the corresponding interpolation polynomial, which is now used to replace the integrand $f(t, y(t))$. This yields the *implicit Adams method* of order $k+1$, which takes the form

$$y_{n+1} = y_n + hf_{n+1} + h \sum_{i=1}^k \gamma_i^* \nabla^i f_{n+1},$$

with $(\gamma_i^*) = (-\frac{1}{2}, -\frac{1}{12}, -\frac{1}{24}, -\frac{19}{720}, \dots)$. The equation for y_{n+1} is solved approximately by one or at most two fixed-point iterations, taking the result from the explicit Adams method as the starting iterate (the *predictor*) and inserting its function value on the right-hand side of the implicit Adams method (the *corrector*).

In a variable-order, variable-step-size implementation, the required starting values are built up by starting with the methods of increasing order $1, 2, 3, \dots$, one after the other. Strategies for increasing or lowering the order are based on monitoring the backward difference terms. Changing the step size is computationally more expensive, since it requires a recalculation of all method coefficients. It is facilitated by passing information from one step to the next by the *Nordsieck vector*, which collects the values of the interpolation polynomial and all its derivatives at t_n scaled by powers of the step size.

3.5 Linear Multistep Methods

Both explicit and implicit Adams methods (with constant step size) belong to the class of *linear multistep methods*

$$\sum_{j=0}^k \alpha_j y_{n+j} = h \sum_{j=0}^k \beta_j f_{n+j},$$

with $f_i = f(t_i, y_i)$ and $\alpha_k \neq 0$. This class also includes important methods for stiff problems, in particular the backward differentiation formulas to be described in the next section. The theoretical study of linear multistep methods was initiated by Dahlquist in 1956. He showed that for such methods

$$\text{consistency} + \text{stability} \iff \text{convergence},$$

which, together with the contemporaneous Lax equivalence theorem for discretizations of partial differential equations, forms a basic principle of numerical analysis. What this means here is described in more detail below.

In contrast to one-step methods, having high order does not by itself guarantee that a multistep method converges as $h \rightarrow 0$. In fact, choosing the method coefficients in such a way that the order is maximized for a given k leads to a method that produces wild oscillations, which increase in magnitude with decreasing step size. One requires in addition a stability condition, which can be phrased as saying that all solutions to the linear difference equation $\sum_{j=0}^k \alpha_j y_{n+j} = 0$ stay bounded as $n \rightarrow \infty$, or equivalently:

All roots of the polynomial $\sum_{j=0}^k \alpha_j \zeta^j$ are in the complex unit disk, and those on the unit circle are simple.

If this stability condition is satisfied and the method is of order p , then the error satisfies $y_n - y(t_n) = \mathcal{O}(h^p)$ on bounded time intervals, provided that the error in the starting values is $\mathcal{O}(h^p)$.

Dahlquist also proved *order barriers*: the order of a stable k -step method cannot exceed $k + 2$ if k is even, $k + 1$ if k is odd, and k if the method is explicit ($\beta_k = 0$).

3.6 General Linear Methods

Predictor–corrector Adams methods fall neither into the class of multistep methods, since they use the predictor as an internal stage, nor into the class of Runge–Kutta methods, since they use previous function values. Linear multistep methods and Runge–Kutta methods are extreme cases of a more general class of methods

$$u_{n+1} = Su_n + h\Phi(t_n, u_n, h),$$

where u_n is a vector (usually of dimension a multiple of the dimension of the differential equation) from which the solution approximation $y_n \approx y(t_n)$ can be obtained by a linear mapping, S is a square matrix, and Φ depends on function values of f . (For example, for predictor–corrector methods we would have $u_n = (y_n, y_n^{\text{pred}}, y_{n-1}, \dots, y_{n-k+1})$ in this framework.)

More general methods like these have been studied since the mid-1960s with the objective of looking for the “greatest good as a mean between extremes” (in the words of Aristotle and John Butcher). They include a number of methods of potential interest for both nonstiff and stiff problems, such as two-step Runge–Kutta methods or general linear methods with inherent Runge–Kutta stability, but as of now do not appear to

have found their way into applications via competitive software.

4 Stiff Problems

We saw in the introduction that for important classes of differential equations, called stiff equations, the implicit Euler method yields a drastic improvement over the explicit Euler method. Are there higher-order methods with similarly good properties?

4.1 Backward Differentiation Formula Methods

The k -step implicit Adams methods, though naturally extending the implicit Euler method, perform disappointingly on stiff problems for $k > 1$. Multistep methods from another extension of the implicit Euler method, which is based on numerical differentiation rather than integration, turn out to be better for stiff problems. Suppose that k solution approximations y_{n-k+1}, \dots, y_n have already been computed, and consider the interpolation polynomial $u(t)$ passing through y_{n+1-j} at t_{n+1-j} for $j = 0, \dots, k$, including the as yet unknown approximation y_{n+1} . We then require the *collocation* condition

$$u'(t) = f(t, u(t)) \quad \text{at } t = t_{n+1},$$

or equivalently, in the case of a constant step size h ,

$$\sum_{j=1}^k \frac{1}{j} \nabla^j y_{n+1} = h f_{n+1}.$$

This *backward differentiation formula* (BDF) is an implicit linear multistep method of order k , which is found to be unstable for $k > 6$. Methods for smaller k , however, up to $k \leq 5$, are currently the most widely used methods for stiff problems, which are implemented in numerous computer codes. The usefulness of these methods was first observed by Curtiss and Hirschfelder in 1952, who also coined the notion of stiff differential equations. Bill Gear’s BDF code “DIFSUB” from 1971 was the first widely used code for stiff problems. It brought BDF methods (“Gear’s method”) to the attention of practitioners in many fields.

4.2 A-Stability and Related Notions

Which properties make BDF methods successful for stiff problems? In 1963, Dahlquist systematically studied the behavior of multistep methods on the scalar linear differential equation

$$y' = \lambda y \quad \text{with } \lambda \in \mathbb{C}, \operatorname{Re} \lambda \leq 0,$$

whose use as a test equation can be justified by linearization of the differential equation and diagonalization of the Jacobian matrix. The behavior of a numerical method on this deceptively simple scalar linear differential equation gives much insight into its usefulness for more general stiff problems, as is shown by both numerical experience and theory.

Clearly, the exact solution $y(t) = e^{t\lambda}y_0$ remains bounded for $t \rightarrow +\infty$ when $\operatorname{Re} \lambda \leq 0$. Following Dahlquist, a method is called *A-stable* if for every $\lambda \in \mathbb{C}$ with $\operatorname{Re} \lambda \leq 0$, the numerical solution y_n stays bounded as $n \rightarrow \infty$ for every step size $h > 0$ and every choice of starting values. The implicit Euler method and the second-order BDF method are A-stable, but the BDF methods of higher order are not. *Dahlquist's second-order barrier* states that the order of an A-stable linear multistep method cannot exceed 2. This fundamental, if negative, theoretical result has led to much work aimed at circumventing the barrier by using other methods or weaker notions of stability.

The *stability region* S is the set of all complex $z = h\lambda$, such that every numerical solution of the method applied to $y' = \lambda y$ with step size h stays bounded. The stability regions of explicit and implicit k -step Adams methods with $k > 1$ are bounded, which leads to step-size restrictions when λ has large absolute value. The BDF methods up to order 6 are A(α)-stable; that is, the stability region contains an unbounded sector $|\arg(-z)| \leq \alpha$ with $\alpha = 90^\circ, 90^\circ, 86^\circ, 73^\circ, 51^\circ, 17^\circ$ for $k = 1, \dots, 6$, respectively. The higher-order BDF methods therefore perform well for differential equations where the Jacobian has large eigenvalues near the negative real half-axis, but they behave poorly when there are large eigenvalues near the imaginary axis.

4.3 Implicit Runge-Kutta Methods

It turns out that there is no order barrier for A-stable Runge-Kutta methods.

Explicit Runge-Kutta methods cannot be A-stable because application of such a method to the linear test equation yields $y_{n+1} = P(h\lambda)y_n$, where P is a polynomial of degree s , the number of stages. The stability region of such a method is necessarily bounded, since $|P(z)| \rightarrow \infty$ as $|z| \rightarrow \infty$.

On the other hand, an *implicit* Runge-Kutta method has

$$y_{n+1} = R(h\lambda)y_n$$

with a rational function $R(z)$, called the *stability function* of the method, which is an approximation to the

exponential at the origin, $R(z) = e^z + \mathcal{O}(z^{p+1})$ as $z \rightarrow 0$. The method is A-stable if $|R(z)| \leq 1$ for $\operatorname{Re} z \leq 0$. The subtle interplay between order and stability is clarified by the theory of *order stars*, developed by Wanner, Hairer, and Nørsett in 1978. In particular, this theory shows that among the PADÉ APPROXIMANTS [IV.9 §2.4] $R_{k,j}(z)$ to the exponential (the rational approximations of numerator degree k and denominator degree j of highest possible order $p = j + k$), precisely those with $k \leq j \leq k + 2$ are A-stable. Optimal-order implicit Runge-Kutta methods having the diagonal Padé approximants $R_{s,s}$ as stability function are the collocation methods based on the Gauss quadrature nodes, while those having the subdiagonal Padé approximants $R_{s-1,s}$ are the collocation methods based on the right-hand Radau quadrature nodes. We turn to these important implicit Runge-Kutta methods next.

4.4 Gauss and Radau Methods

A *collocation method* based on the nodes $0 \leq c_1 < \dots < c_s \leq 1$ determines a polynomial $u(t)$ of degree at most s such that $u(t_0) = y_0$ and the differential equation is satisfied at the s points $t_0 + c_i h$:

$$u'(t) = f(t, u(t)) \quad \text{at } t = t_0 + c_i h, \quad i = 1, \dots, s.$$

The solution approximation at the endpoint is then

$$y_1 = u(t_0 + h),$$

which is taken as the starting value for the next step. As was shown by Ken Wright (in 1970), such a collocation method is equivalent to an implicit Runge-Kutta method, the order of which is equal to the order of the underlying interpolatory quadrature with nodes c_i . The highest order $p = 2s$ is thus obtained with Gauss nodes. Nevertheless, Gauss methods have found little use in stiff initial-value problems (as opposed to boundary-value problems; see section 6). The reason for this is that the stability function here satisfies $|R(z)| \rightarrow 1$ as $z \rightarrow -\infty$, whereas $e^z \rightarrow 0$ as $z \rightarrow -\infty$.

The desired damping property at infinity is obtained for the subdiagonal Padé approximant. This is the stability function for the collocation method at Radau points, which are the nodes of the quadrature formula of order $p = 2s - 1$ with $c_s = 1$. Let us collect the basic properties: the s -stage Radau method is an implicit Runge-Kutta method of order $p = 2s - 1$; it is A-stable and has $R(\infty) = 0$.

The Radau methods have some more remarkable features: they are nonlinearly stable with the so-called *algebraic stability* property; their last internal stage

equals the starting value for the next step (this property is useful for very stiff and for differential-algebraic equations); and their internal stages all have order s .

The last property does indeed hold for every collocation method with s nodes. It is important because of the phenomenon of *order reduction*; in the application of an implicit Runge-Kutta method to stiff problems, the method may have only the stage order, or stage order + 1, with stiffness-independent error constants, instead of the full classical order p that is obtained with nonstiff problems.

The implementation of Radau methods by Hairer and Wanner (from 1991) is known for its robustness in dealing with stiff problems and differential-algebraic equations of the type $M\dot{y}' = f(t, y)$ with a singular matrix M .

4.5 Linearly Implicit Methods

BDF and implicit Runge-Kutta methods are fully implicit, and the resulting systems of nonlinear equations need to be solved by variants of Newton's method. To reduce the computational cost while retaining favorable linear stability properties, linearly implicit methods have been proposed, such as the *linearly implicit Euler method*, in which only a single iteration of Newton's method is done in each step:

$$(I - hJ_n)(y_{n+1} - y_n) = hf_n,$$

where $J_n \approx \partial_y f(t_n, y_n)$. Thus just one linear system of equations is solved in each time step. The method is identical to the implicit Euler method for linear problems and therefore inherits its A-stability. Higher-order linearly implicit methods can be obtained by Richardson extrapolation of the linearly implicit Euler method, or they are specially constructed *Rosenbrock methods*. Like explicit Runge-Kutta methods, these methods determine the solution approximation as

$$y_1 = y_0 + h \sum_{i=1}^s b_i Y'_i, \quad Y_i = y_0 + h \sum_{j=1}^{i-1} a_{ij} Y'_j,$$

but compute the derivative stages consecutively by solving s linear systems of equations (written here for an autonomous problem, $f(t, y) = f(y)$ and $J = \partial_y f(y_0)$):

$$(I - \gamma h J) Y'_i = f(Y_i) + h J \sum_{j=1}^{i-1} \gamma_{ij} Y'_j.$$

Such methods are easy to implement, and they have gained popularity in the numerical integration of

spatial semidiscretizations of partial differential equations. For large problems, the dominating numerical cost is in the solution of the systems of linear equations, using either direct sparse solvers or iterative methods such as preconditioned Krylov subspace methods.

4.6 Exponential Integrators

While it appears an obvious idea to use the exponential of the Jacobian in a numerical method, this was for a long time considered impractical, and particularly so for large problems. This attitude changed, however, in the mid-1990s when it was realized that Krylov subspace methods for approximating a matrix exponential times a vector, $e^{yhJ}v$, show superlinear convergence, whereas there is generally only linear convergence for solving linear systems $(I - yhJ)x = v$. Unless a good preconditioner for the linear system is available, computing the action of the matrix exponential is therefore computationally less expensive than solving a corresponding linear system. This fact led to a revival of methods using the exponential or related functions like $\varphi(z) = (e^z - 1)/z$, such as the *exponential Euler method*

$$y_{n+1} = y_n + h\varphi(hJ_n)f_n.$$

The method is exact for linear $f(y) = Jy + c$. It differs from the linearly implicit Euler method in that the entire function $\varphi(z)$ replaces the rational function $1/(1 - z)$. Higher-order exponential methods of one-step and multistep type have also been constructed. Exponential integrators have proven useful for large-scale problems in physics and for nonlinear parabolic equations, as well as for highly oscillatory problems like those considered in section 5.6.

4.7 Chebyshev Methods

For moderately stiff problems one can avoid numerical linear algebra altogether by using *explicit* Runge-Kutta methods of low order (2 or 4) and high stage number, which are constructed to have a large stability domain covering a strip near the negative real semi-axis. The stability function of such methods is a high-degree polynomial related to Chebyshev polynomials. The stage number is chosen adaptively to include the product of the step size with the dominating eigenvalues of the Jacobian in the stability domain. With s stages, one can cover intervals on the negative real axis of a length proportional to s^2 . The quadratic growth of the stability interval with the stage number makes

these methods suitable for problems with large negative real eigenvalues of the Jacobian, such as spatial semidiscretizations of parabolic partial differential equations.

5 Structure-Preserving Methods

The methods discussed so far are designed for general differential equations, and a distinction was drawn only between nonstiff and stiff problems. There are, however, important classes of differential equations with a special, often geometric, structure, whose preservation in the numerical discretization leads to substantially better methods, especially when integrating over long times. The most prominent of these are Hamiltonian systems, which are all-important in physics. Their flow has the geometric property of being symplectic.

In respecting the phase space geometry under discretization and analyzing its effect on the long-time behavior of a numerical method, there is a shift of viewpoint from concentrating on the approximation of a single solution trajectory to considering the numerical method as a discrete dynamical system that approximates the flow of a differential equation.

While many differential equations have interesting structures to preserve under discretization—and much work has been done in devising and analyzing appropriate numerical methods for doing so—we will restrict our attention to Hamiltonian systems here. Their numerical treatment has been an active research area for the past two decades.

5.1 Symplectic Methods

The time- t flow of a differential equation $y' = f(y)$ is the map φ_t that associates with an initial value y_0 at time 0 the solution value at time t : $\varphi_t(y_0) = y(t)$. Consider a Hamiltonian system

$$p' = -\nabla_q H(p, q), \quad q' = \nabla_p H(p, q),$$

or equivalently, for $y = (p, q)$,

$$y' = J^{-1} \nabla H(y) \quad \text{with } J = \begin{pmatrix} 0 & I \\ -I & 0 \end{pmatrix}.$$

The flow φ_t of a Hamiltonian system is *symplectic*; that is, the derivative $D\varphi_t$ with respect to the initial value satisfies

$$D\varphi_t(y)^T J D\varphi_t(y) = J$$

for all y and t for which $\varphi_t(y)$ exists. This is a quadratic relation formally similar to orthogonality, with J in place of the identity matrix I , but it is related to the preservation of areas rather than lengths in phase space.

A numerical one-step method $y_{n+1} = \Phi_h(y_n)$ is called symplectic if the numerical flow Φ_h is a symplectic map:

$$D\Phi_h(y)^T J D\Phi_h(y) = J.$$

Such methods exist; the “symplectic Euler method” of section 1.3 is indeed symplectic. Great interest in symplectic methods was spurred when, in 1988, Lasagni, Sanz-Serna, and Suris independently characterized symplectic Runge-Kutta methods as those whose coefficients satisfy the condition

$$b_i a_{ij} + b_j a_{ji} - b_i b_j = 0.$$

Gauss methods (see section 4.4) were already known to satisfy this condition and were thus found to be symplectic. Soon after those discoveries it was realized that a numerical method is symplectic if and only if the modified differential equation of backward analysis (section 2.5) is again Hamiltonian. This made it possible to prove rigorously the almost-conservation of energy over times that are exponentially long in the inverse step size, as well as further favorable long-time properties such as the almost-preservation of KAM (Kolmogorov-Arnold-Moser) tori of perturbed integrable systems over exponentially long times.

5.2 The Störmer-Verlet Method

By the time symplecticity was entering the field of numerical analysis, scientists in molecular simulation had been doing symplectic computations for more than 20 years without knowing it; the standard integrator of molecular dynamics, the method used successfully ever since Luc Verlet introduced it to the field in 1967, is symplectic. For a Hamiltonian $H(p, q) = \frac{1}{2} p^T M^{-1} p + V(q)$ with a symmetric positive-definite mass matrix M , the method is explicit and is given by the formulas

$$\begin{aligned} p_{n+1/2} &= p_n - \frac{1}{2} h \nabla V(q_n), \\ q_{n+1} &= q_n + h M^{-1} p_{n+1/2}, \\ p_{n+1} &= p_{n+1/2} - \frac{1}{2} h \nabla V(q_{n+1}). \end{aligned}$$

Such a method was also formulated by the astronomer Störmer in 1907, and in fact it can even be traced back to Newton's *Principia* from 1687, where it was used as a theoretical tool in the proof of the preservation of angular momentum in the two-body problem (Kepler's

second law), which is indeed preserved by this method. Given that there are already sufficiently many Newton methods in numerical analysis, it is fair to refer to the method as the *Störmer–Verlet method* (the Verlet method and the leapfrog method are also often-used names). As will be discussed in the next three subsections, the symplecticity of this method can be understood in various ways by relating the method to different classes of methods that have proven useful in a variety of applications.

5.3 Composition Methods

Let us denote the one-step map $(p_n, q_n) \mapsto (p_{n+1}, q_{n+1})$ of the Störmer–Verlet method by Φ_h^{SV} , that of the symplectic Euler method of section 1.3 by Φ_h^{SE} , and that of the adjoint symplectic Euler method by $\Phi_h^{\text{SE}*}$, where instead of the argument (p_{n+1}, q_n) one uses (p_n, q_{n+1}) . The second-order Störmer–Verlet method can then be interpreted as the *composition* of the first-order symplectic Euler methods with halved step size:

$$\Phi_h^{\text{SV}} = \Phi_{h/2}^{\text{SE}*} \circ \Phi_{h/2}^{\text{SE}}.$$

Since the composition of symplectic maps is symplectic, this shows the symplecticity of the Störmer–Verlet method. We further note that the method is *time reversible* (or *symmetric*): $\Phi_{-h} \circ \Phi_h = \text{id}$, or equivalently $\Phi_h = \Phi_h^*$ with the adjoint method $\Phi_h^* := \Phi_{-h}^{-1}$. This is known to be another favorable property for conservative systems.

Moreover, from first-order methods we have obtained a second-order method. More generally, starting from a low-order method Φ_h , methods of arbitrary order can be constructed by suitable compositions

$$\Phi_{c_sh} \circ \dots \circ \Phi_{c_1h} \quad \text{or} \quad \Phi_{b_sh}^* \circ \Phi_{a_sh} \circ \dots \circ \Phi_{b_1h}^* \circ \Phi_{a_1h}.$$

The first to give systematic approaches to high-order compositions were Suzuki and Yoshida in 1990. Whenever the base method is symplectic, so is the composed method. The coefficients can be chosen such that the resulting method is symmetric.

5.4 Splitting Methods

Splitting the Hamiltonian $H(p, q) = T(p) + V(q)$ into its kinetic energy $T(p) = \frac{1}{2}p^T M^{-1} p$ and its potential energy $V(q)$, we have that the flows φ_t^T and φ_t^V of the systems with Hamiltonians T and V , respectively, are obtained by solving the trivial differential equations

$$\varphi_t^T: \begin{cases} p' = 0, \\ q' = M^{-1}p, \end{cases} \quad \varphi_t^V: \begin{cases} p' = -\nabla V(q), \\ q' = 0. \end{cases}$$

We then note that the Störmer–Verlet method can be interpreted as a composition of the exact flows of the split differential equations:

$$\Phi_h^{\text{SV}} = \varphi_{h/2}^T \circ \varphi_h^V \circ \varphi_{h/2}^T.$$

Since the flows $\varphi_{h/2}^T$ and φ_h^V are symplectic, so is their composition.

Splitting the vector field of a differential equation and composing the flows of the subsystems is a structure-preserving approach that yields methods of arbitrary order and is useful in the time integration of a variety of ordinary and partial differential equations, such as linear and nonlinear Schrödinger equations.

5.5 Variational Integrators

For the Hamiltonian $H(p, q) = \frac{1}{2}p^T M^{-1} p + V(q)$, the Hamilton equations of motion $\dot{p} = -\nabla V(q)$, $\dot{q} = M^{-1}p$ can be combined to give the second-order differential equation

$$M\ddot{q} = -\nabla V(q),$$

which can be interpreted as the Euler–Lagrange equations for minimizing the action integral

$$\int_{t_0}^{t_N} L(q(t), \dot{q}(t)) dt \quad \text{with } L(q, \dot{q}) = \frac{1}{2}\dot{q}^T M \dot{q} - V(q)$$

over all paths $q(t)$ with fixed endpoints. In the Störmer–Verlet method, eliminating the momenta yields the second-order difference equations

$$M(q_{n+1} - 2q_n + q_{n-1}) = -h^2 \nabla V(q_n),$$

which are the discrete Euler–Lagrange equations for minimizing the discretized action integral

$$\sum_{n=0}^{N-1} \frac{1}{2}h \left(L\left(q_n, \frac{q_{n+1} - q_n}{h}\right) + L\left(q_{n+1}, \frac{q_{n+1} - q_n}{h}\right) \right),$$

which results from a trapezoidal rule approximation to the action integral and piecewise-linear approximation to $q(t)$. The Störmer–Verlet method can thus be interpreted as resulting from the direct discretization of the Hamilton variational principle. Such an interpretation can in fact be given for every symplectic method. Conversely, symplectic methods can be *constructed* by minimizing a discrete action integral. In particular, approximating the action integral by a quadrature formula and the positions $q(t)$ by a piecewise polynomial leads to a symplectic partitioned Runge–Kutta method, which in general uses different Runge–Kutta formulas for positions and momenta. With Gauss quadrature one reinterprets in this way the Gauss methods

of section 4.4, and with higher-order Lobatto quadrature formulas one obtains higher-order relatives of the Störmer–Verlet method.

5.6 Oscillatory Problems

Highly oscillatory solution behavior in Hamiltonian systems typically arises when the potential is a multi-scale sum $V = V^{[\text{slow}]} + V^{[\text{fast}]}$, where the Hessian of $V^{[\text{fast}]}$ has positive eigenvalues that are large compared with those of $V^{[\text{slow}]}$. (Here we assume that $M = I$ for simplicity.) With standard methods such as the Störmer–Verlet method, very small time steps would be required, for reasons of both accuracy and stability. Various numerical methods have been devised with the aim of overcoming this limitation. We describe just one such method here: a *multiple-time-stepping method* that reduces the computational work significantly when the slow force $f^{[\text{slow}]} = -\nabla V^{[\text{slow}]}$ is far more expensive to evaluate than the fast force $f^{[\text{fast}]} = -\nabla V^{[\text{fast}]}$. A basic principle is to rely on averages instead of pointwise force evaluations. In the *averaged-force method*, the force $f_n = -\nabla V(q_n)$ in the Störmer–Verlet method is replaced by an averaged force \bar{f}_n as follows. We freeze the slow force at q_n and consider the auxiliary differential equation

$$\ddot{u} = f^{[\text{slow}]}(q_n) + f^{[\text{fast}]}(u)$$

with initial values $u(0) = q_n$, $\dot{u}(0) = 0$. We then define the averaged force as

$$\bar{f}_n = \int_{-1}^1 (1 - |\theta|)(f^{[\text{slow}]}(q_n) + f^{[\text{fast}]}(u(\theta h))) d\theta,$$

which equals

$$\bar{f}_n = \frac{1}{h^2}(u(h) - 2u(0) + u(-h)).$$

The value $u(h)$ is computed approximately using smaller time steps, noting that $u(h) = u(-h)$.

The argument of $f^{[\text{slow}]}$ might preferably be replaced with an averaged value \bar{q}_n in order to mitigate the adverse effect of possible step-size resonances that appear when the product of h with an eigenfrequency of the Hessian is close to an integral multiple of π .

If the fast potential is quadratic, $V^{[\text{fast}]}(q) = \frac{1}{2}q^T A q$, the auxiliary differential equation can be solved exactly in terms of trigonometric functions of the matrix $h^2 A$. The resulting method can then be viewed as an exponential integrator, as considered in section 4.6.

6 Boundary-Value Problems

In a two-point boundary-value problem, the differential equation is coupled with boundary conditions of the same dimension:

$$\begin{aligned} y'(t) &= f(t, y(t)), \quad a \leq t \leq b, \\ r(y(a), y(b)) &= 0. \end{aligned}$$

As an important class of examples, such problems arise as the Euler–Lagrange equations of variational problems, typically with separated boundary conditions $r_a(y(a)) = 0$, $r_b(y(b)) = 0$.

6.1 The Sensitivity Matrix

The problem of existence and uniqueness of a solution is more subtle than for initial-value problems. For a linear boundary-value problem

$$\begin{aligned} y'(t) &= C(t)y(t) + g(t), \quad a \leq t \leq b, \\ Ay(a) + By(b) &= q, \end{aligned}$$

a unique solution exists if and only if the *sensitivity matrix* $E = A + BU(b, a)$ is invertible, where $U(t, s)$ is the propagation matrix yielding $v(t) = U(t, s)v(s)$ for every solution of the linear differential equation $v'(t) = C(t)v(t)$.

A solution of a nonlinear boundary-value problem is locally unique if the linearization along this solution has an invertible sensitivity matrix.

6.2 Shooting

Just as Newton's method replaces a nonlinear system of equations with a sequence of linear systems, the shooting method replaces a boundary-value problem with a sequence of initial-value problems. The objective is to find an initial value x such that the solution of the differential equation with this initial value, denoted $y(t; x)$, satisfies the boundary conditions

$$F(x) := r(x, y(b; x)) = 0.$$

Newton's method is now applied to this nonlinear system of equations; starting from an initial guess x^0 , one iterates

$$x^{k+1} = x^k + \Delta x^k \quad \text{with } DF(x^k)\Delta x^k = -F(x^k).$$

Here, the derivative matrix $DF(x^k)$ turns out to be the sensitivity matrix E^k of the linearization of the boundary-value problem along $y(t; x^k)$. In the k th iteration, one solves numerically the initial-value problem with initial value x^k together with its linearization

$$(Y^k)'(t) = \partial_y f(t, y(t; x^k))Y^k(t), \quad Y^k(a) = I.$$

6.3 Multiple Shooting

The conceptual elegance of the shooting method—that it reduces everything to the solution of initial-value problems over the whole interval—can easily turn into its computational obstruction. Newton’s method may be very sensitive to the choice of the initial value x^0 . The norms of the matrices E^{-1} and $U(b, a)$, which determine the effect of perturbations in the boundary-value problem and the initial-value problem, respectively, are unrelated and may differ widely.

The problem can be avoided by subdividing the interval $a = t_0 < t_1 < \dots < t_N = b$, shooting on every subinterval, and requiring continuity of the solution at the nodes t_n . With $y(t; t_n, x_n)$ denoting the solution of the differential equation that starts at t_n with initial value x_n , this approach leads to a larger nonlinear system with the continuity conditions

$$F_n(x_{n-1}, x_n) = y(t_n; t_{n-1}, x_{n-1}) - x_n = 0$$

for $n = 1, \dots, N$ together with the boundary conditions

$$F_0(x_0, x_N) := r(x_0, x_N) = 0.$$

Newton’s method is now applied to this system of equations. In each iteration one solves initial-value problems on the subintervals together with their linearization, and then a linear system with a large sparse matrix is solved for the increments in (x_0, \dots, x_N) .

6.4 Collocation

In the collocation approach to the boundary-value problem, one determines an approximation $u(t)$ that is a continuous, piecewise polynomial of degree at most s and that satisfies the boundary conditions and the differential equation at a finite number of collocation points $t_{n,i} = t_{n-1} + c_i(t_n - t_{n-1})$ (for $n = 1, \dots, N$ and $i = 1, \dots, s$):

$$\begin{aligned} u'(t) &= f(t, u(t)) \quad \text{at } t = t_{n,i}, \\ r(u(a), u(b)) &= 0. \end{aligned}$$

The method can be interpreted, and implemented, as a multiple-shooting method in which a single step with a collocation method for initial-value problems, as considered in section 4.4, is made to approximate the solution in each subinterval. The most common choice, as first implemented by Ascher, Christiansen, and Russell in 1979, is collocation at Gauss nodes, which has good stability properties in the forward and backward directions. The order of approximation at the grid points t_n is $p = 2s$. Moreover, if the boundary-value problem results from a variational problem, then Gauss

collocation can be interpreted as a direct discretization of the variational problem (see section 5.5).

7 Summary

The numerical solution of ordinary differential equations is an area driven by both applications and theory, with efficient computer codes alongside beautiful theorems, both relying on the insight and knowledge of the researchers that are active in this field. It is an area that interacts with neighboring fields in computational mathematics (NUMERICAL LINEAR ALGEBRA [IV.10], the NUMERICAL SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS [IV.13], and OPTIMIZATION [IV.11]), with the theory of DIFFERENTIAL EQUATIONS [IV.2] and DYNAMICAL SYSTEMS [IV.20], and time and again with the application areas in science and engineering in which numerical methods for differential equations are used.

IV.13 Numerical Solution of Partial Differential Equations

Endre Süli

1 Introduction

Numerical solution of partial differential equations (PDEs) is a rich and active field of modern applied mathematics. The subject's steady growth is stimulated by ever-increasing demands from the natural sciences, from engineering, and from economics to provide accurate and reliable approximations to mathematical models involving PDEs whose exact solutions are either too complicated to determine in closed form or (as is the case for many) are not known to exist. While the history of numerical solution of ordinary differential equations is firmly rooted in eighteenth- and nineteenth-century mathematics, the mathematical foundations of the field of numerical solution of PDEs are much more recent; they were first formulated in the landmark paper “Über die partiellen Differenzengleichungen der mathematischen Physik” (“On the partial difference equations of mathematical physics”) by Richard Courant, Karl Friedrichs, and Hans Lewy, which was published in 1928. Today, there is a vast array of powerful numerical techniques for specific PDEs, including the following:

- level set and fast-marching methods for front-tracking and interface problems;
- numerical methods for PDEs on (possibly evolving) manifolds;
- immersed boundary methods;
- mesh-free methods;
- particle methods;
- vortex methods;
- various numerical homogenization methods and specialized numerical techniques for multiscale problems;
- wavelet-based multiresolution methods;
- sparse finite-difference and finite-element methods, greedy algorithms, and tensorial methods for high-dimensional PDEs;
- domain-decomposition methods for geometrically complex problems; and
- numerical methods for PDEs with stochastic coefficients that arise in a variety of applications, including UNCERTAINTY QUANTIFICATION [II.34] problems.

Our brief review cannot do justice to this huge and rapidly evolving subject. We shall therefore confine ourselves to the most standard and well-established techniques for the numerical solution of PDEs: finite-difference methods, finite-element methods, finite-volume methods, and spectral methods. Before embarking on our survey, it is appropriate to take a brief excursion into the theory of PDEs in order to fix the relevant notational conventions and to describe some typical model problems.

2 Model Partial Differential Equations

A linear partial differential operator L of *order* m with real-valued coefficients $a_\alpha = a_\alpha(x)$, $|\alpha| \leq m$, on a domain $\Omega \subset \mathbb{R}^d$, defined by

$$L := \sum_{|\alpha| \leq m} a_\alpha(x) \partial^\alpha, \quad x \in \Omega,$$

is called *elliptic* if, for every $x := (x_1, \dots, x_d) \in \Omega$ and every nonzero $\xi := (\xi_1, \dots, \xi_d) \in \mathbb{R}^d$,

$$Q_m(x, \xi) := \sum_{|\alpha|=m} a_\alpha(x) \xi^\alpha \neq 0.$$

Here, $\alpha := (\alpha_1, \dots, \alpha_d)$ is a d -component vector with nonnegative integer entries, called a *multi-index*, $|\alpha| := \alpha_1 + \dots + \alpha_d$ is the *length* of the multi-index α , $\partial^\alpha := \partial_{x_1}^{\alpha_1} \dots \partial_{x_d}^{\alpha_d}$, with $\partial_{x_j} := \partial/\partial x_j$, and $\xi^\alpha := \xi_1^{\alpha_1} \dots \xi_d^{\alpha_d}$. In the case of complex-valued coefficients a_α , the definition above is modified by demanding that $|Q_m(x, \xi)| \neq 0$ for all $x \in \Omega$ and all nonzero $\xi \in \mathbb{R}^d$. A typical example of a first-order elliptic operator with complex coefficients is the *Cauchy-Riemann operator* $\partial_z := \frac{1}{2}(\partial_x + i\partial_y)$, where $i := \sqrt{-1}$. With this general definition of ellipticity, even-order operators can exhibit some rather disturbing properties. For example, the Bitsadze equation $\partial_{xx}u + 2i\partial_{xy}u - \partial_{yy}u = 0$ admits infinitely many solutions on the unit disk Ω in \mathbb{R}^2 centered at the origin, all of which vanish on the boundary $\partial\Omega$ of Ω . Indeed, with $z = x + iy$, $u(x, y) = (1 - |z|^2)f(z)$ is a solution that vanishes on $\partial\Omega$ for any complex analytic function f . A stronger requirement, referred to as *uniform ellipticity*, is therefore frequently imposed: for real-valued coefficients a_α , $|\alpha| \leq m$, and $m = 2k$, where k is a positive integer, uniform ellipticity demands the existence of a constant $C > 0$ such that $(-1)^k Q_{2k}(x, \xi) \geq C|\xi|^{2k}$ for all $x \in \Omega$ and all nonzero $\xi \in \mathbb{R}^d$.

The archetypal linear second-order uniformly elliptic PDE is $-\Delta u + c(x)u = f(x)$, $x \in \Omega$. Here, c and f are real-valued functions defined on Ω , and $\Delta := \sum_{i=1}^d \partial_{x_i}^2$ is the *Laplace operator*. When $c < 0$ the

equation is called the *Helmholtz equation*. In the special case when $c(x) \equiv 0$ the equation is referred to as *Poisson's equation*, and when $c(x) \equiv 0$ and $f(x) \equiv 0$ it is referred to as *Laplace's equation*. Elliptic PDEs arise in a range of mathematical models in continuum mechanics, physics, chemistry, biology, economics, and finance. For example, in a two-dimensional flow of an incompressible fluid with flow velocity $u = (u_1, u_2, 0)$, the stream function ψ , related to u by $u = \nabla \times (0, 0, \psi)$, satisfies Laplace's equation. The potential Φ of a gravitational field, due to an attracting massive object of density ρ , satisfies Poisson's equation $\Delta\Phi = 4\pi G\rho$, where G is the universal gravitational constant.

More generally, one can consider fully nonlinear second-order PDEs:

$$F(x, u, \nabla u, D^2 u) = 0,$$

where F is a real-valued function defined on the set $Y := \Omega \times \mathbb{R} \times \mathbb{R}^d \times \mathbb{R}_{\text{symm}}^{d \times d}$, with a typical element $v := (x, z, p, R)$, where $x \in \Omega$, $z \in \mathbb{R}$, $p \in \mathbb{R}^d$, and $R \in \mathbb{R}_{\text{symm}}^{d \times d}$; Ω is an open set in \mathbb{R}^d ; $D^2 u$ denotes the Hessian matrix of u ; and $\mathbb{R}_{\text{symm}}^{d \times d}$ is the $d(d+1)/2$ -dimensional linear space of real symmetric $d \times d$ matrices, $d \geq 2$. An equation of this form is said to be elliptic on Y if the $d \times d$ matrix whose entries are $\partial F / \partial R_{ij}$, $i, j = 1, \dots, d$, is positive-definite at each $v \in Y$. An important example, encountered in connection with optimal transportation problems, is the Monge–Ampère equation: $\det D^2 u = f(x)$ with $x \in \Omega$. For this equation to be elliptic it is necessary to demand that the twice continuously differentiable function u be uniformly convex at each point of Ω , and for such a solution to exist we must also have f positive.

Parabolic and hyperbolic PDEs typically arise in mathematical models in which one of the independent physical variables is time, denoted by t . For example, the PDEs

$$\partial_t u + Lu = f \quad \text{and} \quad \partial_{tt} u + Lu = f,$$

where L is a uniformly elliptic partial differential operator of order $2m$ and u and f are functions of (t, x_1, \dots, x_d) , are *uniformly parabolic* and *uniformly hyperbolic*, respectively. The simplest examples are the (uniformly parabolic) unsteady heat equation and the (uniformly hyperbolic) second-order wave equation, where

$$Lu := - \sum_{i,j=1}^d \partial_{x_j} (a_{ij}(t, x) \partial_{x_i} u),$$

and where $a_{ij}(t, x) = a_{ij}(t, x_1, \dots, x_d)$, $i, j = 1, \dots, d$, are the entries of a $d \times d$ matrix, which is positive-definite, uniformly with respect to (t, x_1, \dots, x_d) .

Not all PDEs are of a certain fixed type. For example, the following PDEs are *mixed elliptic-hyperbolic*; they are elliptic for $x > 0$ and hyperbolic for $x < 0$:

$$\partial_{xx} u + \text{sign}(x) \partial_{yy} u = 0 \quad (\text{Lavrentiev equation}),$$

$$\partial_{xx} u + x \partial_{yy} u = 0 \quad (\text{Tricomi equation}),$$

$$x \partial_{xx} u + \partial_{yy} u = 0 \quad (\text{Keldysh equation}).$$

Stochastic analysis is a fertile source of PDEs of *nonnegative characteristic form*, such as

$$\partial_t u - \sum_{i,j=1}^d \partial_{x_j} (a_{ij} \partial_{x_i} u) + \sum_{i=1}^d b_i \partial_{x_i} u + cu = f,$$

where b_i , c , and f are real-valued functions of (t, x_1, \dots, x_d) , and $a_{ij} = a_{ij}(t, x_1, \dots, x_d)$, $i, j = 1, \dots, d$, are the entries of a *positive-semidefinite* matrix; since the a_{ij} are dependent on the temporal variable t , the equation is, potentially, of *changing type*. An important special case is when the a_{ij} are all identically equal to zero, resulting in the following first-order hyperbolic equation, which is also referred to as the *advection* (or *transport*) *equation*:

$$\partial_t u + \sum_{i=1}^d b_i(t, x) \partial_{x_i} u + c(t, x) u = f(t, x).$$

The nonlinear counterpart of this equation,

$$\partial_t u + \sum_{i=1}^d \partial_{x_i} [f(t, x, u)] = 0,$$

plays an important role in compressible fluid dynamics, traffic flow models, and flow in porous media. Special cases include the Burgers equation $\partial_t u + \partial_x (\frac{1}{2} u^2) = 0$ and the Buckley–Leverett equation $\partial_t u + \partial_x (u^2 / (u^2 + \frac{1}{4}(1-u)^2)) = 0$.

PDEs are rarely considered in isolation; additional information is typically supplied in the form of boundary conditions (imposed on the boundary $\partial\Omega$ of the domain $\Omega \subset \mathbb{R}^d$ in which the PDE is studied) or, in the case of parabolic and hyperbolic equations, as initial conditions at $t = 0$. The PDE in tandem with the boundary/initial conditions is referred to as a *boundary-value problem/initial-value problem* or, when both boundary and initial data are supplied, as an *initial-boundary-value problem*.

3 Finite-Difference Methods

We begin by considering finite-difference methods for elliptic boundary-value problems. The basic idea behind the construction of finite-difference methods is to *discretize* the closure, $\bar{\Omega}$, of the (bounded) domain

of definition $\Omega \subset \mathbb{R}^d$ of the solution (the so-called *analytical solution*) to the PDE by approximating it with a finite set of points in \mathbb{R}^d , called the *mesh points* or *grid points*, and replacing the partial derivatives of the analytical solution appearing in the equation by *divided differences* (difference quotients) of a *grid function*, i.e., a function that is defined at all points in the finite-difference grid. The process results in a finite set of equations with a finite number of unknowns, the values of the grid function representing the finite-difference approximation to the analytical solution over the finite-difference grid. We illustrate the construction by considering a simple second-order uniformly elliptic PDE subject to a *homogeneous Dirichlet boundary condition*:

$$-\Delta u + c(x, y)u = f(x, y) \quad \text{in } \Omega, \quad (1)$$

$$u = 0 \quad \text{on } \partial\Omega \quad (2)$$

on the unit square $\Omega := (0, 1)^2$; here, c and f are real-valued functions that are defined and continuous on Ω , and $c \geq 0$ on Ω . Let us suppose for simplicity that the grid points are equally spaced. Thus we take $h := 1/N$, where $N \geq 2$ is an integer. The corresponding finite-difference grid is then $\bar{\Omega}_h := \{(x_i, y_j) : i, j = 0, \dots, N\}$, where $x_i := ih$ and $y_j := jh$, $i, j = 0, \dots, N$. We also define $\Omega_h := \bar{\Omega}_h \cap \Omega$ and $\partial\Omega_h := \bar{\Omega}_h \setminus \Omega_h$.

It is helpful to introduce the following notation for *first-order divided differences*:

$$D_x^+ u(x_i, y_j) := \frac{u(x_{i+1}, y_j) - u(x_i, y_j)}{h}$$

and

$$D_x^- u(x_i, y_j) := \frac{u(x_i, y_j) - u(x_{i-1}, y_j)}{h},$$

with $D_y^+ u(x_i, y_j)$ and $D_y^- u(x_i, y_j)$ defined analogously. Then,

$$D_x^2 u(x_i, y_j) := D_x^- D_x^+ u(x_i, y_j),$$

$$D_y^2 u(x_i, y_j) := D_y^- D_y^+ u(x_i, y_j)$$

are referred to as the *second-order divided difference* of u in the x -direction and the y -direction, respectively, at $(x_i, y_j) \in \Omega_h$.

Assuming that $u \in C^4(\bar{\Omega})$ (i.e., that u and all of its partial derivatives up to and including those of fourth order are defined and continuous on $\bar{\Omega}$), we have that, at any $(x_i, y_j) \in \Omega_h$,

$$D_x^2 u(x_i, y_j) = \frac{\partial^2 u}{\partial x^2}(x_i, y_j) + \mathcal{O}(h^2) \quad (3)$$

and

$$D_y^2 u(x_i, y_j) = \frac{\partial^2 u}{\partial y^2}(x_i, y_j) + \mathcal{O}(h^2) \quad (4)$$

as $h \rightarrow 0$. Omission of the $\mathcal{O}(h^2)$ terms in (3) and (4) above yields that

$$D_x^2 u(x_i, y_j) \approx \frac{\partial^2 u}{\partial x^2}(x_i, y_j),$$

$$D_y^2 u(x_i, y_j) \approx \frac{\partial^2 u}{\partial y^2}(x_i, y_j),$$

where the symbol “ \approx ” signifies approximate equality in the sense that as $h \rightarrow 0$ the expression on the left of the symbol converges to the expression on its right. Hence,

$$\begin{aligned} & -(D_x^2 u(x_i, y_j) + D_y^2 u(x_i, y_j)) + c(x_i, y_j)u(x_i, y_j) \\ & \approx f(x_i, y_j) \quad \text{for all } (x_i, y_j) \in \Omega_h, \end{aligned} \quad (5)$$

$$u(x_i, y_j) = 0 \quad \text{for all } (x_i, y_j) \in \partial\Omega_h. \quad (6)$$

It is instructive to note the similarity between (1) and (5), and between (2) and (6). Motivated by the form of (5) and (6), we seek a grid function U whose value at the grid point $(x_i, y_j) \in \bar{\Omega}_h$, denoted by U_{ij} , approximates $u(x_i, y_j)$, the unknown exact solution to the boundary-value problem (1), (2) evaluated at (x_i, y_j) , $i, j = 0, \dots, N$. We define U to be the solution to the following system of linear algebraic equations:

$$\begin{aligned} & -(D_x^2 U_{ij} + D_y^2 U_{ij}) + c(x_i, y_j)U_{ij} \\ & = f(x_i, y_j) \quad \text{for all } (x_i, y_j) \in \Omega_h, \end{aligned} \quad (7)$$

$$U_{ij} = 0 \quad \text{for all } (x_i, y_j) \in \partial\Omega_h. \quad (8)$$

As each equation in (7) involves five values of the grid function U (namely, U_{ij} , $U_{i-1,j}$, $U_{i+1,j}$, $U_{i,j-1}$, $U_{i,j+1}$), the finite-difference method (7) is called the *five-point difference scheme*. The matrix of the linear system (7), (8) is sparse, symmetric, and positive-definite, and for given functions c and f it can be efficiently solved by iterative techniques from NUMERICAL LINEAR ALGEBRA [IV.10], including KRYLOV SUBSPACE [II.23] type methods (e.g., the conjugate gradient method) and *multigrid methods*. Multigrid methods were developed in the 1970s and 1980s and are widely used as the iterative solver of choice for large systems of linear algebraic equations that arise from finite-difference and finite-element approximations in many industrial applications. The key objective of a multigrid method is to accelerate the convergence of standard iterative methods (such as Jacobi iteration and successive over-relaxation) by using a hierarchy of coarser-to-finer grids. A multigrid method with an intentionally reduced convergence tolerance can also be used as an efficient *preconditioner* for a Krylov subspace iteration. The preconditioner P for a nonsingular matrix A is an approximation of A^{-1} whose purpose is to ensure

that PA is a good approximation of the identity matrix, thereby ensuring that iterative algorithms for the solution of the preconditioned version, $PAX = Pb$, of the system of linear algebraic equations $Ax = b$ exhibit rapid convergence.

One of the central questions in the numerical analysis of PDEs is the mathematical study of the approximation properties of numerical methods. We will illustrate this by considering the finite-difference method (7), (8). The grid function T defined on Ω_h by

$$\begin{aligned} T_{ij} := & -(D_x^2 u(x_i, y_j) + D_y^2 u(x_i, y_j)) \\ & + c(x_i, y_j)u(x_i, y_j) - f(x_i, y_j) \end{aligned} \quad (9)$$

is called the *truncation error* of the finite-difference method (7), (8). Assuming that $u \in C^4(\bar{\Omega})$, it follows from (3)-(5) that, at each grid point $(x_i, y_j) \in \Omega_h$, $T_{ij} = \mathcal{O}(h^2)$ as $h \rightarrow 0$. The exponent of h in the statement $T_{ij} = \mathcal{O}(h^2)$ (which, in this case, is equal to 2) is called the *order of accuracy* (or *order of consistency*) of the method.

It can be shown that there exists a positive constant c_0 , independent of h , U , and f , such that

$$\begin{aligned} & \left(h^2 \sum_{i=1}^N \sum_{j=1}^{N-1} |D_x^- U_{ij}|^2 \right. \\ & \left. + h^2 \sum_{i=1}^{N-1} \sum_{j=1}^N |D_y^- U_{ij}|^2 + h^2 \sum_{i=1}^{N-1} \sum_{j=1}^{N-1} |U_{ij}|^2 \right)^{1/2} \\ & \leq c_0 \left(h^2 \sum_{i=1}^{N-1} \sum_{j=1}^{N-1} |f(x_i, y_j)|^2 \right)^{1/2}. \end{aligned} \quad (10)$$

Such an inequality (which expresses the fact that the numerical solution $U \in S_{h,0}$ is bounded by the data (in this case $f \in S_h$) uniformly with respect to the grid size h , where $S_{h,0}$ denotes the linear space of all grid functions defined on $\bar{\Omega}_h$ that vanish on $\partial\Omega_h$ and where S_h is the linear space of all grid functions defined on Ω_h) is called a *stability inequality*. The smallest real number $c_0 > 0$ for which (10) holds is called the *stability constant* of the method. It follows in particular from (10) that if $f_{ij} = 0$ for all $i, j = 1, \dots, N-1$, then $U_{ij} = 0$ for all $i, j = 0, \dots, N$. Therefore, the matrix of the system of linear equations (7), (8) is nonsingular, which then implies the existence of a unique solution U to (7), (8) for any $h = 1/N$, $N \geq 2$. Consider the difference operator $L_h: U \in S_{h,0} \mapsto f = L_h U \in S_h$ defined by (7), (8). The left-hand side of (10) is sometimes denoted by $\|U\|_{1,h}$ and the right-hand side by $\|f\|_{0,h}$; hence, the stability inequality (10) can be rewritten as

$$\|U\|_{1,h} \leq c_0 \|f\|_{0,h}$$

with $f = L_h U$, and stability can then be seen to be demanding the existence of the inverse to the linear finite-difference operator $L_h: S_{h,0} \rightarrow S_h$, and its boundedness, uniformly with respect to the discretization parameter h . The mapping $U \in S_{h,0} \mapsto \|U\|_{1,h} \in \mathbb{R}$ is a norm on $S_{h,0}$, called the *discrete (Sobolev) $H^1(\Omega)$ -norm*, and the mapping $f \in S_h \mapsto \|f\|_{0,h} \in \mathbb{R}$ is a norm on S_h , called the *discrete $L^2(\Omega)$ -norm*. It should be noted that the stability properties of finite-difference methods depend on the choice of norm for the data and for the associated solution.

In order to quantify the closeness of the approximate solution U to the analytical solution u at the grid points, we define the *global error* e of the method (7), (8) by $e_{ij} := u(x_i, y_j) - U_{ij}$. Clearly, the grid function $e = u - U$ satisfies (7), (8) if $f(x_i, y_j)$ on the right-hand side of (7) is replaced by T_{ij} . Hence, by the stability inequality, $\|u - U\|_{1,h} = \|e\|_{1,h} \leq c_0 \|T\|_{0,h}$. Under the assumption that $u \in C^4(\bar{\Omega})$ we thus deduce that $\|u - U\|_{1,h} \leq c_1 h^2$, where c_1 is a positive constant, independent of h . The exponent of h on the right-hand side (which is 2 in this case) is referred to as the *order of convergence* of the finite-difference method and is equal to the order of accuracy. Indeed, the fundamental idea that stability and consistency together imply convergence is a recurring theme in the analysis of numerical methods for differential equations.

The five-point difference scheme can be generalized in various ways. For example, instead of using the same grid size h in both coordinate directions, one could have used a grid size $\Delta x = 1/M$ in the x -direction and a possibly different grid size $\Delta y = 1/N$ in the y -direction, where $M, N \geq 2$ are integers. One can also consider boundary-value problems on more complicated polygonal domains Ω in \mathbb{R}^2 such that each edge of Ω is parallel with one of the coordinate axes, for example, the L-shaped domain $(-1, 1)^2 \setminus [0, 1]^2$. The construction above can be extended to domains with curved boundaries in any number of dimensions; at grid points that are on (or next to) the boundary, divided differences with unequally spaced grid points are then used.

In the case of nonlinear elliptic boundary-value problems, such as the Monge–Ampère equation on a bounded open set $\Omega \subset \mathbb{R}^d$, subject to the nonhomogeneous Dirichlet boundary condition $u = g$ on $\partial\Omega$, a finite-difference approximation is easily constructed by replacing at each grid point $(x_i, y_j) \in \Omega$ the value $u(x_i, y_j)$ of the analytical solution u (and its partial derivatives) in the PDE with the numerical solution U_{ij}

(and its divided differences) and by then imposing the numerical boundary condition $U_{ij} = g(x_i, y_j)$ for all $(x_i, y_j) \in \partial\Omega_h$. Unfortunately, such a simple-minded method does not explicitly demand the convexity of U in any sense, and this can lead to instabilities. In fact, there is no reason why the sequence of finite-difference solutions should converge to the (convex) analytical solution of the Monge–Ampère equation as $h \rightarrow 0$. Even in two space dimensions the resulting method may have multiple solutions, and special iterative solvers need to be used to select the convex solution. Enforcing convexity of the finite-difference solution in higher dimensions is much more difficult. A recent development in this field has been the construction of so-called *wide-stencil finite-difference methods*, which are monotone, and the convergence theory of Barles and Souganidis therefore ensures convergence of the sequence of numerical solutions, as $h \rightarrow 0$, to the unique viscosity solution of the Monge–Ampère equation.

We close this section on finite-difference methods with a brief discussion about their application to time-dependent problems. A key result is the *Lax equivalence theorem*, which states that, for a finite-difference method that is consistent with a well-posed initial-value problem for a linear PDE, stability of the method implies convergence of the sequence of grid functions defined by the method on the grid to the analytical solution as the grid size converges to zero, and vice versa. Consider the unsteady heat equation $u_t - \Delta u + u = 0$ for $t \in (0, T]$, with $T > 0$ given, and (x, y) in the unit square $\Omega = (0, 1)^2$, subject to the homogeneous Dirichlet boundary condition $u = 0$ on $(0, T] \times \partial\Omega$ and the initial condition $u(0, x, y) = u_0(x, y)$, $(x, y) \in \Omega$, where u_0 and f are given real-valued continuous functions. The computational domain $[0, T] \times \bar{\Omega}$ is discretized by the grid $\{t^m = m\Delta t : m = 0, \dots, M\} \times \bar{\Omega}_h$, where $\Delta t = T/M$, $M \geq 1$, and $h = 1/N$, $N \geq 2$. We consider the θ -method

$$\frac{U_{ij}^{m+1} - U_{ij}^m}{\Delta t} - (D_x^2 U_{ij}^{m+\theta} + D_y^2 U_{ij}^{m+\theta}) + U_{ij}^{m+\theta} = 0$$

for all $i, j = 1, \dots, N - 1$ and $m = 0, \dots, M - 1$, supplemented with the initial condition $U_{ij}^0 = u_0(x_i, y_j)$, $i, j = 0, \dots, N$, and the boundary condition $U_{ij}^{m+1} = 0$, $m = 0, \dots, M - 1$, for all (i, j) such that $(x_i, y_j) \in \partial\Omega_h$. Here, $\theta \in [0, 1]$ and

$$U_{ij}^{m+\theta} := (1 - \theta)U_{ij}^m + \theta U_{ij}^{m+1},$$

with U_{ij}^m and U_{ij}^{m+1} representing the approximations to $u(t^m, x_i, y_j)$ and $u(t^{m+1}, x_i, y_j)$, respectively. The

values $\theta = 0, \frac{1}{2}, 1$ are particularly relevant; the corresponding finite-difference methods are called the *forward* (or *explicit*) *Euler method*, the *Crank–Nicolson method*, and the *backward* (or *implicit*) *Euler method*, respectively; their truncation errors are defined by

$$\begin{aligned} T_{ij}^{m+1} := & \frac{u(t^{m+1}, x_i, y_j) - u(t^m, x_i, y_j)}{\Delta t} \\ & - (1 - \theta)(D_x^2 u(t^m, x_i, y_j) + D_y^2 u(t^m, x_i, y_j)) \\ & - \theta(D_x^2 u(t^{m+1}, x_i, y_j) + D_y^2 u(t^{m+1}, x_i, y_j)) \\ & + (1 - \theta)u(t^m, x_i, y_j) + \theta u(t^{m+1}, x_i, y_j) \end{aligned}$$

for $i, j = 1, \dots, N - 1$, $m = 0, \dots, M - 1$. Assuming that u is sufficiently smooth, Taylor series expansion yields that $T_{ij} = \mathcal{O}(\Delta t + h^2)$ for $\theta \neq \frac{1}{2}$ and $T_{ij} = \mathcal{O}((\Delta t)^2 + h^2)$ for $\theta = \frac{1}{2}$. Thus, in particular, the forward and backward Euler methods are first-order accurate with respect to the temporal variable t and second-order accurate with respect to the spatial variables x and y , whereas the Crank–Nicolson method is second-order accurate with respect to both the temporal variable and the spatial variables. The stability properties of the θ -method are also influenced by the choice of $\theta \in [0, 1]$; we have that

$$\max_{1 \leq m \leq M} \|U^m\|_{0,h}^2 + \Delta t \sum_{m=0}^{M-1} \|U^{m+\theta}\|_{1,h}^2 \leq \|U^0\|_{0,h}^2$$

for $\theta \in [0, \frac{1}{2}]$, provided that $2d(1 - 2\theta)\Delta t \leq h^2$, with $d = 2$ (space dimensions) in our case; and for $\theta \in [\frac{1}{2}, 1]$, irrespective of the choice of Δt and h . Thus, in particular, the forward (explicit) Euler method is *conditionally stable*, the condition being that $2d\Delta t \leq h^2$, with $d = 2$ here, while the Crank–Nicolson and backward (implicit) Euler methods are *unconditionally stable*.

A finite-difference method approximates the analytical solution using a grid function that is defined over a finite-difference grid contained in the computational domain. Next we will consider finite-element methods, which involve piecewise polynomial approximations of the analytical solution, defined over the computational domain.

4 Finite-Element Methods

Finite-element methods (FEMs) are a powerful and general class of techniques for the numerical solution of PDEs. Their historical roots can be traced back to a paper by Richard Courant, published in 1943, that proposed the use of continuous piecewise affine approximations for the numerical solution of variational problems. This represented a significant advance from a

practical point of view over earlier techniques by Ritz and Galerkin from the early 1900s, which were based on the use of linear combinations of smooth functions (e.g., eigenfunctions of the differential operator under consideration). The importance of Courant's contribution was, unfortunately, not recognized at the time and the idea was forgotten until the early 1950s, when it was rediscovered by engineers. FEMs have since been developed into an effective and flexible computational tool with a firm mathematical foundation.

4.1 FEMs for Elliptic PDEs

Suppose that $\Omega \subset \mathbb{R}^d$ is a bounded open set in \mathbb{R}^d with a Lipschitz-continuous boundary $\partial\Omega$. We will denote by $L^2(\Omega)$ the space of square-integrable functions (in the sense of Lebesgue) equipped with the norm $\|v\|_0 := (\int_{\Omega} |v|^2 dx)^{1/2}$. Let $H^m(\Omega)$ denote the *Sobolev space* consisting of all functions $v \in L^2(\Omega)$ whose (weak) partial derivatives $\partial^\alpha v$ belong to $L^2(\Omega)$ for all α such that $|\alpha| \leq m$. $H^m(\Omega)$ is equipped with the norm $\|v\|_m := (\sum_{|\alpha| \leq m} \|\partial^\alpha v\|_0^2)^{1/2}$. We denote by $H_0^1(\Omega)$ the set of all functions $v \in H^1(\Omega)$ that vanish on $\partial\Omega$.

Let a and c be real-valued functions, defined and continuous on $\bar{\Omega}$, and suppose that there exists a positive constant c_0 such that $a(x) \geq c_0$ for all $x \in \bar{\Omega}$. Assume further that b_i , $i = 1, \dots, d$, are continuously differentiable real-valued functions defined on $\bar{\Omega}$ such that $c - \frac{1}{2}\nabla \cdot b \geq c_0$ on $\bar{\Omega}$, where $b := (b_1, \dots, b_d)$, and let $f \in L^2(\Omega)$. Consider the boundary-value problem

$$-\nabla \cdot (a(x)\nabla u) + b(x) \cdot \nabla u + c(x)u = f(x)$$

for $x \in \Omega$, with $u|_{\partial\Omega} = 0$. The construction of the finite-element approximation of this boundary-value problem commences by considering the following *weak formulation* of the problem: find $u \in H_0^1(\Omega)$ such that

$$B(u, v) = \ell(v) \quad \forall v \in H_0^1(\Omega), \quad (11)$$

where the bilinear form $B(\cdot, \cdot)$ is defined by

$$B(w, v)$$

$$:= \int_{\Omega} [a(x)\nabla w \cdot \nabla v + b(x) \cdot \nabla w v + c(x)w v] dx$$

and $\ell(v) := \int_{\Omega} fv dx$, with $w, v \in H_0^1(\Omega)$. If u is sufficiently smooth (for example, if $u \in H^2(\Omega) \cap H_0^1(\Omega)$), then integration by parts in (11) implies that u is a *strong solution* of the boundary-value problem, i.e., $-\nabla \cdot (a(x)\nabla u) + b(x) \cdot \nabla u + c(x)u = f(x)$ almost everywhere in Ω , and $u|_{\partial\Omega} = 0$. More generally, in the absence of such an additional assumption about smoothness, the function $u \in H_0^1(\Omega)$ satisfying (11) is

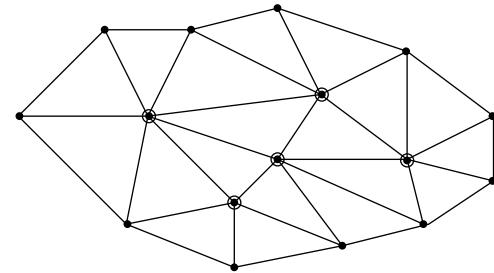

Figure 1 Finite-element triangulation of the computational domain $\bar{\Omega}$, a polygonal region of \mathbb{R}^2 . Vertices on $\partial\Omega$ are denoted by solid dots, and vertices internal to Ω by circled solid dots.

called a *weak solution* of this elliptic boundary-value problem. Under our assumptions on a , b , c , and f , the existence of a unique weak solution follows from the Lax-Milgram theorem.

We will consider the finite-element approximation of (11) in the special case when Ω is a bounded open polygonal domain in \mathbb{R}^2 . The first step in the construction of the FEM is to define a *triangulation* of $\bar{\Omega}$. A triangulation of $\bar{\Omega}$ is a tessellation of $\bar{\Omega}$ into a finite number of closed triangles T_i , $i = 1, \dots, M$, whose interiors are pairwise disjoint, and for each $i, j \in \{1, \dots, M\}$, $i \neq j$, for which $T_i \cap T_j$ is nonempty, $T_i \cap T_j$ is either a common vertex or a common edge of T_i and T_j (see figure 1). The vertices in the triangulation are also referred to as *nodes*.

Let h_T denote the longest edge of a triangle T in the triangulation, and let h be the largest among the h_T . Furthermore, let S_h denote the linear space of all real-valued continuous functions v_h defined on $\bar{\Omega}$ such that the restriction of v_h to any triangle in the triangulation is an affine function, and define $S_{h,0} := S_h \cap H_0^1(\Omega)$. The finite-element approximation of the problem (11) is as follows: find u_h in the *finite-element space* $S_{h,0}$ such that

$$B(u_h, v_h) = \ell(v_h) \quad \forall v_h \in S_{h,0}. \quad (12)$$

Let us denote by x_i , $i = 1, \dots, L$, the set of all vertices (nodes) in the triangulation (see figure 1), and let $N = N(h)$ denote the dimension of the finite-element space $S_{h,0}$. We will assume that the vertices x_i , $i = 1, \dots, L$, are numbered so that x_i , $i = 1, \dots, N$, are within Ω and the remaining $L - N$ vertices are on $\partial\Omega$. Furthermore, let $\{\varphi_j : j = 1, \dots, N\} \subset S_{h,0}$ denote the so-called *nodal basis* for $S_{h,0}$, where the basis functions are defined by $\varphi_j(x_i) = \delta_{ij}$, $i = 1, \dots, L$, $j = 1, \dots, N$. A typical piecewise-linear nodal basis function is shown in figure 2. Thus, there exists a vector $U = (U_1, \dots, U_N)^T \in$

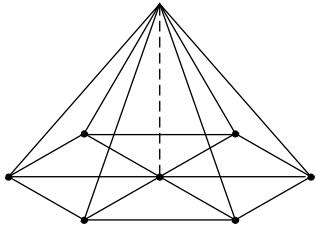

Figure 2 A typical piecewise-linear nodal basis function. The basis function is identically zero outside the patch of triangles surrounding the central node, at which the height of the function is equal to 1.

\mathbb{R}^N such that

$$u_h(x) = \sum_{j=1}^N U_j \varphi_j(x). \quad (13)$$

Substitution of this expansion into (12) and taking $v_h = \varphi_k$, $k = 1, \dots, N$, yields the following system of N linear algebraic equations in the N unknowns, U_1, \dots, U_N :

$$\sum_{j=1}^N B(\varphi_j, \varphi_k) U_j = \ell(\varphi_k), \quad k = 1, \dots, N. \quad (14)$$

By recalling the definition of $B(\cdot, \cdot)$, we see that the matrix $A := ([B(\varphi_j, \varphi_k)]_{j,k=1}^N)^T$ of this system of linear equations is sparse and positive-definite (and, if b is identically zero, then the matrix is symmetric as well). The unique solution $U = (U_1, \dots, U_N)^T \in \mathbb{R}^N$ of the linear system, upon substitution into (13), yields the computed approximation u_h to the analytical solution u on the given triangulation of the computational domain $\bar{\Omega}$, using numerical algorithms for SPARSE LINEAR SYSTEMS [IV.10 §6], including Krylov subspace type methods and multigrid methods.

As $S_{h,0}$ is a (finite-dimensional) linear subspace of $H_0^1(\Omega)$, $v = v_h$ is a legitimate choice in (11). By subtracting (12) from (11), with $v = v_h$, we deduce that

$$B(u - u_h, v_h) = 0 \quad \forall v_h \in S_{h,0}, \quad (15)$$

which is referred to as the *Galerkin orthogonality property* of the FEM. Hence, for any $v_h \in S_{h,0}$,

$$\begin{aligned} c_0 \|u - u_h\|_1^2 &\leq B(u - u_h, u - u_h) \\ &= B(u - u_h, u - v_h) \\ &\leq c_1 \|u - u_h\|_1 \|u - v_h\|_1, \end{aligned}$$

where

$$c_1 := (M_a^2 + M_b^2 + M_c^2)^{1/2},$$

with $M_v := \max_{x \in \bar{\Omega}} |v(x)|$, $v \in \{a, b, c\}$. We therefore have that

$$\|u - u_h\|_1 \leq \frac{c_1}{c_0} \min_{v_h \in S_{h,0}} \|u - v_h\|_1. \quad (16)$$

This result is known as *Céa's lemma*, and it is an important tool in the analysis of FEMs. Suppose, for example, that $u \in H^2(\Omega) \cap H_0^1(\Omega)$, and denote by I_h the *finite-element interpolant* of u defined by

$$I_h u(x) := \sum_{j=1}^N u(x_j) \varphi_j(x).$$

It follows from (16) that $\|u - u_h\|_1 \leq (c_1/c_0) \|u - I_h u\|_1$. Assuming further that the triangulation is *shape regular* in the sense that there exists a positive constant c_* , independent of h , such that for each triangle in the triangulation the ratio of the longest edge to the radius of the inscribed circle is bounded below by c_* , arguments from approximation theory imply the existence of a positive constant \hat{c} , independent of h , such that $\|u - I_h u\|_1 \leq \hat{c} h \|u\|_2$. Hence, the following *a priori error bound* holds in the H^1 -norm:

$$\|u - u_h\|_1 \leq (c_1/c_0) \hat{c} h \|u\|_2.$$

We deduce from this inequality that, as the triangulation is refined by letting $h \rightarrow 0$, the sequence of finite-element approximations u_h computed on successively refined triangulations converges to the analytical solution u in the H^1 -norm. It is also possible to derive *a priori* error bounds in other norms, such as the L^2 -norm.

The inequality (16) of Céa's lemma can be seen to express the fact that the approximation $u_h \in S_{h,0}$ to the solution $u \in H_0^1(\Omega)$ of (11) delivered by the FEM (12) is a *near-best approximation* to u from the linear subspace $S_{h,0}$ of $H_0^1(\Omega)$. Clearly, $c_1/c_0 \geq 1$. When the constant $c_1/c_0 \gg 1$, the numerical solution u_h supplied by the FEM is typically a poor approximation to u in the $\|\cdot\|_1$ -norm, unless h is very small; for example, if $a(x) = c(x) \equiv \varepsilon$ and $b(x) = (1, 1)^T$, then $c_1/c_0 = \sqrt{2}(1 + \varepsilon^2)^{1/2}/\varepsilon \gg 1$ if $0 < \varepsilon \ll 1$. Such non-self-adjoint elliptic boundary-value problems arise in mathematical models of diffusion-advection-reaction, where advection dominates diffusion and reaction in the sense that $|b(x)| \gg a(x) > 0$ and $|b(x)| \gg c(x) > 0$ for all $x \in \bar{\Omega}$. The stability and approximation properties of the classical FEM (12) for such advection-dominated problems can be improved by modifying, in a consistent manner, the definitions of $B(\cdot, \cdot)$ and $\ell(\cdot)$ through the addition of “stabilization terms” or by enriching the finite-element space with special basis functions that are designed so as to capture sharp boundary and interior layers exhibited by typical solutions of advection-dominated problems. The resulting FEMs are generally referred to as *stabilized finite-element methods*. A typical example is the *streamline-diffusion finite-element*

method, in which the bilinear form of the standard FEM is supplemented with an additional numerical diffusion term, which acts in the streamwise direction only, i.e., in the direction of the vector b , in which classical FEMs tend to exhibit undesirable numerical oscillations.

If, on the other hand, b is identically zero on $\bar{\Omega}$, then $B(\cdot, \cdot)$ is a *symmetric* bilinear form, in the sense that $B(w, v) = B(v, w)$ for all $w, v \in H_0^1(\Omega)$. The norm $\|\cdot\|_B$ defined by $\|v\|_B := [B(v, v)]^{1/2}$ is called the *energy norm* on $H_0^1(\Omega)$ associated with the elliptic boundary-value problem (11). In fact, (11) can then be restated as the following (equivalent) variational problem: find $u \in H_0^1(\Omega)$ such that

$$J(u) \leq J(v) \quad \forall v \in H_0^1(\Omega),$$

where

$$J(v) := \frac{1}{2}B(v, v) - \ell(v).$$

Analogously, the FEM (12) can then be restated equivalently as follows: find $u_h \in S_{h,0}$ such that $J(u_h) \leq J(v_h)$ for all $v_h \in S_{h,0}$. Furthermore, Céa's lemma, in terms of the energy norm, $\|\cdot\|_B$, becomes $\|u - u_h\|_B = \min_{v_h \in S_{h,0}} \|u - v_h\|_B$. Thus, in the case when the function b is identically zero the numerical solution $u_h \in S_{h,0}$ delivered by the FEM is the *best approximation* to the analytical solution $u \in H_0^1(\Omega)$ in the energy norm $\|\cdot\|_B$.

We illustrate the extension of these ideas to nonlinear elliptic PDEs through a simple model problem. For a real number $p \in (1, \infty)$, let $L^p(\Omega) := \{v: \int_{\Omega} |v|^p dx < \infty\}$ and $W^{1,p}(\Omega) := \{v \in L^p(\Omega): |\nabla v| \in L^p(\Omega)\}$. Furthermore, let $W_0^{1,p}(\Omega)$ denote the set of all $v \in W^{1,p}(\Omega)$ such that $v|_{\partial\Omega} = 0$. For $f \in L^q(\Omega)$, where $1/p + 1/q = 1$, $p \in (1, \infty)$, consider the problem of finding the minimizer $u \in W_0^{1,p}(\Omega)$ of the functional

$$J(v) := \frac{1}{p} \int_{\Omega} |\nabla v|^p dx - \int_{\Omega} f v dx, \quad v \in W_0^{1,p}(\Omega).$$

With $S_{h,0}$ as above, the finite-element approximation of the problem then consists of finding $u_h \in S_{h,0}$ that minimizes $J(v_h)$ over all $v_h \in S_{h,0}$. The existence and uniqueness of the minimizers $u \in W_0^{1,p}(\Omega)$ and $u_h \in S_{h,0}$ in the respective problems is a direct consequence of the convexity of the functional J . Moreover, as $h \rightarrow 0$, u_h converges to u in the norm of the Sobolev space $W^{1,p}(\Omega)$.

Problems in electromagnetism and continuum mechanics are typically modeled by systems of PDEs involving several dependent variables, which may need to be approximated from different finite-element spaces because of the disparate physical nature of the variables and the different boundary conditions that they

may be required to satisfy. The resulting finite-element methods are called *mixed finite-element methods*. In order for a mixed FEM to possess a unique solution and for the method to be stable, the finite-element spaces from which the approximations to the various components of the vector of unknowns are sought cannot be chosen arbitrarily; they need to satisfy a certain compatibility condition, usually referred to as the *inf-sup condition*.

FEMs of the kind described in this section—where the finite-element space containing the approximate solution is a subset of the function space in which the weak solution to the problem is sought—are called *conforming finite-element methods*. Otherwise, the FEM is called *nonconforming*. Nonconforming FEMs are necessary in some application areas because in certain problems (such as div-curl problems from electromagnetism and variational problems exhibiting a Lavrentiev phenomenon, for example), conforming FEMs may converge to spurious solutions. *Discontinuous Galerkin finite-element methods* (DGFEMs) are extreme instances of nonconforming FEMs, in the sense that pointwise interelement continuity requirements in the piecewise polynomial approximation are completely abandoned, and the analytical solution is approximated by discontinuous piecewise polynomial functions. FEMs have several advantages over finite-difference methods: the concept of higher-order discretization is inherent to FEMs; it is, in addition, particularly convenient from the point of view of adaptivity that FEMs can easily accommodate very general tessellations of the computational domain, with local polynomial degrees in the approximation that may vary from element to element. Indeed, the notion of *adaptivity* is a powerful and important idea in the field of numerical approximation of PDEs, and it is this that we will further elaborate on in the context of finite-element methods below.

4.2 A Posteriori Error Analysis and Adaptivity

Provided that the analytical solution is sufficiently smooth, a priori error bounds guarantee that, as the grid size h tends to 0, the corresponding sequence of numerical approximations converges to the exact solution of the boundary-value problem. In practice, one may unfortunately only be able to afford to compute on a small number of grids/triangulations, the minimum grid size attainable being limited by the computational resources available. A further practical consideration is that the regularity of the analytical solution

may exhibit large variations over the computational domain, with singularities localized at particular points (e.g., at corners and edges of the domain) or low-dimensional manifolds in the interior of the domain (e.g., shocks and contact discontinuities in nonlinear conservation laws, or steep internal layers in advection-dominated diffusion equations). The error between the unknown analytical solution and numerical solutions computed on locally refined grids, which are best suited for such problems, cannot be accurately quantified by typical a priori error bounds and asymptotic convergence results that presuppose uniform refinement of the computational grid as the grid size tends to 0. The alternative is to perform a computation on a chosen computational grid/triangulation and use the computed approximation to the exact solution to quantify the approximation error a posteriori, and also to identify parts of the computational domain in which the grid size was inadequately chosen, necessitating local, so-called *adaptive*, refinement or coarsening of the computational grid/triangulation (*h*-*adaptivity*). In FEMs it is also possible to locally vary the degree of the piecewise polynomial function in the finite-element space (*p*-*adaptivity*). Finally, one may also make adjustments to the computational grid/triangulation by moving/relocating the grid points (*r*-*adaptivity*). The adaptive loop for an *h*-adaptive FEM has the following form:

SOLVE → ESTIMATE → MARK → REFINE.

Thus, a finite-element approximation is first computed on a certain fixed, typically coarse, triangulation of the computational domain. Then, in the second step, an a posteriori error bound is used to estimate the error in the computed solution; a typical a posteriori error bound for an elliptic boundary-value problem $Lu = f$ (where L is a second-order uniformly elliptic operator and f is a given right-hand side) is of the form $\|u - u_h\|_1 \leq C_* \|R(u_h)\|_*$, where C_* is a (computable) constant; $\|\cdot\|_*$ is a certain norm, depending on the problem; and $R(u_h) = f - Lu_h$ is the (computable) *residual*, which measures the extent to which the computed numerical solution u_h fails to satisfy the PDE $Lu = f$. In the third step, on the basis of the a posteriori error bound, selected triangles in the triangulation are marked as having an inadequate size (i.e., too large or too small, relative to a fixed local tolerance, which is usually chosen as a suitable fraction of the prescribed overall tolerance, TOL). Finally, in the fourth step, the marked triangles are refined or coarsened,

as the case may be. This four-step adaptive loop is repeated either until a certain termination criterion is reached (e.g., $C_* \|R(u_h)\|_* < \text{TOL}$) or until the computational resources are exhausted. A similar adaptive loop can be used in *p*-adaptive FEMs, except that the step REFINE is then interpreted as adjustment (i.e., an increase or decrease) of the local polynomial degree, which may then vary from triangle to triangle instead of being a fixed integer over the entire triangulation. It is also possible to combine different adaptive strategies; for example, simultaneous *h*- and *p*-adaptivity is referred to as *hp*-*adaptivity*; thanks to the simple communication at the boundaries of adjacent elements in the subdivision of the computational domain, *hp*-adaptivity is particularly easy to incorporate into DGFEMs (see figure 3).

5 Finite-Volume Methods

Finite-volume methods have been developed for the numerical solution of PDEs in divergence form, such as CONSERVATION LAWS [II.6] that arise in continuum mechanics. Consider, for example, the following system of nonlinear PDEs:

$$\frac{\partial u}{\partial t} + \nabla \cdot f(u) = 0, \quad (17)$$

where $u := (u_1, \dots, u_n)^T$ is an n -component vector function of the variables $t \geq 0$ and $x := (x_1, \dots, x_d)$; the vector function $f(u) := (f_1(u), \dots, f_d(u))^T$ is the corresponding *flux function*. The PDE (17) is supplemented with the initial condition $u(0, x) = u_0(x)$, $x \in \mathbb{R}^d$. Suppose that \mathbb{R}^d has been tessellated into disjoint closed simplexes κ (intervals if $d = 1$, triangles if $d = 2$, and tetrahedrons if $d = 3$), whose union is the whole of \mathbb{R}^d and such that each pair of distinct simplexes from the tessellation is either disjoint or has only closed simplexes of dimension less than or equal to $d - 1$ in common. In the theory of finite-volume methods the simplexes κ are usually referred to as *cells* (rather than elements). For each particular cell κ in the tessellation of \mathbb{R}^d the PDE (17) is integrated over κ , which gives

$$\int_{\kappa} \frac{\partial u}{\partial t} dx + \int_{\kappa} \nabla \cdot f(u) dx = 0. \quad (18)$$

By defining the *volume average*

$$\bar{u}_{\kappa}(t) := \frac{1}{|\kappa|} \int_{\kappa} u(t, x) dx, \quad t \geq 0,$$

where $|\kappa|$ is the measure of κ , and applying the divergence theorem, we deduce that

$$\frac{d\bar{u}_{\kappa}}{dt} + \frac{1}{|\kappa|} \oint_{\partial\kappa} f(u) \cdot \nu dS = 0,$$

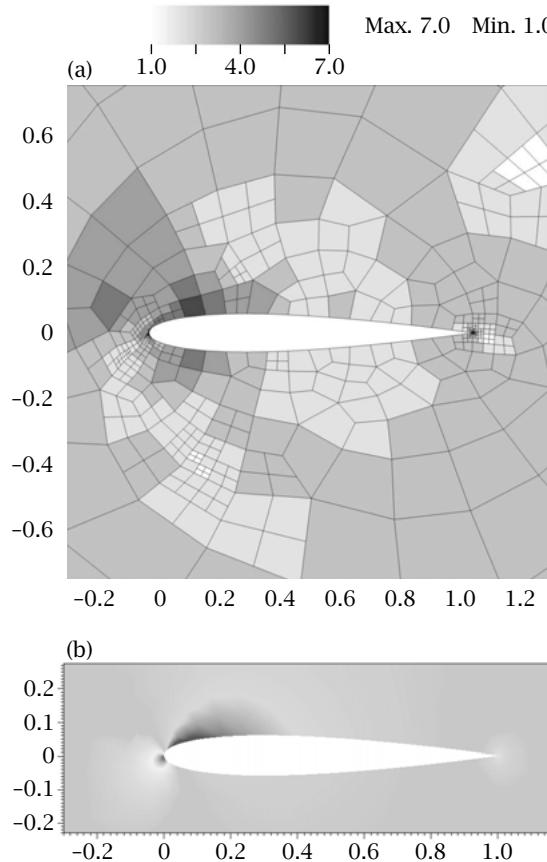

Figure 3 An hp -adaptive finite-element grid: (a) in a discontinuous Galerkin finite-element approximation of the compressible Euler equations of gas dynamics with local polynomial degrees ranging from 1 to 7; and (b) the approximate density on the grid. (Figure courtesy of Paul Houston.)

where $\partial\kappa$ is the boundary of κ and v is the unit outward normal vector to $\partial\kappa$.

In the present construction the constant volume average is assigned to the barycenter of a cell, and the resulting finite-volume method is therefore referred to as a *cell-center finite-volume method*. In the theory of finite-volume methods the local region κ over which the PDE is integrated is called a *control volume*. In the case of cell-center finite-volume methods, the control volumes therefore coincide with the cells in the tessellation. An alternative choice, resulting in *vertex-centered finite-volume methods*, is that for each vertex in the computational grid one considers the patch of cells surrounding the vertex and assigns to the vertex a control volume contained in the patch of elements (e.g.,

in the case of $d = 2$, the polygonal domain defined by connecting the barycenters of cells that surround a vertex).

Thus far, no approximation has taken place. In order to construct a practical numerical method, the integral over $\partial\kappa$ is rewritten as a sum of integrals over all $(d - 1)$ -dimensional open faces contained in $\partial\kappa$, and the integral over each face is approximated by replacing the normal flux $f(u) \cdot v$ over the face, appearing as the integrand, by interpolation or extrapolation of control volume averages. This procedure can be seen as a replacement of the exact normal flux over a face of a control volume with a *numerical flux function*. Thus, for example, denoting by $e_{\kappa\lambda}$ the $(d - 1)$ -dimensional face of the control volume κ that is shared with a neighboring control volume λ , we have that

$$\oint_{\partial\kappa} f(u) \cdot v \, dS \approx \sum_{\lambda: e_{\kappa\lambda} \subset \partial\kappa} g_{\kappa\lambda}(\bar{u}_\kappa, \bar{u}_\lambda),$$

where the numerical flux function $g_{\kappa\lambda}$ is required to possess the following two crucial properties.

Conservation ensures that fluxes from adjacent control volumes that share a mutual interface exactly cancel when summed. This is achieved by demanding that the numerical flux satisfies the identity

$$g_{\kappa\lambda}(u, v) = -g_{\lambda\kappa}(v, u)$$

for each pair of neighboring control volumes κ and λ .

Consistency ensures that, for each face of each control volume, the numerical flux with identical state arguments reduces to the true total flux of that same state passing through the face, i.e.,

$$g_{\kappa\lambda}(u, u) = \int_{e_{\kappa\lambda}} f(u) \cdot v \, dS$$

for each pair of neighboring control volumes κ and λ with common face $e_{\kappa\lambda} := \kappa \cap \lambda$.

The resulting spatial discretization of the nonlinear conservation law is then further discretized with respect to the temporal variable t by time stepping, in steps of Δt , starting from the given initial datum u_0 , the simplest choice being to use the explicit Euler method.

The historical roots of this construction date back to the work of Sergei Godunov in 1959 on the gas dynamics equations; Godunov used piecewise-constant solution representations in each control volume with value equal to the average over the control volume and calculated a single numerical flux from the local

solution of the Riemann problem posed at the interfaces. A Riemann problem (named after Bernhard Riemann) consists of a conservation law together with piecewise-constant data having a single discontinuity. Additional resolution beyond the first-order accuracy of the Godunov scheme can be attained by *reconstruction/recovery* from the computed cell averages (as in the MUSCL (monotonic upstream-centered scheme for conservation laws) scheme of Van Leer, which is based on piecewise-linear reconstruction, or by piecewise quadratic reconstruction, as in the piecewise parabolic method of Colella and Woodward) by exactly evolving discontinuous piecewise-linear states instead of piecewise-constant states, or by completely avoiding the use of Riemann solvers (as in the Nessyahu-Tadmor and Kurganov-Tadmor central difference methods).

Thanks to their built-in conservation properties, finite-volume methods have been widely and successfully used for the numerical solution of both scalar nonlinear conservation laws and systems of nonlinear conservation laws, including the compressible Euler equations of gas dynamics. There is a satisfactory convergence theory of finite-volume methods for scalar multidimensional conservation laws; efforts to develop a similar body of theory for multidimensional systems of nonlinear conservation laws are, however, hampered by the incompleteness of the theory of well-posedness for such PDE systems.

6 Spectral Methods

While finite-difference methods provide approximate solutions to PDEs at the points of the chosen computational grid, and finite-element and finite-volume methods supply continuous or discontinuous piecewise polynomial approximations on tessellations of the computational domain, spectral methods deliver approximate solutions in the form of polynomials of a certain fixed degree, which are, by definition, smooth functions over the entire computational domain. If the solution to the underlying PDE is a smooth function, a spectral method will provide a highly accurate numerical approximation to it.

Spectral approximations are typically sought as linear combinations of ORTHOGONAL POLYNOMIALS [II.29] over the computational domain. Consider a nonempty open interval (a, b) of the real line and a nonnegative weight function w , which is positive on (a, b) , except perhaps at countably many points in (a, b) , and such

that

$$\int_a^b w(x)|x|^k dx < \infty \quad \forall k \in \{0, 1, 2, \dots\}.$$

Furthermore, let $L_w^2(a, b)$ denote the set of all real-valued functions v defined on (a, b) such that

$$\|v\|_w := \left(\int_a^b w(x)|v(x)|^2 dx \right)^{1/2} < \infty.$$

Then $\|\cdot\|_w$ is a norm on $L_w^2(a, b)$, induced by the inner product $(u, v)_w := \int_a^b w(x)u(x)v(x) dx$. We say that $\{P_k\}_{k=0}^\infty$ is a system of orthogonal polynomials on (a, b) if P_k is a polynomial of exact degree k and $(P_m, P_n)_w = 0$ when $m \neq n$. For example, if $(a, b) = (-1, 1)$ and $w(x) = (1-x)^\alpha(1+x)^\beta$, with $\alpha, \beta \in (-1, 1)$ fixed, then the resulting system of orthogonal polynomials are the Jacobi polynomials, special cases of which are the Gegenbauer (or ultraspherical) polynomials ($\alpha = \beta \in (-1, 1)$), Chebyshev polynomials of the first kind ($\alpha = \beta = -\frac{1}{2}$), Chebyshev polynomials of the second kind ($\alpha = \beta = \frac{1}{2}$), and Legendre polynomials ($\alpha = \beta = 0$). On a multidimensional domain $\Omega \subset \mathbb{R}^d$, $d \geq 2$, that is the Cartesian product of nonempty open intervals (a_k, b_k) , $k = 1, \dots, d$, of the real line and a multivariate weight function w of the form $w(x) = w_1(x_1) \cdots w_d(x_d)$, where $x = (x_1, \dots, x_d)$ and w_k is a univariate weight function of the variable $x_k \in (a_k, b_k)$, $k = 1, \dots, d$, orthogonal polynomials with respect to the inner product $(\cdot, \cdot)_w$ defined by $(u, v)_w = \int_\Omega w(x)u(x)v(x) dx$ are simply products of univariate orthogonal polynomials with respect to the weights w_k , defined on the intervals (a_k, b_k) , $k = 1, \dots, d$, respectively.

Spectral Galerkin methods for PDEs are based on transforming the PDE problem under consideration into a suitable weak form by multiplication with a *test function*, integration of the resulting expression over the computational domain Ω , and integration by parts, if necessary, in order to incorporate boundary conditions. As in the case of finite-element methods, an approximate solution u_N to the analytical solution u is sought from a finite-dimensional linear space $S_N \subset L_w^2(\Omega)$, which is now, however, spanned by the first $(N+1)^d$ elements of a certain system of orthogonal polynomials with respect to the weight function w . The function u_N is required to satisfy the same weak formulation as the analytical solution, except that the test functions are confined to the finite-dimensional linear space S_N . In order to exploit the orthogonality properties of the chosen system of orthogonal polynomials, the weight function w has to be incorporated into the weak formulation of the problem, which is not always

easy, unless of course the weight function w already appears as a coefficient in the differential equation, or if the orthogonal polynomials in question are the Legendre polynomials (since then $w(x) \equiv 1$). We describe the construction for a uniformly elliptic PDE subject to a *homogeneous Neumann* boundary condition:

$$\begin{aligned} -\Delta u + u &= f(x) \quad x \in \Omega := (-1, 1)^d, \\ \frac{\partial u}{\partial \nu} &= 0 \quad \text{on } \partial\Omega, \end{aligned}$$

where $f \in L^2(\Omega)$ and ν denotes the unit outward normal vector to $\partial\Omega$ (or, more precisely, to the $(d-1)$ -dimensional open faces contained in $\partial\Omega$). Let us consider the finite-dimensional linear space

$$S_N := \text{span}\{L_\alpha := L_{\alpha_1} \cdots L_{\alpha_d} : 0 \leq \alpha_k \leq N, k = 1, \dots, d\},$$

where L_{α_k} is the univariate Legendre polynomial of degree α_k of the variable $x_k \in (-1, 1)$, $k = 1, \dots, d$. The *Legendre-Galerkin spectral approximation* of the boundary-value problem is defined as follows: find $u_N \in S_N$ such that

$$B(u_N, v_N) = \ell(v_N) \quad \forall v_N \in S_N, \quad (19)$$

where the linear functional $\ell(\cdot)$ and the bilinear form $B(\cdot, \cdot)$ are defined by

$$\ell(v) := \int_{\Omega} f v \, dx$$

and

$$B(w, v) := \int_{\Omega} (\nabla w \cdot \nabla v + w v) \, dx,$$

respectively, with $w, v \in H^1(\Omega)$. As $B(\cdot, \cdot)$ is a symmetric bilinear form and S_N is a finite-dimensional linear space, the task of determining u_N is equivalent to solving a system of linear algebraic equations with a symmetric square matrix $A \in \mathbb{R}^{K \times K}$ with $K := \dim(S_N) = (N+1)^d$. Since $B(V, V) = \|V\|_1^2 > 0$ for all $V \in S_N \setminus \{0\}$, where, as before, $\|\cdot\|_1$ denotes the $H^1(\Omega)$ -norm, the matrix A is positive-definite, and therefore invertible. Thus we deduce the existence and uniqueness of a solution to (19). Céa's lemma (see (16)) for (19) takes the form

$$\|u - u_N\|_1 = \min_{v_N \in S_N} \|u - v_N\|_1. \quad (20)$$

If we assume that $u \in H^s(\Omega)$, $s > 1$, results from approximation theory imply that the right-hand side of (20) is bounded by a constant multiple of $N^{1-s} \|u\|_s$, and we thus deduce the error bound

$$\|u - u_N\|_1 \leq CN^{1-s} \|u\|_s, \quad s > 1.$$

Furthermore, if $u \in C^\infty(\bar{\Omega})$ (i.e., all partial derivatives of u of any order are continuous on $\bar{\Omega}$), then $\|u - u_N\|_1$ will converge to zero at a rate that is faster than any algebraic rate of convergence; such a superalgebraic convergence rate is usually referred to as *spectral convergence* and is the hallmark of spectral methods.

Since $u_N \in S_N$, there exist $U_\alpha \in \mathbb{R}$, with multi-indices $\alpha = (\alpha_1, \dots, \alpha_d) \in \{0, \dots, N\}^d$, such that

$$u_N(x) = \sum_{\alpha \in \{0, \dots, N\}^d} U_\alpha L_\alpha(x).$$

Substituting this expansion into (19) and taking $v_N = L_\beta$, with $\beta = (\beta_1, \dots, \beta_d) \in \{0, \dots, N\}^d$, we obtain the system of linear algebraic equations

$$\sum_{\alpha \in \{0, \dots, N\}^d} B(L_\alpha, L_\beta) U_\alpha = \ell(L_\beta), \quad \beta \in \{0, \dots, N\}^d, \quad (21)$$

for the unknowns U_α , $\alpha \in \{0, \dots, N\}^d$, which is reminiscent of the system of linear equations (14) encountered in connection with finite-element methods. There is, however, a fundamental difference: whereas the matrix of the linear system (14) was symmetric, positive-definite, and *sparse*, the one appearing in (21) is symmetric, positive-definite, and *full*. It has to be noted that because

$$B(L_\alpha, L_\beta) = \int_{\Omega} \nabla L_\alpha \cdot \nabla L_\beta \, dx + \int_{\Omega} L_\alpha L_\beta \, dx,$$

in order for the matrix of the system to become diagonal, instead of Legendre polynomials one would need to use a system of polynomials that are orthogonal in the *energy inner product* $(u, v)_B := B(u, v)$ induced by B .

If the homogeneous Neumann boundary condition considered above is replaced with a 1-periodic boundary condition in each of the d coordinate directions and the function f appearing on the right-hand side of the PDE $-\Delta u + u = f(x)$ on $\Omega = (0, 1)^d$ is a 1-periodic function in each coordinate direction, then one can use trigonometric polynomials instead of Legendre polynomials in the expansion of the numerical solution. This will then result in what is known as a *Fourier-Galerkin spectral method*. Because trigonometric polynomials are orthogonal in both the $L^2(\Omega)$ and the $H^1(\Omega)$ inner product, the matrix of the resulting system of linear equations will be diagonal, which greatly simplifies the solution process. Having said this, the presence of (periodic) nonconstant coefficients in the PDE will still destroy orthogonality in the associated energy inner product $(\cdot, \cdot)_B$, and the matrix of the resulting system of linear equations will then, again,

become full. Nevertheless, significant savings can be made in spectral computations through the use of fast transform methods, such as the fast Fourier transform or the fast Chebyshev transform, and this has contributed to the popularity of Fourier and Chebyshev spectral methods.

Spectral collocation methods seek a numerical solution u_N from a certain finite-dimensional space S_N , spanned by orthogonal polynomials, just as spectral Galerkin methods do, except that after expressing u_N as a finite linear combination of orthogonal polynomials and substituting this linear combination into the differential equation $Lu = f$ under consideration, one demands that $Lu_N(x_k) = f(x_k)$ at certain carefully chosen points x_k , $k = 1, \dots, N$, called the *collocation points*. Boundary and initial conditions are enforced analogously. A trivial requirement in selecting the collocation points is that one ends up with as many equations as the number of unknowns, which is, in turn, equal to the dimension of the linear space S_N .

We illustrate the procedure by considering the parabolic equation

$$\partial_t u - \partial_{xx}^2 u = 0, \quad (t, x) \in (0, \infty) \times (-1, 1),$$

subject to the initial condition $u(0, x) = u_0(x)$ with $x \in [-1, 1]$ and the homogeneous Dirichlet boundary conditions $u(t, -1) = 0$, $u(t, 1) = 0$, $t \in (0, \infty)$. A numerical approximation u_N is sought in the form of the finite linear combination

$$u_N(t, x) = \sum_{k=0}^N a_k(t) T_k(x)$$

with $(t, x) \in [0, \infty) \times [-1, 1]$, where

$$T_k(x) := \cos(k \arccos(x)), \quad x \in [-1, 1],$$

is the *Chebyshev polynomial* (of the first kind) of degree $k \geq 0$. Note that there are $N + 1$ unknowns, the coefficients $a_k(t)$, $k = 0, 1, \dots, N$. We thus require the same number of equations. The function u_N is substituted into the PDE and it is demanded that, for $t \in (0, \infty)$ and $k = 1, \dots, N - 1$,

$$\partial_t u_N(t, x_k) - \partial_{xx}^2 u_N(t, x_k) = 0.$$

It is further demanded that $u_N(t, -1) = 0$ and $u_N(t, 1) = 0$ for $t \in (0, \infty)$ and that $u_N(0, x_k) = u_0(x_k)$ for $k = 0, \dots, N$, where the $(N + 1)$ collocation points are defined by $x_k := \cos(k\pi/N)$, $k = 0, \dots, N$; these are the $(N + 1)$ points of extrema of T_N on the interval $[-1, 1]$. By writing $u^k(t) := u_N(t, x_k)$, after some calculation based on properties of Chebyshev polynomials

one arrives at the following set of ordinary differential equations:

$$\frac{du^k(t)}{dt} = \sum_{l=1}^{N-1} (D_N^2)_{kl} u^l(t), \quad k = 1, \dots, N - 1,$$

where D_N^2 is the *spectral differentiation matrix of second order*, whose entries $(D_N^2)_{kl}$ can be explicitly calculated. One can then use any standard numerical method for a system of ordinary differential equations to evolve the values $u^k(t) = u_N(t, x_k)$ of the approximate solution u_N at the collocations points x_k , $k = 1, \dots, N - 1$, contained in $(-1, 1)$, from the values of the initial datum u_0 at the same points.

7 Concluding Remarks

We have concentrated on four general and widely applicable families of numerical methods: finite-difference, finite-element, finite-volume, and spectral methods. For additional details the reader is referred to the books listed below and to the rich literature on numerical methods for PDEs for the construction and analysis of other important techniques for specialized PDE problems.

IV.14 Applications of Stochastic Analysis

Bernt Øksendal and Agnès Sulem

1 Introduction

Stochastic analysis is a relatively young mathematical discipline, characterized by a unification of *probability theory* (stochastics) and *mathematical analysis*. Key elements of stochastic analysis are, therefore, integration and differentiation of random/stochastic functions. Stochastic analysis is currently applied to a wide variety of applications in a number of different areas, including finance, physics, engineering, biology, and also within other fields of mathematics itself. We can mention only some of these applications here, and we refer the reader to the list of further reading at the end of the article for more information.

Probability theory and mathematical analysis were traditionally disjoint mathematical disciplines that had little or no interaction. In 1923 Norbert Wiener gave a mathematically rigorous description of the erratic motion of pollen grains in water, a phenomenon that was observed by Robert Brown in 1828. This motion, called Brownian motion, was modeled by Wiener as a *stochastic process* called the *Wiener process*, denoted by $W(t) = W(t, \omega)$ or $B(t) = B_t = B_t(\omega) = B(t, \omega)$. Heuristically, one could say that the position of a pollen grain at time t is represented by $B(t, \omega)$. Here, ω is a “scenario” parameter that could represent, for example, a pollen grain or an experiment, depending on the model setup.

Wiener showed that $t \rightarrow B(t, \omega)$ is continuous but nowhere differentiable for almost all $\omega \in \Omega$ (i.e., for all ω except on a set of P -measure zero, where P is the probability law of $B(\cdot)$). Nevertheless, he showed that it is possible to define what was later called the *Wiener*

integral, namely,

$$I(f)(\omega) := \int_0^T f(t) dB(t, \omega) \quad (T > 0 \text{ fixed}), \quad (1)$$

as a square-integrable element with respect to P for all deterministic square-integrable functions f with respect to the Lebesgue measure on $[0, T]$. This construction represents the first combination of probability and analysis, and as such marks the birth of stochastic analysis.

Subsequently, in 1942 Kiyoshi Itô extended Wiener’s construction to include stochastic integrands $\varphi(t, \omega)$ that are *adapted* (to \mathcal{F}_t), in the sense that for each t the value of $\varphi(t, \omega)$ can be expressed in terms of the *history* \mathcal{F}_t of $B(t, \omega)$, i.e., in terms of previous values of $B(s, \omega)$, $s \leq t$. He showed that in this case the integral can in some sense be represented as a limit of Riemann sums:

$$\int_0^T \varphi(t, \omega) dB(t, \omega) = \lim_{N \rightarrow \infty} \sum_{i=1}^N \varphi(t_{i+1})(B_{t_{i+1}} - B_{t_i}) \quad (2)$$

($0 = t_0 < t_1 < \dots < t_N = T$ being a partition of $[0, T]$) if φ satisfies

$$\int_0^T \varphi^2(t, \omega) dt < \infty \text{ a.s.},$$

and then the limit in (2) exists in a weak sense (in probability with respect to P ; “a.s.” is an abbreviation for “almost surely,” i.e., with probability 1).

Itô proceeded to study such integrals and their properties in a series of papers in the 1950s. He proved a useful chain rule, now called the Itô formula, for processes that are sums of Itô integrals and integrals with respect to Lebesgue measure. Such processes are today known as *Itô processes*. Moreover, he studied corresponding *stochastic differential equations* of the form

$$\left. \begin{aligned} dX(t) &= b(t, X(t)) dt + \sigma(t, X(t)) dB_t, \quad 0 \leq t \leq T, \\ X(0) &= x \in \mathbb{R}, \end{aligned} \right\} \quad (3)$$

where $b: [0, T] \times \mathbb{R} \rightarrow \mathbb{R}$ and $\sigma: [0, T] \times \mathbb{R} \rightarrow \mathbb{R}$ are given functions satisfying certain conditions, and he proved the existence and uniqueness of solutions $X(\cdot)$ of such equations, later known as (Itô) stochastic differential equations (SDEs). Note that (3) is just a shorthand notation for the stochastic *integral* equation

$$X(t) = x + \int_0^t b(s, X(s)) ds + \int_0^t \sigma(s, X(s)) dB_s, \quad 0 \leq t \leq T. \quad (4)$$

For several years the work of Itô was considered an interesting theoretical construction, but one without

any applications. But this changed in the late 1960s and early 1970s when Henry McKean published a book with a useful introduction to the stochastic analysis of Itô and Samuelson proposed modeling the price of a stock in a financial market by the solution $X(t)$ of an SDE of the form

$$\left. \begin{aligned} dX(t) &= \alpha X(t) dt + \beta X(t) dB(t), \quad 0 \leq t \leq T, \\ X(0) &= x > 0, \end{aligned} \right\} \quad (5)$$

with $\beta > 0$ and α constants. This was the beginning of a wide range of applications of stochastic analysis. The amazing subsequent development of the subject can be seen as the result of fruitful interplay between applications and theory. We think this strong two-way communication between problems and concepts in applications and the development of corresponding mathematical theory is unique to stochastic analysis.

In the following sections we will briefly review some examples of this interaction.

2 Applications to Finance

The application of stochastic analysis to finance is undoubtedly one of the most spectacular examples of the application of mathematics in our society. Before stochastic analysis entered the field, finance was, with a few exceptions, an area almost devoid of mathematics. Today, though, finance is strongly influenced by the theory and methods of stochastic analysis. Here we give just a brief introduction to this area of application, while we refer to the articles on FINANCIAL MATHEMATICS [V.9] and PORTFOLIO THEORY [V.10] elsewhere in this volume for more information on this huge and active research topic.

The breakthrough came in the late 1960s/early 1970s, when

- Jan Mossin studied a discrete-time financial model and solved the problem of finding the portfolio that maximizes the expected utility of the terminal wealth, using dynamic programming,
- Robert Merton used the (continuous-time) financial market model of Samuelson (see above) and solved the optimal-portfolio problem by using the Hamilton–Jacobi–Bellman equation, and
- Fischer Black and Myron Scholes developed their famous Black–Scholes option-pricing formula.

Merton and Scholes were awarded the Nobel Memorial Prize in Economic Sciences for these achievements in 1997 (Black died in 1995).

To see why stochastic analysis is such a natural tool for finance, let us consider a simple financial market model with two investment possibilities.

- (1) A risk-free investment with constant unit price $S_0(t) = 1$.
 - (2) A risky investment, with unit price $S_1(t)$ given by
- $$\left. \begin{aligned} dS_1(t) &= S_1(t)[\alpha dt + \beta dB(t)], \quad t \geq 0, \\ S_1(0) &> 0, \end{aligned} \right.$$
- as in Samuelson's model.

If $\varphi(t) = (\varphi_0(t), \varphi_1(t))$ is a *portfolio*, giving the number of units held at time t of the risk-free and risky investments, respectively, then

$$X^\varphi(t) := \varphi_0(t)S_0(t) + \varphi_1(t)S_1(t)$$

is the total value of the portfolio at time t . We say that the portfolio is *self-financing* if the infinitesimal change in the wealth at a given time t , $dX^\varphi(t)$, comes from the change in the market prices only, i.e., if

$$dX^\varphi(t) = \varphi_0(t) dS_0(t) + \varphi_1(t) dS_1(t).$$

We assume from now on that all portfolios are self-financing. Since $dS_0(t) = 0$, this gives the integral representation

$$\begin{aligned} X_X^\varphi(t) &= x + \int_0^t \varphi_1(s) dS_1(s) \\ &= x + \int_0^t \varphi_1(s) \alpha S_1(s) ds + \int_0^t \varphi_1(s) \beta S_1(s) dB_s, \end{aligned} \quad (6)$$

where x is the initial value and the last integral is the Itô integral.

Note that this integral representation is natural because of the interpretation (2) of the Itô integral as a limit of Riemann sums, where the portfolio choice $\varphi_1(t_i)$ is taken as the *left-hand side* of the partitioning intervals $[t_i, t_{i+1})$ of $[0, T]$. Heuristically, first we decide on the portfolio, then comes the price change. With this mathematical setup the breakthroughs of Mossin and Merton can be formulated more precisely, as follows.

2.1 The Portfolio-Optimization Problem (Mossin/Merton)

Given a *utility* function (i.e., a continuous, increasing, concave function) $U: [0, \infty) \rightarrow \mathbb{R}$, find a portfolio $\varphi^* \in \mathcal{A}$ (the family of admissible portfolios) such that

$$\sup_{\varphi \in \mathcal{A}} E[U(X^\varphi(T))] = E[U(X^{\varphi^*}(T))], \quad (7)$$

where $T > 0$ is a given terminal time and $E[\cdot]$ denotes expectation with respect to P . This may be regarded as a stochastic control problem. With specific choices of utility functions, e.g., $U(x) = \ln x$ or $U(x) = (1/\gamma)x^\gamma$ for some constant $\gamma \in (-\infty, 1) \setminus \{0\}$, this problem can be solved explicitly by dynamic programming, as Merton did (see section 4).

2.2 The Option-Pricing Problem (Black–Scholes)

Suppose that at time $t = 0$ you are offered a contract that pays $(S(T) - K)^+ (= \max\{S(T) - K, 0\})$ at a specified future time T . Here, $K > 0$ is a constant, also specified in the contract. Such a contract is called a *European call option*, and K is called the exercise price. This contract is equivalent to a contract that gives the owner the right, but not the obligation, to buy one unit of the risky asset at time T at the price K . To see this equivalence, we argue as follows. If the market price $S(T)$ turns out to be greater than K , then according to the second contract the owner can buy one unit at the price K and then immediately sell it at $S(T)$, giving a profit of $S(T) - K$. If, however, $S(T) \leq K$, the contract is worthless and the payoff is 0. This leads to the contract payoff $(S(T) - K)^+$ in general, which is in agreement with the first contract. The question is, then, how much would you be willing to pay at time $t = 0$ for such a contract? If you are a careful person, you might argue as follows.

If I pay an amount z for the contract, I start with an initial wealth $-z$, and with this initial wealth it should be possible for me to find a portfolio $\varphi \in \mathcal{A}$ (in particular, a self-financing portfolio) such that the sum of the corresponding terminal wealth $X_{-z}^\varphi(T)$ and the payoff of the contract is, almost surely, nonnegative.

This gives the following expression for the buyer's price of a call option:

$$p_{\text{buyer}} := \sup\{z; \text{there exists } \varphi \in \mathcal{A} \text{ such that } X_{-z}^\varphi(T) + (S(T) - K)^+ \geq 0 \text{ a.s.}\}.$$

This problem of finding the option price p_{buyer} is of a different type from the Merton problem in (7). The *Black–Scholes option-pricing formula* states that

$$p_{\text{buyer}} = E_Q[(S(T) - K)^+], \quad (8)$$

where E_Q means expectation with respect to the measure Q , defined to be the unique probability measure Q equivalent to P such that $S_1(t)$ is a *martingale* under Q , i.e.,

$$E_Q[S_1(t) | \mathcal{F}_s] = S_1(s)$$

for all $0 \leq s \leq t \leq T$.

Such a measure is called an *equivalent martingale measure*. In this financial market there is only one equivalent martingale measure, and it is given by

$$dQ(\omega) = \exp\left(-\frac{\alpha}{\beta}B(T) - \frac{1}{2}\left(\frac{\alpha}{\beta}\right)^2T\right)dP(\omega) \text{ on } \mathcal{F}_T.$$

Substituting this into (8) and using the probabilistic properties of Brownian motion we get an explicit formula for the call option price p_{buyer} in terms of K , β , and T . A surprising feature of this formula is that it does not contain α , and we are therefore led to the important conclusion that the option price does not depend on the drift coefficient α .

The ground-breaking results in sections 2.1 and 2.2 motivated a lot of research activity. Other models were introduced and studied, and at the same time other areas of applications were found (see section 7).

We now proceed to present some applications that are not necessarily connected to finance.

3 Backward Stochastic Differential Equations

Returning to the equation (6) for the wealth $X_x^\varphi(t)$ corresponding to a given (self-financing) portfolio $\varphi(t) = (\varphi_0(t), \varphi_1(t))$, one may ask the following question. Given a random variable $F(\omega)$, assumed to depend only on the history \mathcal{F}_T of $B(t, \omega)$ up to time t , does there exist a portfolio φ such that $X_x^\varphi(T) = F$ a.s.?

If we substitute

$$Z(t) := \varphi_1(t)S(t)$$

into (6), we see that this question can be formulated as follows. Given F , find $X(t)$ and $Z(t)$ such that

$$dX(t) = \frac{\alpha}{\beta}Z(t)dt + Z(t)dB(t), \quad 0 \leq t \leq T,$$

$$X(T) = F \text{ a.s.}$$

This is called a *backward stochastic differential equation* (BSDE) in the two unknown (adapted) processes X and Z . In contrast to (3), it is the terminal value F of X that is given, not the initial value. More generally, given a function $g(t, y, z, \omega) : [0, T] \times \mathbb{R} \times \mathbb{R} \times \Omega \rightarrow \mathbb{R}$ and a random variable F , as above, the corresponding BSDE in the two unknown (adapted) processes $Y(t), Z(t)$ has the form

$$\begin{aligned} dY(t) &= -g(t, Y(t), Z(t), \omega)dt + Z(t)dB_t, \quad 0 \leq t \leq T, \\ Y(T) &= F \text{ a.s.} \end{aligned}$$

The process g is sometimes called the *driver*.

The original motivation for studying BSDEs came from stochastic control theory (see section 4), but a number of other developments have since been found,

such as the probabilistic representations of solutions of nonlinear parabolic partial differential equations developed by Pardoux and Peng in 1990. In the 1990s, Duffie and Epstein used BSDEs to introduce the concept of the *recursive utility* of a consumption process, and around ten to fifteen years ago BSDEs were used to define *convex risk measures* as a model for the risk of a financial position.

4 Optimal Stochastic Control

The portfolio-optimization problem presented in section 2 may be regarded as a special case of a general *optimal stochastic control problem* of the following type. Suppose that the state $X(t) = X_{s,x}(t)$ of a system at time t is described by a stochastic differential equation of the form

$$dX(t) = b(t, X(t), u(t), \omega) dt + \sigma(t, X(t), u(t), \omega) dB_t \quad (9)$$

for $s \leq t \leq T$, with $X(s) = x$, ($x \in \mathbb{R}$ and $0 \leq s \leq T$ given), where $b: [0, T] \times \mathbb{R} \times \mathbb{V} \times \Omega \rightarrow \mathbb{R}$ and $\sigma: [0, T] \times \mathbb{R} \times \mathbb{V} \times \Omega \rightarrow \mathbb{R}$ are given functions such that $b(\cdot, x, v, \cdot)$ and $\sigma(\cdot, x, v, \cdot)$ are adapted processes for each given $x \in \mathbb{R}$ and $v \in \mathbb{V}$, a given set of control values. The process $u(t) = u(t, \omega)$ is our *control* process. To be admissible it is required that u be adapted and that $u(t, \omega) \in \mathbb{V}$ for all $t \in [0, T]$ and almost all $\omega \in \Omega$. The set of admissible control processes is denoted by \mathcal{A} . With each choice of $u \in \mathcal{A}$, $(s, x) \in [0, T] \times \mathbb{R}$, we associate a *performance* $J_u(s, x)$ given by

$$J_u(s, x) = E \left[\int_0^T f(t, X_{s,x}(t), u(t), \omega) dt + g(X_{s,x}(T), \omega) \right], \quad (10)$$

where $f: [0, T] \times \mathbb{R} \times \mathbb{V} \times \Omega \rightarrow \mathbb{R}$ and $g: \mathbb{R} \times \Omega \rightarrow \mathbb{R}$ are given functions. Sometimes f is called the *profit rate* and g is called the *bequest* or *salvage* function. We assume that $f(\cdot, x, v, \cdot)$ is adapted and that $g(x, \cdot)$ depends only on the history \mathcal{F}_T of the underlying Brownian motion $B(t, \omega)$, $s \leq t \leq T$, for each x and v .

The problem is to find a control $u^* \in \mathcal{A}$ and a function $\Phi(s, x)$ such that

$$\Phi(s, x) = \sup_{u \in \mathcal{A}} J_u(s, x) = J_{u^*}(s, x), \quad (s, x) \in [0, T] \times \mathbb{R}. \quad (11)$$

Such a process u^* (if it exists) is called an *optimal control*, and Φ is called the *value function*.

For example, if we represent the portfolio in (6) by the fraction $\pi(t)$ of the total wealth $X(t)$ invested in

the risky asset at time t , then

$$\pi(t) = \frac{\psi_1(t)S_1(t)}{X(t)}$$

and (6) can be written

$$\begin{aligned} dX(t) &= \pi(t)X(t)[\alpha dt + \beta dB(t)], \quad 0 \leq t \leq T, \\ X(0) &= x > 0. \end{aligned} \quad (12)$$

Comparing (12) and (7) with (9)-(11), we see that the optimal-portfolio problem is an example of an optimal stochastic control problem, as claimed.

There are two main solution methods for stochastic control problems: the dynamic programming principle and the maximum principle.

4.1 The Dynamic Programming Principle

The *dynamic programming principle*, introduced by R. Bellman in the 1950s, applies only to *Markovian* problems. These are problems where the coefficients $b(s, x, v)$, $\sigma(s, x, v)$, $f(s, x, v)$, and $g(x)$, for fixed values of s , x , and v , do not depend on ω . Moreover, the control process $u(t)$ must be Markovian, in the sense that $u(t) = u_0(t, X(t))$ for some deterministic function $u_0: [0, T] \times \mathbb{R} \rightarrow \mathbb{V}$. (Such a control is called a feedback control.) In this case, the dynamic programming principle leads to the *Hamilton-Jacobi-Bellman equation*, which (under some conditions) states the following.

Suppose that φ is a smooth function such that

$$f(s, x, v) + A^v \varphi(s, x) \leq 0, \quad 0 \leq s \leq T, \quad x \in \mathbb{R}, \quad v \in \mathbb{V},$$

and that

$$\varphi(T, x) = g(x).$$

Then

$$\varphi(s, x) \geq \Phi(s, x), \quad (s, x) \in [s, T] \times \mathbb{R}.$$

Moreover, assume that, in addition, for all $(s, x) \in [0, T] \times \mathbb{R}$ there exists $u_0(s, x) \in \mathbb{V}$ such that

$$f(s, x, u_0(s, x)) + A^{u_0(s, x)} \varphi(s, x) = 0. \quad (13)$$

Then

$$\varphi(s, x) = \Phi(s, x), \quad (s, x) \in [s, T] \times \mathbb{R}$$

and

$$u^*(t) := u^0(t, X(t))$$

is an optimal (Markovian) control.

Here, A^v denotes the *generator* of the Markov process $X_{s,x}^v(t)$ obtained by using the constant control

$u(t) := v \in \mathbb{V}$. It is a parabolic second-order partial differential operator given by

$$\begin{aligned} A^v \varphi(s, x) := & \frac{\partial \varphi}{\partial s}(s, x) + b(s, x, v) \frac{\partial \varphi}{\partial x}(s, x) \\ & + \frac{1}{2} \sigma^2(s, x, v) \frac{\partial^2 \varphi}{\partial x^2}(s, x). \end{aligned}$$

For example, for the problem (7) with (12) we get

$$\begin{aligned} A^v \varphi(s, x) := & \frac{\partial \varphi}{\partial s}(s, x) + \alpha v x \frac{\partial \varphi}{\partial x}(s, x) \\ & + \frac{1}{2} \beta^2 v^2 x^2(s, x, v) \frac{\partial^2 \varphi}{\partial x^2}(s, x), \end{aligned}$$

which is maximal when

$$v = v^* = -\frac{\alpha \varphi'(s, x)}{\beta^2 x \varphi''(s, x)},$$

where

$$\varphi'(s, x) = \frac{\partial \varphi}{\partial x}(s, x) \quad \text{and} \quad \varphi''(s, x) = \frac{\partial^2 \varphi}{\partial x^2}(s, x).$$

Substituting into (13) we get

$$\frac{\partial \varphi}{\partial s}(s, x) - \frac{\alpha^2 (\varphi')^2(s, x)}{2\beta^2 \varphi''(s, x)} = 0.$$

In particular, if

$$U(x) = g(x) = \frac{1}{\gamma} x^\gamma, \quad x > 0,$$

for some parameter $\gamma \in (-\infty, 1) \setminus \{0\}$, then we see that the above equation holds for

$$\varphi(s, x) = h(s)x^\gamma,$$

where

$$\begin{aligned} h'(s) - \frac{\alpha^2 \gamma}{2\beta^2(\gamma-1)} h(s) &= 0, \quad 0 \leq s \leq T, \\ h(T) &= 1/\gamma. \end{aligned}$$

This gives an optimal control (portfolio)

$$u^*(t) = \pi^*(t) = -\frac{\alpha h(t) \gamma x^{\gamma-1}}{\beta^2 x y (\gamma-1) h(t) x^{\gamma-2}} = \frac{\alpha}{\beta^2 (1-\gamma)},$$

which is one of the classical results of Mossin and Merton.

4.2 The Maximum Principle

The *maximum principle* goes back to L. Pontryagin and his group, who developed this method for deterministic control problems in the 1950s. It was adapted to stochastic control by J.-M. Bismut and subsequently extended further by A. Bensoussan, E. Pardoux, S. Peng, and others throughout the 1970s, 1980s, and 1990s. Basically, the maximum principle approach to the stochastic control problem (11) is as follows.

First, we define the associated *Hamiltonian* $H: \mathbb{R}^5 \rightarrow \mathbb{R}$ by

$$J(t, x, u, p, q) = f(t, x, u) + b(t, x, u)p + \sigma(t, x, u)q. \quad (14)$$

Here, p, q are adjoint variables, somehow related to Lagrange multipliers.

Next, associated with the Hamiltonian we consider, for given $u \in \mathcal{A}$, the BSDE

$$\left. \begin{aligned} dp(t) &= -\frac{\partial H}{\partial x}(t, X(t), u(t), p(t), q(t)) dt + q(t) dB_t, \\ p(T) &= g'(X(T)) \end{aligned} \right\} \quad 0 \leq t \leq T, \quad (15)$$

in the two unknown adjoint processes $p(t) = p^{(u)}(t)$, $q(t) = q^{(u)}(t)$, where $X(t) = X^{(u)}(t)$ is the solution of (9) corresponding to the control u .

The *maximum principle* relates the maximization of $J_u(s, x)$ in (10) to the maximization of the Hamiltonian. For example, under some concavity assumptions we have the following result.

The sufficient maximum principle (assumes concavity). Suppose that $\hat{u} \in \mathcal{A}$, with associated solution $\hat{X}(t) = X^{(\hat{u})}(t)$, $\hat{p}(t) = p^{(\hat{u})}(t)$, and $\hat{q}(t) = q^{(\hat{u})}(t)$ of the forward-backward SDE system (9), (15). Suppose that for each t , $u = \hat{u}(t)$ maximizes the Hamiltonian, in the sense that

$$u \rightarrow H(t, \hat{X}(t), u, \hat{p}(t), \hat{q}(t))$$

is maximal for $u = \hat{u}(t)$. Then, $\hat{u}(\cdot)$ is an optimal control for the problem (11).

To illustrate how this result works, let us apply it to once again solve the problem (12), (7); in this case, the Hamiltonian becomes, with $u = \pi$,

$$H(t, x, \pi, p, q) = \pi x \alpha p + \pi x \beta q \quad (16)$$

and

$$\left. \begin{aligned} d\hat{p}(t) &= -(\hat{\pi}(t) \alpha \hat{p}(t) + \hat{\pi}(t) \beta \hat{q}(t)) dt + \hat{q}(t) dB(t), \\ \hat{p}(t) &= U'(\hat{X}(T)). \end{aligned} \right\} \quad (17)$$

Since H is linear in π , the only possibility for the existence of a maximum of

$$\pi \rightarrow H(t, \hat{X}(t), \pi, \hat{p}(t), \hat{q}(t))$$

is that

$$\alpha \hat{p}(t) + \beta \hat{q}(t) = 0,$$

i.e.,

$$\hat{q}(t) = -\frac{\alpha}{\beta} \hat{p}(t). \quad (18)$$

Substituting this into (17) we get

$$d\hat{p}(t) = -\frac{\alpha}{\beta} \hat{p}(t) dB(t),$$

which has the solution

$$\hat{p}(t) = \hat{p}(0) \exp\left(-\frac{\alpha}{\beta}B(t) - \frac{1}{2}\left(\frac{\alpha}{\beta}\right)^2 t\right). \quad (19)$$

Now assume, as above, that

$$U(x) = \frac{1}{y}x^y. \quad (20)$$

The requirement

$$\hat{p}(T) = U'(\hat{X}(T)) \quad (21)$$

then gives the equation

$$\begin{aligned} & \hat{p}(0) \exp\left(-\frac{\alpha}{\beta}B(T) - \frac{1}{2}\left(\frac{\alpha}{\beta}\right)^2 T\right) \\ &= x^{y-1} \exp\left((y-1) \int_0^T \hat{\pi}(t) \beta dB(t) \right. \\ &\quad \left. + (y-1) \int_0^T (\hat{\pi}(t) \alpha - \frac{1}{2} \hat{\pi}^2(t) \beta^2) dt\right). \end{aligned} \quad (22)$$

From (22), it is natural to try $\hat{\pi}$ such that

$$(y-1)\hat{\pi}(t)\beta = -\frac{\alpha}{\beta},$$

i.e.,

$$\hat{\pi}(t) = \frac{\alpha}{\beta^2(1-y)}. \quad (23)$$

Since, by (19), $\hat{p}(t)$ is a martingale, from (21) we obtain $\hat{p}(0) = E[U'(\hat{X}(T))]$, and substituting this into (22) we verify that (22) holds with $\hat{\pi}$ as in (23).

This confirms the result we found in section 4.1.

5 Optimal Stopping

To describe the problem of optimal stopping of a stochastic process $S(t)$, we first need to explain the crucial concept of a *stopping time*.

A random time $\tau: \Omega \rightarrow [0, \infty]$ is called a *stopping time* (with respect to the history of $S(\cdot)$) if, for any time t , the decision of whether or not to stop at time t is based only on the history of $S(s)$ for $s \leq t$.

For example, if $S(t)$ is the position at time t of a car driving along a road in a city, then

$\tau_1 :=$ the *first* time we come to a traffic light

will be a stopping time because this instant can be decided simply by recording the history of S up to that time. On the other hand, if we define

$\tau_2 :=$ the *last* time we come to a traffic light,

then τ_2 will *not* be a stopping time because we would need to know the future in order to decide whether or not a given traffic light is the last one.

Thus, since we cannot assume knowledge about the future, we see that stopping times are the natural random times to consider in applications: the optimal time to sell (or buy) an object with a stochastic price process, the optimal time to start a new business, the optimal time to close down a factory, and so on.

If the state $Y(t) \in \mathbb{R}^k$ at time t is described by an SDE of the form

$$\left. \begin{aligned} dY(t) &= b(Y(t)) dt + \sigma(Y(t)) dB(t), & t \geq 0, \\ y(0) &= y \in \mathbb{R}^k, \end{aligned} \right\} \quad (24)$$

then the associated *optimal stopping problem* is to find a stopping time τ^* (with respect to $Y(\cdot)$), called an *optimal stopping time*, such that

$$\begin{aligned} \Phi(y) &:= \sup_{\tau \in \mathcal{T}} E^y \left[\int_0^\tau f(Y(t)) dt + g(Y(\tau)) \right] \\ &= E^y \left[\int_0^{\tau^*} f(Y(t)) dt + g(Y(\tau^*)) \right], \end{aligned} \quad (25)$$

where \mathcal{T} is the set of all $Y(\cdot)$ stopping times and we interpret $g(Y(\tau))$ as 0 if $\tau = \infty$. Here, f and g are given functions, and E^y denotes the expectation assuming that $Y(0) = y$. The function Φ is called the *value function* of the optimal stopping problem.

As in stochastic control problems, it often turns out that in order to find an optimal stopping time τ^* , it helps to simultaneously try to find the value function Φ . In fact, under some technical conditions one can prove the following.

The optimal stopping theorem. Let A be the generator of $Y(\cdot)$ (see section 4).

(a) Then

- (a) $A\Phi(y) + f(y) \leq 0$ for all y and
- (b) $\Phi(y) \geq g(y)$ for all y .

Moreover, at all points y , at least one of the two inequalities holds with equality. We can therefore combine (i) and (ii) into the equation

$$\max\{A\Phi(y) + f(y), g(y) - \Phi(y)\} = 0 \quad \text{for all } y. \quad (26)$$

(b) Let D be the continuation region, defined by $D = \{y; g(y) < \Phi(y)\}$. Then it is optimal to stop the first time that $Y(t)$ exits from D , i.e.,

$$\tau^* = \inf\{t > 0; Y(t) \notin D\}. \quad (27)$$

(c) Moreover, Φ and g meet smoothly at ∂D , i.e.,

$$\nabla\Phi(y) = \nabla g(y) \quad \text{for } y \in \partial D \quad (28)$$

(this is called the *high contact* or *smooth fit principle*).

This theorem shows that there is a close connection between optimal stopping problems (which are stochastic) and *variational inequality problems* and *free boundary problems*, which are nonstochastic classical analysis problems.

Regarding *variational inequality problems*, the equation (26) is an example of a classical *variational inequality*. The operator A and the functions f and g are given, and the problem is to find Φ such that (26) holds. A classical example in which this problem appears is the problem of finding the wet region in a porous sand wall of a dam.

A *free boundary problem* is a problem of the following type. Given a differential operator A and functions f and g , find a function Φ and a domain D such that

- (i) $A\Phi(y) + f(y) = 0$ for $y \in D$,
- (ii) $\Phi(y) = g(y)$ for $y \in \partial D$, and
- (iii) $\nabla\Phi(y) = \nabla g(y)$ for $y \in \partial D$,

where ∇ denotes the gradient operator. Applications of this type of problem include the problem of finding the boundary of a melting ice cube.

The link between the optimal stopping problem and the free boundary problem is provided by the high contact principle (28).

It can also be shown that optimal stopping problems are related to *reflected BSDEs*. In a reflected BSDE we are given a driver g as in section 3 as well as a *lower barrier process* $L(t)$, and we want to find processes $Y(t)$, $Z(t)$ and a nondecreasing process $K(t)$ (all of them adapted) with $K(0) = 0$ such that the following hold:

- $dY(t) = -g(Y(t), Z(t), \omega) dt + Z(t) dB(t) - dK(t)$,
and
- $Y(t) \geq L(t)$ for all t .

6 Filtering Theory

Suppose we model the size of a population, e.g., the fish population in a lake, by a stochastic logistic differential equation of the form

$$dX(t) = X(t)[K - X(t)](\alpha dt + \beta dB(t)), \quad t \geq 0, \quad (29)$$

where α , β , and $K > 0$ are constants. K is called the carrying capacity of the lake; it represents the maximal population size that the lake can sustain. Heuristically, the “noisy” factor $\alpha + \beta(dB(t)/dt)$ representing the nutritional quality of the lake, subject to random fluctuations (the quantity $dB(t)/dt$, called *white noise*), can be rigorously defined as a *stochastic distribution*.

Even if there are good theoretical reasons for choosing such a model, the problem of how to estimate the coefficients α , β , and K , and also $X(t)$ itself, remains. To simplify matters, let us assume that α , β , and K are known. How do we find $X(t)$?

The problem is that we do not know the precise value of $X(t_0)$ for any t_0 . To compensate for this, we make (necessarily imprecise, or “noisy”) observations $Y(t)$ on $X(t)$, i.e., we observe

$$Y(t) = X(t) + \gamma \frac{dB_1(t)}{dt}$$

or

$$dY(t) = X(t) dt + \gamma dB_1(t), \quad t \geq t_0,$$

where $\gamma > 0$ is a known constant and $B_1(\cdot)$ is another Brownian motion, usually assumed to be independent of $B(\cdot)$.

The *filtering problem* is as follows: what is the *best estimate*, $\hat{X}(t)$, of $X(t)$ *based on* the observations $Y(s)$, $s \leq t$?

By saying that an estimate $\hat{X}(t)$ is *based on* $Y(s)$, $s \leq t$, we mean that it should be possible to express $\hat{X}(t)$ by means of the values $Y(s)$, $s \leq t$, only. In other words, $\hat{X}(\cdot)$ should be *adapted* to the history (filtration) $\{\mathcal{F}_t^Y\}_{t \leq 0}$ generated by $Y(t)$, $t \geq 0$. By saying that $\hat{X}(t)$ is the *best estimate* based on Y , we mean best in the sense of *minimal mean square error*, i.e.,

$$E[(X(t) - \hat{X}(t))^2] = \inf_{\hat{X} \in Y} E[(X(t) - \hat{X}(t))^2], \quad (30)$$

where Y is the set of all estimates based on Y . The solution of the problem (30) can be expressed as

$$\hat{X}(t) = E[X(t) | \mathcal{F}_t^Y], \quad (31)$$

where the right-hand side denotes the *conditional expectation* of $X(t)$ with respect to \mathcal{F}_t^Y . The filtering problem is therefore the problem of finding this conditional expectation of $X(t)$.

The filtering problem is difficult in general, and an explicit solution is known only in special cases. The most famous solvable case is the *linear* case, in which we have

$$dX(t) = F(t)X(t) dt + C(t) dB(t) \quad (\text{signal process}),$$

$$dY(t) = G(t)X(t) dt + D(t) dB_1(t) \quad (\text{observations}),$$

where $F(t)$, $C(t)$, $G(t)$, and $D(t) > 0$ are known, bounded deterministic functions, $D(t)$ being bounded away from 0.

The *Kalman–Bucy filtering theorem* then states that the best estimate $\hat{X}(t)$ solves the SDE

$$\left. \begin{aligned} d\hat{X}(t) &= \left(F(t) - \frac{G^2(t)S(t)}{D^2(t)} \right) \hat{X}(t) dt \\ &\quad + \frac{G(t)S(t)}{D^2(t)} dY(t), \\ \hat{X}(0) &= E[X(0)], \end{aligned} \right\} \quad (32)$$

where $S(t) := E[(X(t) - \hat{X}(t))^2]$ (the minimal mean square error) satisfies the (deterministic) *Riccati equation*

$$\left. \begin{aligned} \frac{dS(t)}{dt} &= 2F(t)S(t) - \frac{G^2(t)}{D^2(t)}S^2(t) + C^2(t), \quad t \geq 0, \\ S(0) &= E[(X(0) - E[X(0)])^2]. \end{aligned} \right\} \quad (33)$$

Note that in (32), $\hat{X}(t)$ is indeed expressed in terms of the observations $Y(s)$, $s \leq t$, only, assuming that the initial distribution of $X(0)$ is Gaussian, with given mean $E[X(0)]$ and variance $S(0)$.

7 Outlook

In this short article we have been able to discuss only the classical stochastic calculus based on Brownian motion and some of the well-known (and spectacular) applications of this theory. But we should point out that in recent years there has been rapid research development both in the mathematical foundations of stochastic analysis and in further applications of the subject.

- For example, the theory of stochastic integration has been extended to other integrator processes, such as Lévy processes, Poisson random measures, and, more generally, semimartingales.
- Stochastic differential equations and more general *stochastic integral* or *stochastic functional* differential equations, and even stochastic *partial* differential equations driven by such processes, are being studied. In particular, *mean-field* SDEs are used in connection with the modeling of *systemic risk* in finance.
- Stochastic optimization methods (stochastic control, singular control, impulse control, optimal stopping) for such systems are being developed accordingly, with associated generalized BSDEs.
- Various ways of representing *model uncertainty* in applications have been introduced and studied, including *nonlinear expectation* theory and the theory of *G-Brownian motion*.

- An axiomatic approach to the concept of *convex risk measures* has been developed. Such risk measures can be represented either by a BSDE or by a dual approach, using a family of probability measures that are absolutely continuous with respect to P .
- The relationship between performance and available information is being studied. In particular, what is the optimal performance of a controller for which only *partial* (e.g., *delayed*) *information* is available? This topic may also combine optimal control with filtering.
- In the opposite direction, *anticipative* stochastic calculus, i.e., stochastic calculus with nonadapted integrands, has been developed. Combined with the recently developed *stochastic calculus of variations* (*Malliavin calculus*) and the *Hida white noise calculus*, this gives an efficient mathematical tool for investigating the actions of insiders in financial markets.

- *Stochastic differential games* involving players with *asymmetric information* is another hot topic with obvious applications in several areas, including biology, engineering, investment theory, and finance. This is a challenging area of research in which the full force of the mathematical machinery discussed above is needed.

IV.15 Inverse Problems

Fadil Santosa and William W. Symes

1 What Is an Inverse Problem?

In inverse problems one is interested in determining parameters of a system from measurements. Much of applied mathematics is about modeling and understanding phenomena that occur in the world. The models are often based on first principles: physical laws, empirical laws, etc. A common use of models is for prediction; if we know all the parameters of a model, we can predict how the model will respond to a given excitation. In inverse problems we perform experiments in which the response of a model to prescribed excitations is measured. The goal is to determine the unknown parameters of the model from the measured data.

1.1 Background and History

Perhaps the oldest formally studied inverse problem—dating back to the work of Herglotz (1907) and Wiechert (1910)—is that of determining properties of the Earth’s subsurface from measurement of seismological data. This problem falls into the category of geophysical inverse problems, which includes techniques for imaging the near subsurface for deposits of oil and other minerals.

In physics the classical inverse problem involves finding the potential in the Schrödinger equation from scattering experiments. Still in the same family are scattering problems involving geometrical scatterers where one is interested in determining the geometrical shape from measurements of the acoustic or electromagnetic response of the object. In military applications such problems fall under the study of sonar and RADAR [VII.17].

Medical imaging has been a driving force in the development of inverse problems. The ability to visualize and characterize the internal structures of a patient is of great value in diagnostics. A very important imaging modality, X-RAY COMPUTED TOMOGRAPHY [VII.9, VII.19] (abbreviated X-ray CT and also known as computer-assisted tomography), can be viewed as an inverse problem. The conductivities of biological tissues can

also be a target of medical imaging and could potentially provide further diagnostic capabilities that complement other imaging modalities.

2 Language and Concepts

One of the most influential researchers in the area of inverse problems was Pierre Sabatier, who is responsible for formalizing its study. He provided much of the vocabulary of the subject, which we describe in some detail below.

2.1 The Forward Map

In inverse problems, we are interested in determining the properties of a system that we call a *model*, m . The model is related to observations that we call *data*, d . To be mathematically precise, we call M the set of all possible models under consideration. We would normally attach mathematical properties to this set that are consistent with the physics. The space of data D also needs to be characterized. The *forward map* is the mathematical relationship between a model and its associated measurement. Let us indicate this by $F(m)$. In an inverse problem we are given data d from which we wish to find, to the extent possible, the unknown model m . Thus, we wish to “solve” $F(m) \approx d$ for a given d . We use the approximation symbol “ \approx ” above because noise is inherent in any measurement. In most inverse problems it is unlikely that the data d is in the range of the forward map for all m in M .

To illustrate the above concept let us consider the inverse problem of X-ray CT. The model in question will be X-ray attenuation, described by an attenuation coefficient $\rho(x)$ that is a function of position x . A possible space of functions for the model is a set of nonnegative functions with an upper bound, namely $L^\infty(\Omega)$, where Ω is the domain being scanned. The data are input and output X-ray intensities, I_0 and I , respectively, parametrized by X-ray trajectory L (see figure 1), usually given as the logarithm of their ratio: $\log(I(L)/I_0(L))$. The forward map, based on Beer’s law, is

$$R(\rho; I_0, L) = - \int_L \rho \, d\ell,$$

that is, $R(\rho; I_0, L)$ is the line integral of $\rho(x)$ along line L . The inverse problem of a computer-assisted tomography scan is to determine $\rho(x)$ from the data $\log(I(L)/I_0(L))$. The found $\rho(x)$ is often displayed as a set of images, aiding in diagnostics.

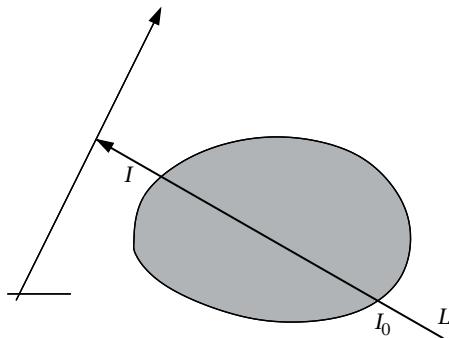

Figure 1 Schematic of a generic X-ray CT setup. The intensity of the X-ray entering the body is I_0 ; the intensity at exit is I . The data value is $\log(I/I_0)$ for the ray L . The forward map is the line integral of the attenuation coefficient $\rho(x)$ along the line L . The inversion of $\rho(x)$ depends on the measurement setup and is particularly straightforward in two dimensions, as described in section 3.1.

2.2 Inversion and Data Fitting

There are instances where the solution to the equation $F(m) = d$ can be written down explicitly. That is, we have a formula for m in terms of the given data d . An example is when F is a linear operator whose inverse can be calculated. Another popular approach is to view the inverse problem as a data-fitting problem. In this case we seek a model m that minimizes the misfit $\|F(m) - d\|$. The choice of norm is critical and depends on what additional information is available about the map F and the data d . The most important information is the regularity of the map and the statistical properties of the noise embedded in the data.

2.3 Linear and Nonlinear Inverse Problems

In a linear inverse problem, the forward map satisfies the property

$$F(m_1 + m_2) = F(m_1) + F(m_2).$$

In practical terms, linearity often means that the problem is easy to solve. If both m and d are finite dimensional, then a linear forward map can be represented as a matrix. In this instance, the linear inverse problem amounts to a linear system of equations.

For nonlinear inverse problems, the above relationship does not hold. Nonlinear inverse problems are usually more difficult to analyze and to solve, and iterative techniques are often employed for solving them.

One can linearize a nonlinear inverse problem by assuming that the unknown model can be written as

$$m = m_0 + \Delta m,$$

where m_0 is known and Δm is small. The concept of smallness can be made precise mathematically. Then, if the forward map $F(\cdot)$ associated with the problem is differentiable, we approximate it by a two-term Taylor series:

$$F(m) \approx F(m_0) + G\Delta m.$$

Here, G is a linear operator representing the derivative (Jacobian) of the forward map $F(\cdot)$. Thus, given data d , the linearized inverse problem seeks to determine Δm from the equation

$$G\Delta m = d - F(m_0).$$

In some situations we can solve a nonlinear inverse problem by successively seeking solutions to a sequence of linearized inverse problems. Such an approach, when applied to a least-squares formulation, may be viewed as a Gauss–Newton method.

2.4 Ill-Posedness and Ill-Conditioning

Hadamard defined a mathematical problem as *well-posed* if it has a unique solution that depends continuously on the data. Another way to put this is to say that a problem is well-posed if (i) a solution to the problem exists, (ii) the solution is unique, and (iii) the solution depends continuously on the data. A mathematical problem that does not possess these three attributes is called *ill-posed*. There are instances in which a problem is well-posed but is unstable to perturbations in the data. That is, the continuity in (iii) is weak. Such problems are often called ill-conditioned or unstable. It turns out that most inverse problems of interest are ill-posed, or at least ill-conditioned.

To put these concepts in the context of an inverse problem, violating (i) is equivalent to saying that, given data d and a forward map $F(\cdot)$, the equation $F(m) = d$ does not have a solution. Violating condition (ii) is equivalent to the existence of two models, m_1 and m_2 , distinct from each other, such that

$$F(m_1) = F(m_2).$$

Finally, violating condition (iii) is equivalent to saying that there are m_1 and m_2 such that

$$\|m_1 - m_2\| \text{ is arbitrarily large}$$

even if

$$\|F(m_1) - F(m_2)\| \text{ is finite.}$$

This notion is best understood in terms of limits of sequences.

These ideas are very easy to see in the case of a finite-dimensional linear inverse problem where the mapping $F(\cdot)$ is a matrix operation: $F(m) = Gm$ for some matrix G . Consider an inverse problem of finding m in $Gm = d$. Nonexistence is equivalent to having data d that are not in the range of G . Nonuniqueness amounts to G having a null space, i.e., nontrivial solutions to $Gx = 0$. If G has a null space with x being a null vector, then if $m_1 - m_2 = ax$, $Gm_1 - Gm_2 = 0$ while $a \rightarrow \infty$, thus violating condition (iii). Finally, ill-conditioning means that the inverse of F has a large norm, a circumstance that can be succinctly described by the SINGULAR VALUE DECOMPOSITION [II.32].

The study of inverse problems is often about mathematically overcoming ill-posedness or ill-conditioning. Various techniques can help ameliorate its disastrous effects, as we now explain.

2.5 A Priori Information and Preferences

We often have prior information about the unknown in an inverse problem, and such information can be valuable in solving the problem. We have previously alluded to situations where the model is of the form

$$m = m_0 + \Delta m.$$

Under such circumstance, we can view m as a priori information. There are also situations in which we know some characteristics of the unknown. An example is in imaging, where the model is an image. Suppose we know that the image is piecewise constant or that the image is sparse. We can then formulate the problem such that the solution has the desired properties. The technique to be described next is often employed to enforce a preference.

2.6 Regularization

Tikhonov regularization is an approach for solving an ill-posed or ill-conditioned problem. It involves introducing auxiliary terms that make the problem well-posed. The classical inverse problem considered by Tikhonov is a linear inverse problem. Here, the forward map is a linear operator acting on the model parameters, given by Gm . We are given data d and wish to find m . Instead of posing an equation for m , we seek the minimizer to

$$\|Gm - d\|^2 + \lambda \|Bm\|^2. \quad (1)$$

Here, we have used the L_2 -norm. The second term in (1) is often referred to as the penalty term. The linear operator B is called the regularizing operator. Some mathematical properties are imposed on B . Examples include $B = I$ (the identity) when enforcing smallness in m , and B equal to the equivalent of the spatial derivative with m when it represents parameters distributed over space when enforcing smoothness of B .

The point of Tikhonov theory is a notion of “consistency.” To get a sense of its mathematical significance, suppose that G is not invertible. Let m_0 be the true model; thus, $d_0 = Gm_0$ is noiseless data for the inverse problem. We use $e = d - d_0$, to represent the noise in the data for a given experiment. Denote by m the minimizer of (1) for a given d . Tikhonov theory states that under the right mathematical assumptions on G and B , there exists a sequence of values for λ such that if there is a sequence of data $d \rightarrow d_0$, then the minimizer $m \rightarrow m_0$.

While such a theory is of limited practical value, the use of regularization is very powerful for solving ill-conditioned inverse problems. The main challenge in its use is choosing the penalty parameter λ . There are two main methods used for setting λ : the L-curve method and the method of cross-validation. The former is intuitive, whereas the latter is based on statistical assumptions on the noise in the data.

It should be pointed out that different choices of the regularizing operator B and the norms used can give very different answers. For example, when B is the derivative operator and the L_1 -norm is used, we get the well-known total variation regularization. When $B = I$ and the L_1 -norm is again used, we get what is now known as COMPRESSED SENSING [VII.10].

2.7 A Statistical Approach

Bayesian statistics offer a different point of view when solving inverse problems. In this statistical approach we view the inverse problem as one where we have a prior distribution on the unknown model m . The data d is used to update the prior.

To be more precise, instead of a model m and an observation d , we consider random variables M and D representing models and data. By having a prior for the model, we mean that we have a probability distribution $\pi(m)$. For example, m could be finite dimensional and $\pi(m)$ could be a multivariate normal distribution. In the statistical framework, data d is observed and we wish to know the conditional probability distribution

$\pi(m|d)$. The question becomes that of updating the prior probability distribution for m given that we have observed d .

The update is done using BAYES'S RULE [V.11 §1]. This requires a model for the joint probability distribution $\pi(m, d)$, which may be as simple as

$$\pi(m, d) = f(Gm - d),$$

depending on the assumptions.

Computationally, statistical methods can be very costly. However, the payoff can be large because one is often able to get an answer to an inverse problem with confidence intervals. The method of applying the Bayesian framework to inverse problems is often referred to as inversion with uncertainty quantification. Aside from the computational cost, a critique sometimes leveled against this approach is that the prior probability distribution for the model $\pi(m)$ is very difficult to obtain in practice. Nevertheless, Bayesian approaches have become a major tool for solving inverse problems.

3 Selected Examples of Inverse Problems

3.1 X-Ray Computed Tomography

X-ray CT is a method by which the X-ray absorption coefficients of a body are estimated. We have already briefly mentioned the mathematical problem associated with CT in section 2.1. We provide more detail here.

We consider the problem in two dimensions. In figure 2 the path of the X-ray is indicated by the dashed line, denoted by $L_{\theta,s}$. The angle θ is one of the parameters of the ray, the other being the displacement s . The ray path $L_{\theta,s}$ is given by

$$x \cos \theta + y \sin \theta - s = 0.$$

Letting $\rho(x, y)$ be the attenuation and letting $d\ell$ be the length element along the path, the forward map for the inverse problem of CT is

$$R_\theta[\rho](s) = \int_{L_{\theta,s}} \rho(x, y) d\ell.$$

In the inverse problem, we are given data $P_\theta(s)$ for $0 \leq \theta < 2\pi$ and $a \leq s \leq b$, and we solve

$$R_\theta[\rho](s) = P_\theta(s)$$

for $\rho(x, y)$. We may assume that $\rho(x, y)$ is compactly supported. Modern CT can be attributed to the work of Cormack and Hounsfield, who shared the 1979 Nobel Prize in Physiology or Medicine for their work. However,

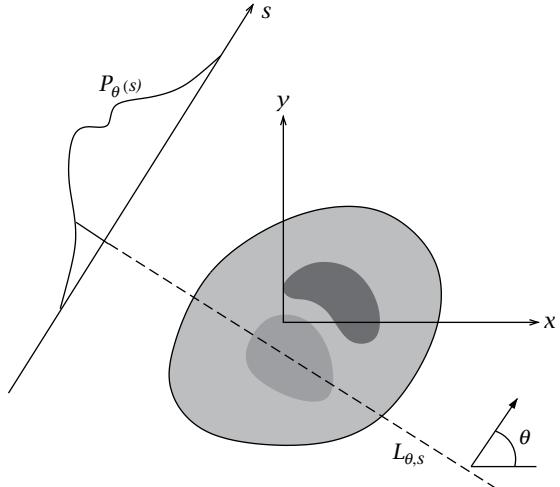

Figure 2 Schematic of X-ray CT in two dimensions. The dashed line represents the path of the X-ray. The projection is parametrized by the angle θ . Data at this angle are the function $P_\theta(s)$, where s parametrizes the ray displacement as indicated.

the mathematics that makes CT a reality dates back to the work of Radon, who in 1907 showed that a function could be reconstructed from its projections. One can use Radon's theory to obtain an inversion formula for $\rho(x, y)$ given $P_\theta(s)$, which is given by

$$\rho(x, y) = \frac{1}{2\pi^2} \int_0^\pi \int_{-\infty}^\infty \frac{P'_\theta(s)}{x \cos \theta + y \sin \theta - s} ds d\theta,$$

although the formula is of limited practical use. Here, $P'_\theta(s)$ is the derivative of $P_\theta(s)$ with respect to s .

Several practical computational approaches are available for solving the inverse problem of X-ray CT. Some are based on Fourier transforms, while others are based on solving a system of linear equations. Modern CT scanners are designed for high-speed data acquisition and low X-ray dosage. Algorithms are designed for each machine in order to optimize computational efficiency and accuracy.

3.2 Seismic Travel-Time Tomography

In travel-time tomography, the data consist of records of the time taken for a wave packet to leave a source, travel through the Earth's interior, and arrive at a point on the surface of the Earth. Such data are called travel-time data and can be extracted from seismic records. In the simplest model, the Earth is flat and two dimensional. The sound speed depends only on depth, and the source is located on the surface. Using geometrical

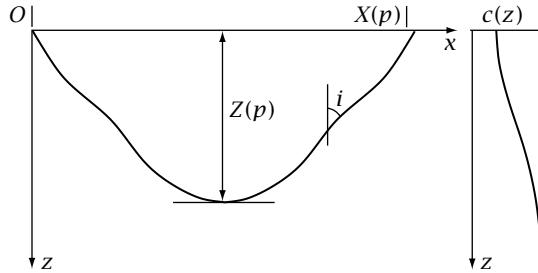

Figure 3 Schematic of a travel-time inverse problem. A wave source is located at the origin. A ray emanates from the source, and its trajectory is determined by the take-off angle and the sound speed profile $c(z)$. It returns to the surface at $x = X(p)$, where p is the ray parameter. The inverse problem is to find $c(z)$ from $X(p)$.

optics we follow a ray emanating from the source and trace its path back to the surface (see figure 3). A ray is parametrized by the angle it makes with the surface at the source.

Suppose that the unknown sound speed profile as a function of depth is $c(z)$. Let us locate the source at the origin. A ray leaves the origin, making an angle i_0 with respect to the vertical. According to geometrical optics, the quantity

$$p = \frac{\sin i}{c(z)}$$

is constant along the ray, where i is the angle the ray makes at depth z , measured clockwise from the vertical. This quantity is called the ray parameter. Fermat's principle governs the ray trajectory, and the point at which a ray with parameter p arrives on the surface, $X(p)$, is given by

$$X(p) = \int_0^{Z(p)} \frac{p \, dz}{\sqrt{c(z)^{-2} - p^2}}.$$

The function $Z(p)$ is the maximum depth the ray reaches in its trajectory, and it is the solution to

$$c(Z(p)) = 1/p,$$

since the ray's angle i is $\pi/2$ at this point. In the inverse problem, we are given travel-time data $X(p)$ for a range of values of p , and the goal is to recover $c(z)$ to a maximum depth possible.

This problem was considered by Herglotz (1907) and Wiechert (1910), who provided a formula for the solution. It is related to the well-known Abel problem in which one attempts to find the shape of a hill given the return times of a particle that goes up the hill at fixed velocities. Bôcher (1909) studied the Abel problem and

arrived at the mathematical conditions under which the hill can be constructed uniquely. The techniques of Bôcher can be applied to the geophysical travel-time problem. A solution that gives z as a function of c is available for this problem:

$$z(c) = -\frac{1}{\pi} \int_{c_0^{-1}}^{c^{-1}} \frac{X(p)}{\sqrt{p^2 - c^{-2}}} \, dp.$$

The formula is valid when $X(p)$ has continuous derivatives. In particular, it is not valid when $X(p)$ is multivalued, which occurs when $c(z)$ has a “low-velocity zone,” i.e., an interval in which $c(z)$ dips below an otherwise-increasing trend.

3.3 Geophysical Inversion for Near-Surface Properties

In an attempt to determine the near-surface (several kilometers in depth) properties of the Earth, geophysicists perform experiments on the surface to gather data from which they hope to infer the properties of the subsurface. One such experiment is seismic exploration, wherein elastic waves are used to probe the Earth. As these waves propagate into the Earth, the inhomogeneities in the Earth diffract and reflect the waves in a process called scattering. The scattered waves are measured on the surface using geophones. The inverse problem is to determine the material properties of the Earth from the scattered data.

In a typical measurement, a localized source, in the form of heavy equipment that “thumps” the surface, is introduced. An array of geophones collects the response of the Earth to the source. Data collection is over a given time window. Such a measurement is called a “shot.” The measurement is then repeated at another source location. The totality of the data consist of geophone readings from a number of shots (see figure 4).

Geophysicists have developed a number of approximation methods to interpret such data. These methods have been successful in situations where the wave phenomena are well modeled by the approximations. Current research focuses on more accurate modeling of the wave phenomena, the development of problem formulations that are computationally feasible, and computational methods that exploit the power of modern computers.

In the simplest useful approximation, the Earth is modeled as an acoustic fluid occupying a two- or three-dimensional half-space, with spatially variable bulk

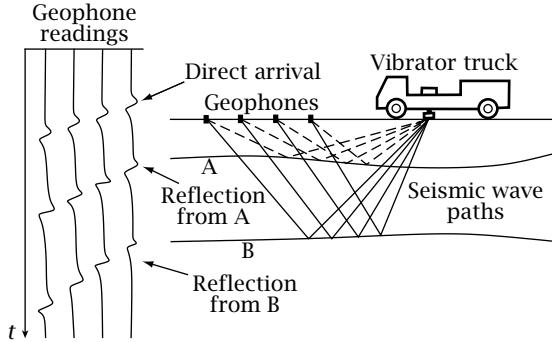

Figure 4 Data collection in seismic exploration. The vibrator truck is capable of “thumping” the surface and produces waves that travel into the interior of the Earth. These waves are reflected by the inhomogeneities in the Earth and return to the surface. Geophones record the reflected waves. This “shot” is repeated after the source and the receiver array have been moved to a new location.

modulus $\kappa(x)$ and constant density ρ . Despite the neglect of significant physics, this model underlies the vast bulk of contemporary seismic imaging and inversion technology.

The examples that follow are two dimensional. The state of the acoustic Earth is captured by the pressure field $u(x, t)$: $x = (x_1, x_2)$ are spatial coordinates with $x_2 > 0$, and t is time. The acoustic wave equation satisfied by $u(x, t)$ is

$$\frac{\partial^2 u}{\partial t^2} = \frac{\kappa}{\rho} \Delta u + f^{(i)}(x, t),$$

where $f^{(i)}(x, t)$ is a time-varying and spatially localized source of energy and $f^{(i)}(x, t) = 0$ for $t < 0$. The index i refers to the location of the source. On the boundary $\{x: x_2 = 0\}$, representing the Earth’s surface, we assume the Dirichlet boundary condition $u = 0$. This is a reasonable approximation, as pressures in the air are orders of magnitude smaller than pressures in the water or rock.

Since the seismic experiment consists of several shots, it produces several pressure fields $u^{(i)}(x, t)$, caused by several source fields $f^{(i)}(x, t)$ representing varying placements of the “thumping” machinery, $i = 1, 2, \dots, n$. The data recorded by the geophones is the pressure at a number of geophone locations $\{x_j^{(i)}: j = 1, 2, \dots, m\}$ near the surface (but not on it: there, $u = 0$!). Note that the geophone locations may depend on the shot index i ; the entire apparatus of the survey may move from shot to shot, not just the energy source equipment.

The seismic inverse problem can be posed as a data-fitting optimization problem, as explained in section 2.2. In the terminology of that section, the model m is the bulk modulus $\kappa(x)$ and the data d are the vectors of functions of time, one for each shot and receiver location. The value of the forward map F is the sampling of the pressure field predicted via solution of the wave equation:

$$F[\kappa] = \{u^{(i)}(x_j^{(i)}, t): i = 1, \dots, n, \\ j = 1, \dots, m, 0 < t < T\}.$$

The inverse problem is to determine $\kappa(x)$ (insofar as possible) from the data $\{d_j^{(i)}(t): i = 1, \dots, n, j = 1, \dots, m, 0 < t < T\}$:

$$F[\kappa] \approx d.$$

The most commonly used optimization formulation of this problem seeks to choose κ to minimize the mean-square residual

$$\|F[\kappa] - d\|^2 = \sum_{i=1}^n \sum_{j=1}^m \int_0^T |u^{(i)}(x_j^{(i)}, t) - d_j^{(i)}(t)|^2 dt.$$

In the current seismic literature, estimation of κ (or other mechanical parameter fields) by minimization of the mean-square residual is known as *full waveform inversion* (FWI). This approach to extracting information about the Earth from seismic data was first studied in the 1980s. Early implementations were generally unsuccessful, partly because at that time only two-dimensional simulation was feasible. Since the turn of the twenty-first century, though, advances in algorithms and hardware performance have enabled three-dimensional simulation and iterative minimization of the mean-square residual for three-dimensional distributions of κ and similar parameters. While the technology is still in the early stages of development, it has already become clear that FWI can produce information about the geometry of subsurface rock that is far better in terms of both quality and resolution than that obtainable with older methods based on more drastic approximation.

While plenty of FWI success stories can be found, we see failures too: failures driven by a fundamental mathematical difficulty. This issue was discovered in the 1980s, the first period of active research on FWI, and remains the main impediment to its widespread use.

The problem is easy to illustrate with a two-dimensional example. Figure 5(a) displays an example two-dimensional bulk modulus κ that is widely used in

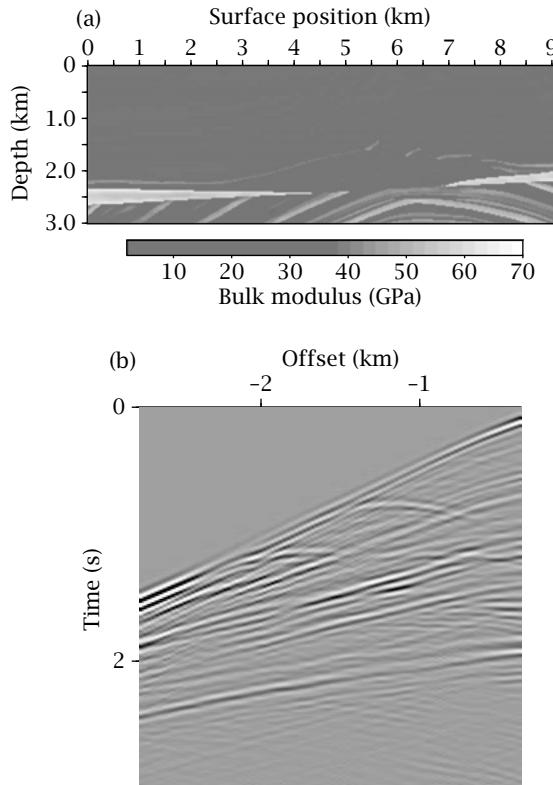

Figure 5 (a) The Marmousi model for the bulk modulus. (b) The simulated seismic data associated with the model.

research on FWI: the Marmousi model. We choose one source location and solve the wave equation numerically to produce the simulated data depicted in figure 5(b). The simulated data consist of pressure readings at a set of geophones located equidistant from each other, starting some distance from the source. The figure displays the recordings for a single shot, at horizontal position 6 km from the left edge of the model in figure 5(a), at a depth of 6 m. The horizontal axis in figure 5(b) is receiver index ($j = 1, \dots, m$, $m = 96$) and the vertical axis is time. The pressure reading is given a gray level value.

To demonstrate the sensitivity of the cost function to a small change in the bulk modulus, we made a convex combination of the bulk modulus in figure 5(a) (95%) with a constant background of $\kappa_0 = 2.25$ GPa (5%). Let κ_1 be the bulk modulus in figure 5(a), and let $\kappa_2 = 0.95\kappa_1 + 0.05\kappa_0$. We will measure the difference in the forward maps for these two bulk moduli. The forward map at κ_2 is the simulated pressure field shown in

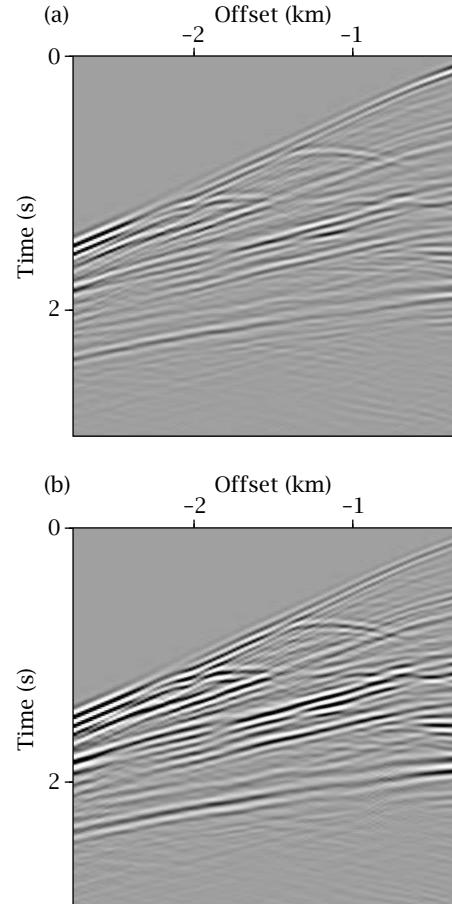

Figure 6 (a) The simulated seismic data with a different model, consisting of 0.95 times the model in figure 5(a) added to 0.05 times a constant bulk modulus of 2.25 GPa; the net difference is well under 5% root mean square. (b) The residual, which is the difference between figure 5(a) and part (a) of this figure.

figure 6(a), and the residual, the difference between the two maps, $F(\kappa_2) - F(\kappa_1)$, is shown in figure 6(b). The difference $F(\kappa_2) - F(\kappa_1)$ is very visible. In fact, the L_2 -norm of the difference is almost twice as large (184%) as the norm of the simulated data $F(\kappa_1)$.

From this example we can already see that the predicted data may change very rapidly as a function of the model. The reason for this rapid change is that the oscillatory signal has shifted in time by a large fraction of a wavelength, which yields a large mean-square (L_2) change. This “cycle skipping” phenomenon arises from the influence of the bulk modulus on the speed of the waves embedded in the solution of the wave equation.

The size of the predicted data (figure 6(a)) has not changed much, however. For a variety of reasons, principally conservation of acoustic energy, the overall size of the data (measured with the L^2 -norm, for example) depends only weakly on the model (κ). This combination of very rapid change while staying the same size suggests that the predicted data cannot continue to “run away” from the “observed” data; the distance between them must oscillate.

In another numerical experiment we made a convex combination of 90% Marmousi bulk modulus and 10% constant bulk modulus, i.e., $\kappa_3 = 0.9\kappa_1 + 0.1\kappa_0$. We found $\|F(\kappa_3) - F(\kappa_1)\|/\|F(\kappa_1)\|$ to be 144%. We note that this is smaller than $\|F(\kappa_2) - F(\kappa_1)\|/\|F(\kappa_1)\|$. That is, we have observed that *the least-squares objective function (the mean-square residual) has local minima other than its global minimum*, at least when restricted to the line segment through the target model in figure 5(a) and the homogeneous $\kappa = \kappa_0$.

This is a very serious obstacle because the computational size of these problems is so large that only variants of local search algorithms (mainly, Newton’s method) are (barely) feasible, and these find only local extrema.

The problem of local minima turns up with considerable regularity in research into, and field applications of, FWI. Since, in the field, we do not know the answer a priori, a frequent result is “zombie inversion”: a failure to accurately estimate the structure of the Earth without any effective indication of failure. Quality control of FWI is a current research topic of great interest. Acquisition of unusually low-frequency data can lead to an escape from the local-minimum problem, and this is another topic of great current interest. At the time of writing, there is still no mathematical justification of the effectiveness of low-frequency inversion. Finally, considerable effort is being put into alternative objective functions with better convexity properties than the least-squares function studied here.

3.4 Electrical Impedance Tomography

In electrical impedance tomography we are given an object whose spatially dependent conductivity is unknown (see figure 7). Electrostatic measurements are taken on the boundary of the object. The objective is to determine the unknown conductivity from these boundary measurements. This problem is often referred to as the “Calderon problem” because Alberto Calderon was the first to study it mathematically, in 1980.

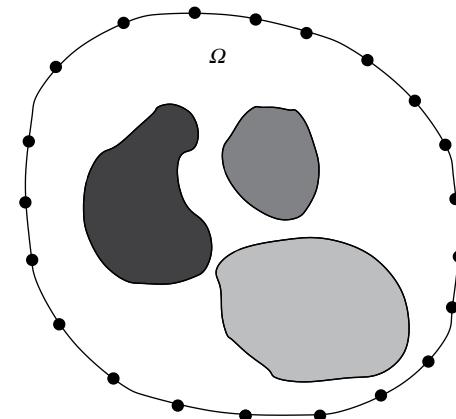

Figure 7 A schematic of electrical impedance tomography. The body Ω has variable conductivity in its interior. The inverse problem is to determine the conductivity distribution from boundary measurements. In practice, the measurement is done by attaching electrodes to the boundary of Ω , indicated in the figure by black circles. Current is assigned to the electrodes, while voltages are measured at all the electrodes. The data so collected represent a sampling of the Dirichlet-to-Neumann map.

Let $\sigma(x)$, where x is the spatial variable in two or three dimensions, represent the conductivity of the object Ω . Potential theory, which follows from Ohm’s law, states that the electrical potential in Ω satisfies

$$\nabla \cdot \sigma(x) \nabla u = 0$$

if there are no sources in the interior of Ω . In the idealized mathematical problem, we are allowed to prescribe any boundary value g to $u(x)$, i.e.,

$$u|_{\partial\Omega} = g.$$

For each g we measure the normal derivative of the potential $u(x)$ at the boundary:

$$\left. \frac{\partial u}{\partial \nu} \right|_{\partial\Omega} = f.$$

We therefore have an f for every g . The totality of these pairs of functions is our data. The mathematical name for such data is the Dirichlet-to-Neumann map. It is clear that it depends on $\sigma(x)$. Denoting this map by Γ_σ , we have $f = \Gamma_\sigma g$. The inverse problem is to determine $\sigma(x)$ given Γ_σ .

In practice, we are not given the Dirichlet-to-Neumann map in its entirety. Rather, we are given a finite collection of pairs

$$\{f^{(i)}, g^{(i)}\}, \quad i = 1, 2, \dots, n.$$

A practical approach to measurement is to attach a number of electrodes to the surface of the object.

Current is made to flow between a pair of electrodes, while voltage is measured on all the electrodes. Therefore, in practice, we do not have $(f^{(i)}, g^{(i)})$ but rather samples of their values at the electrodes.

The Calderon problem has received a lot of attention in the past thirty years due to its practical importance. Barber and Brown developed a practical medical imaging device using this principle in 1984. The same problem crops up in other applications such as nondestructive testing and geophysical prospecting.

The mathematical question of unique determination of $\sigma(x)$ from Γ_σ is a well-developed area. The results depend on the number of dimensions. In two dimensions, the earliest uniqueness result (from 1984) is due to Kohn and Vogelius, who showed that if $\sigma(x)$ is analytic then it is uniquely determined by Γ_σ . The next seminal result on this subject was due to Sylvester and Uhlmann in 1987. They proved global uniqueness results in dimensions three and higher. Their approach is based on the powerful method of complex geometrical optics. Global uniqueness was proved a few years later by Nachman in two dimensions using a method called ∂ -bar.

Recent work has focused on how rough $\sigma(x)$ can be while retaining uniqueness and on the case where $\sigma(x)$ is a matrix function. The latter study has led to the discovery of TRANSFORMATION OPTICS [VI.1], which has provided a strategy for cloaking and invisibility.

While uniqueness can be established, it is very difficult to reconstruct $\sigma(x)$ from actual measurements in practice. This is due to the fact that the problem of determining $\sigma(x)$ from Γ_σ is very ill-conditioned. There have been several successful approaches. They are based on linearization of the relationship between Γ_σ and σ , on least-squares fitting, and on a direct reconstruction method called the ∂ -bar method. The last approach involves synthesizing data for a scattering problem from the measured data, which in itself is ill-conditioned.

4 Related Problems

There are problems that could be viewed as inverse problems but do not go by that name. One set arises in the study of control theory for distributed parameter systems. Statisticians view an inverse problem as a problem of parameter estimation from data. This point of view precedes the more recent statistical approaches to inverse problems.

5 Outlook

Inverse problems is an active research field with several devoted journals and a community of researchers coming from many disciplines. Many of the problems arise in engineering and scientific applications but the core language and tools are mathematical in nature. Progress in new imaging technologies, including functional magnetic resonance imaging and photoacoustic tomography, has been made possible by advances in inverse problems. Inverse problems techniques have also made important contributions to engineering fields such as nondestructive evaluation of materials and structures.

IV.16 Computational Science

David E. Keyes

1 Definitions

Computational science—the systematic study of the structure and behavior of natural and human-engineered systems accomplished by computational means—embraces the domains of mathematical modeling, mathematical analysis, numerical analysis, and computing. In order to reach the desired degrees of predictive power, fidelity, and speed of turnaround, computational science often stretches the state of the art of computing in terms of both hardware and software architecture. Because each decision made along

the way—such as the choice between a partial differential equation (PDE) and a particle representation for the model, between a structured and an unstructured grid for the spatial discretization, between an implicit and an explicit time integrator, or between a direct and an iterative method for the linear solver—can greatly affect computational performance, computational science is a highly interdisciplinary field of endeavor.

Definitions of computational science and the related discipline of scientific computing are not universal, but we may usefully distinguish between them by considering computational science to be the vertically integrated *union* of models and data, mathematical technique, and computational technique, while scientific computing is the study of techniques in the *intersection* of many discipline-specific fields of computational science. Computational chemistry, computational physics, computational biology, computational finance, and all of the flavors of computational engineering (chemical, civil, electrical, mechanical, etc.) depend on a common set of techniques connecting the conceptualization of a system to its realization on a computational platform. These techniques—such as representing continuous governing equations with a discrete set of basis functions, encoding this representation for digital hardware, integrating or solving the discrete system, estimating the error in the result, adapting the computational approximation, visualizing functionals of the results, performing sensitivity analyses, or performing optimization or control—span diverse applications from science and engineering and are the elements of scientific computing. Chaining together such techniques to form a simulation to address a specific application constitutes computational science. Practitioners often use the more inclusive terms “computational science and engineering” and “scientific and engineering computing,” but in this article the “engineering” applications are understood to be subsumed in the “scientific.”

Practitioners also often distinguish between computational science executed by means of simulation and that executed by “mining” data, the latter without necessarily possessing a model. Simulation is often referred to as the “third paradigm” of science and data analytics as the “fourth paradigm.” These are in opposition to the “first paradigm” of theory, which is millennia old, and the “second paradigm” of controlled experiment or observation, which is centuries old. The interplay of theoretical hypothesis and controlled

experimentation defines the modern scientific method, in the era since, say, Galileo. Recently, the same standards of REPRODUCIBILITY [VIII.5] and reporting have been applied to simulation, and the interplay among the first three paradigms has become highly productive. Until recently, science generally tended to be “data poor,” but now most scientific campaigns are data rich, with many “drowning” in data, so a contemporary challenge of computational science is to integrate the third and fourth paradigms. When a model is given, its simulation is called the “forward problem.” The availability of data allows aspects of the underlying model to be inferred or improved upon; this is the domain of INVERSE PROBLEMS [IV.15]. Whereas forward problems are by design generally well-posed, inverse problems are often unavoidably ill-posed, due to ill-conditioning or nonuniqueness. There are many elements of scientific computing in this intersecting domain of the third and fourth paradigms, including data assimilation, parameter inversion, optimization and control, and UNCERTAINTY QUANTIFICATION [II.34]. These “post-forward problem” techniques are today applied throughout the computational sciences and they drive a considerable amount of research in applied and computational mathematics. Simulation and data analytics have attained peer status with theory and experiment in many areas of science.

Computer simulation and data analytics enhance or leapfrog theoretical and experimental progress in many areas of science critical to society, such as advanced energy systems (e.g., fuel cells, fusion), biotechnology (e.g., genomics, drug design), nanotechnology (e.g., sensors, storage devices), and environmental modeling (e.g., climate prediction, pollution remediation). Simulation and analytics also offer promising near-term hope for progress in answering a number of scientific questions in such areas as the fundamental structure of matter, the origin of the universe, and the functions of proteins and enzymes.

2 Historical Trends

The strains on theory were apparent to John von Neumann (1903–57) and drove him to pioneer computational fluid dynamics and computational radiation transport, and to contribute to supporting fields, especially numerical analysis and digital computer architecture. Models of fluid and transport phenomena, when expressed as mathematical equations, are inevitably nonlinear, while the bulk of mathematical theory (for

algebraic, differential, and integral equations) is linear. Computation was to von Neumann, and remains today, the best means of making systematic progress in transport phenomena and many other scientific arenas. Breakthroughs in the theory of nonlinear systems come only occasionally, but computational understanding gains steadily with increases in speed and resolution.

The strains on experimentation—the gold standard of scientific truth—have grown along with expectations for it. Unfortunately, many systems and many questions are all but inaccessible to experiment. (We subsume under “experiment” both experiments designed and conducted by scientists and observations of natural phenomena, such as celestial events, that are out of the direct control of scientists.) The experiments that scientists need to perform to answer pressing questions are sometimes deemed unethical (e.g., because of their impact on living beings), hazardous (e.g., because of their impact on our planetary environment), untenable (e.g., because they are prohibited by treaties), inaccessible (e.g., those in astrophysics or core geodynamics), difficult (e.g., those requiring measurements that are too rapid or numerous to be instrumentable), too time-consuming (in that a decision would need to be made before the experimental results could be attained, e.g., certification of a system or a material lifetime), or simply too expensive (including detectors, the Large Hadron Collider facility cost over \$10bn and the International Thermonuclear Experimental Reactor is projected to cost well over \$20bn). There is thus a strong incentive to narrow the regimes that must be investigated experimentally using predictive computational simulation and data analytics.

As experimental means approach practical limits, for more than two decades computational performance on real applications has improved at a rate of more than three orders of magnitude per decade (see HIGH-PERFORMANCE COMPUTING [VII.12]). Over the same period, the acquisition cost of a high-performance computer system designed for scientific applications has fallen by almost three orders of magnitude per decade per unit of performance, together with the electrical power required per unit of performance, so that after a decade a system a thousand times more powerful costs about the same to own and operate. These trends in performance and cost are well documented in the history of the Gordon Bell Prizes and of the annual Top 500 lists (see www.top500.org). Increased computational power can be invested in fine resolution of multiscale phenomena, high fidelity, full dimensionality,

integration of multiple interacting models in complex systems, and running large ensembles of forward problems to gain scientific understanding. Unfortunately, however, after more than two decades of riding Moore’s law, physical barriers to extrapolating the favorable energy trends in computing are approaching, and these barriers are now significant drivers in computational science research.

Contemporary computational science stands at the confluence of four independently and fruitfully developing quests: the mathematization of nature, epitomized by Newton; numerical analysis, epitomized by von Neumann; high-performance computer performance, epitomized by Cray; and scientific software engineering, represented by numerous contemporaries. A predigital computer vision of computational science was proposed by L. F. Richardson in his 1922 monograph on numerical weather prediction. Richardson’s parallel computer was an army of human calculators arrayed at latitudinal and longitudinal increments along the interior surface of a mammoth globe. Richardson’s monograph appeared prior to the existence of not only any digital computer but also to the stability analysis of finite-difference methods for PDEs, which was addressed by Courant, Friedrichs, and Lewy in 1928. Since computers now commit $O(10^{15})$ floating-point rounding errors per second on simulations that execute for days, numerical analysis has a central role.

Until von Neumann and Goldstein’s landmark 1947 work on the stability of Gaussian elimination, it was not clear how large a system (in this case, of linear equations) could be a candidate for computational solution using floating-point arithmetic, due to the accumulation of rounding errors. We can now make use of digital computers to solve systems of equations billions of times larger than the authors considered. Thanks to continued advances in numerical analysis, and particularly in error analysis and optimal algorithms, the size of simulations in many fields continues to grow to take advantage of all of the resolution that computers can provide. Of course, for systems that are fundamentally “chaotic” in continuous form—meaning that solution trajectories that started infinitesimally far apart can diverge exponentially in finite time—the scientific benefit of greater resolution must be carefully considered in relation to the exponent of divergence. In 1950, von Neumann (with Charney and Fjørtoft) introduced a form of PDE stability analysis that was complementary to that of Courant, Friedrichs, and Lewy. This

analysis clarified a fundamental bound on the size of the time step of a simulation relative to the fastest signal speed of the phenomenon being modeled and the granularity of the spatial sampling. The 1950s, 1960s, and 1970s witnessed advances in discretization and equation solving, the development of high-level PROGRAMMING LANGUAGES [VII.11], and improvements in hardware that allowed ambition for computational simulation to soar. By 1979, computational fluid dynamicists were able to claim dramatic reductions in wind tunnel and flight testing of the Boeing 767 thanks to simulations performed to narrow the parameter spaces of design and testing. These simulations, heroic at the time though extremely modest by contemporary standards, gave practical and economic embodiment to the dream of computational science.

Two landmarks defining the ambitions and culture of computational science were the articles by Peter Lax in 1986 championing simulation as the “third leg” of the scientific platform and by Ken Wilson in 1989 on “grand challenges” in computational science. These articles were influential in unlocking funding for computational science campaigns in government, academia, and industry and in democratizing access to high-performance computers, which had previously been the province of relatively few pioneers at national and industrial laboratories.

The formation of the U.S. federal Networking and Information Technology Research and Development organization in 1992 coordinated investments in research, training, and infrastructure from ten federal agencies in high-performance computing and communications and provided recognition for the interdependent ecology of applications, algorithms, software, and architecture. The U.S. Department of Energy’s Accelerated Strategic Computing Initiative of 1997 enshrined predictive simulation as a substitute for weapon detonations under a nuclear test ban in the United States and dramatically expanded investment in training computational scientists and engineers. The Department of Energy’s Scientific Discovery through Advanced Computing (SciDAC) program, established in 2001, extended the culture of the Accelerated Strategic Computing Initiative program throughout mission space, from astrophysics and geophysics to quantum chemistry and molecular biology. The document that founded the SciDAC program declared the computer, after tuning for accuracy and performance, to be a reliable scientific instrument like any microscope,

telescope, beamline, or spectrometer and of more general purpose.

As the Internet expanded to universities, and as the World Wide Web (developed at CERN for the sharing of experimental data sets among theoretical physicists) connected scientists and engineers globally, computational science and engineering forged a global identity. Today, scientific professional societies such as the Society for Industrial and Applied Mathematics, the Institute of Electrical and Electronics Engineers, the Association for Computing Machinery, and the American Physical Society sponsor activities and publications that promote the core enabling technologies of scientific computing. The expectations of large-scale simulation and data analytics to guide scientific discovery, engineering design, and corporate and public policy have never been greater. Nor have the cost-effectiveness and power of computing hardware, which are now driven by commercial market forces far beyond the scientific yearnings that gave birth to computing. Computational science and scientific computing span the gap between ever more demanding applications and ever more complex architectures. These fields provide enormous opportunities for applied and computational mathematicians.

3 Synergies and Hurdles

Simulation has aspects in common with both theory and experiment. First, it is fundamentally theoretical, in that it starts with a model, typically a set of equations. A powerful simulation capability breathes new life into theory by creating a demand for improvements in mathematical models. Simulation is also fundamentally experimental, in that upon constructing and implementing a model, one may systematically observe the transformation of inputs (or controls) into outputs (or observables). Simulation effectively bridges theory and experiment by allowing the execution of “theoretical experiments” on systems, including those that could never exist in the physical world, such as a fluid without viscosity or a perfectly two-dimensional form of turbulence. Computation also bridges theory and experiment by virtue of the computer, which serves as a universal and versatile data host. Once data have been digitized, they can be compared side by side with simulated results in visualization systems built for the simulations. They may also be reliably transmitted and retrievably archived. Moreover, simulation and experiment can complement each other by allowing a more complete picture of a system than either

can provide on its own. Some data may be unmeasurable even with the best experimental techniques available, and some mathematical models may be too sensitive to unknown parameters to invoke with confidence. Simulation can be used to “fill in” the missing experimental fields, using experimentally measured fields as input data. Data assimilation can also be systematically employed throughout a simulation to keep it from “drifting” from measurements, thus overcoming the effect of modeling uncertainty. Many data-mining techniques in effect build statistical models from data that may be as predictive as executing the dynamics of a traditional model.

Some of the ingredients that are required for success in computational science include insights and models from scientists; theory, methods, and algorithms from mathematicians; and software and hardware infrastructure from computer scientists. There are numerous ways to translate a physical model into mathematical algorithms and to implement a computational program on a given computer. Decisions made without considering upstream and downstream stages may cut off highly productive options. A bidirectional dialogue, up and down the hierarchy at each stage, can ensure that the best resources and technologies are employed. To bridge the algorithmic gap between the application and the architecture, mathematicians must consider implications of both. For example, in representing a field that is anticipated to be smooth, one may select a high-order discretization. In anticipating a port to a hybrid architecture emphasizing SIMDization (SIMD stands for single-instruction-multiple-data), one may produce uniformly structured data aggregates even if this over-resolves the modeled phenomena somewhere relative to the required accuracy. If one requires the adjoint of an operator to perform optimization in the presence of PDE constraints, one may pay an extra price in the forward problem to employ an implicit Newton method, which creates a Jacobian matrix that is then available for adjoint use. However, this Jacobian matrix may be the largest single working set of data in the problem, and its layout may dominate implementation decisions.

While the promise of computational science is profound, so are its limitations. The limitations often come down to a question of resolution. Though of vast size, computers are triply finite: they represent individual quantities only to a finite precision, they keep track of only a finite number of such quantities, and they operate at a finite rate. Although all matter is, in fact,

composed of a finite number of atoms, the number of atoms in a macroscopic sample of matter, on the scale of Avogadro’s number, places simulations at macroscopic scales from “first principles” (i.e., from the quantum theory of electronic structure) well beyond any conceivable digital computational capability. Similar problems arise when timescales are considered. For example, the range of timescales in protein folding is at least twelve orders of magnitude, since a process that takes milliseconds to complete occurs in molecular dance steps (bond vibrations) that occur in femtoseconds (a trillion times shorter); again, this is far too wide a range to routinely simulate using first principles.

Some simulations of systems adequately described by PDEs of the macroscopic continuum (fluids such as air or water) can be daunting even for the most powerful computers foreseeable available. Today’s computers are capable of execution rates in the tens of petaflop/s (1 petaflop/s is 10^{15} arithmetic operations per second) and can cost tens to hundreds of millions of dollars to purchase and millions of dollars per year to operate. However, to simulate fluid mechanical turbulence in the boundary and wake regions of a typical vehicle using “first principles” of continuum modeling (Navier-Stokes) would tie up such a computer for months, which makes this level of simulation too expensive and too slow for routine use. To attempt first-principles modeling based on Boltzmann kinetics would be far worse. Practitioners must decide whether upscaled continuum models such as Reynolds-averaged Navier-Stokes or large-eddy simulation will be adequate or whether discrete particle methods such as lattice Boltzmann or discrete simulation Monte Carlo would be more efficient to resolve certain scientific questions on certain architectures.

The “curse of dimensionality” leads to the phenomenon whereby increasing the resolution of a simulation in each relevant dimension quickly eats up any increases in processor power. For explicitly time-discretized problems in three dimensions, the computational complexity of a simulation grows like the fourth power of the resolution in one spatial dimension. Therefore, an increase in computer performance by a factor of 100 provides an increase in resolution in each spatial and temporal dimension by a factor of only slightly more than 3. The “blessing of dimensionality” refers to an entirely different observation: complex dynamics of real systems can often be represented in a relatively small number of principal components. If one represents the dynamics in terms of this efficient

basis, rather than the nodal basis that is implicit in tabulating solution values on a mesh, one's predictive ability may effectively advance by the equivalent of several computer generations with a few strokes of a pen.

A standard means of bringing more computational power to bear on a problem is to divide the work to be done over many processors by means of domain decomposition that partitions mesh cells or particles and employs message-passing between the computational nodes. Typically, the same program runs on each node, but it may execute different instruction streams on different nodes due to encountering different data. This programming model is variously known as “single-program/multiple-data,” “bulk synchronous processing,” or “communicating sequential processes.” Parallelism in computer architecture can provide additional factors of hundreds of thousands, or more, to the aggregate performance available for the solution of a given problem, beyond the factor available from Moore's law (a doubling of transistor density about every eighteen months) applied to individual processors alone. However, the desire for increased resolution and, hence, accuracy is seemingly insatiable. The CURSE OF DIMENSIONALITY [I.3 §2] means that “business as usual” in scaling up today's simulations by riding the computer performance curve alone, without attention to algorithms that squeeze more scientific information out of each byte stored or flop processed, will not be cost-effective.

The “curse” of knowledge explosion—namely, that no one computational scientist can hope to track advances in all of the facets of the mathematical theories, computational models and algorithms, applications and computing systems software, and computing hardware (computers, data stores, and networks) that may be needed in a successful simulation effort—is another substantial hurdle to the progress of simulation. Effective collaboration is a means by which it could be overcome.

4 Cross-cutting Themes

Computational science embraces diverse scientific disciplines; however, themes that cut across different disciplines, and even themes that appear to be universal, do emerge. We discuss some of these in this section.

4.1 Balance of Errors

Computational science proceeds by stages of successive transformation and approximation, including

continuous modeling, numerical discretization, digital solution, and analysis and interpretation of the results, at each of which errors are made. The overall error can be estimated by recursive application of the triangle inequality. The error estimates for individual stages should be made commensurate, since it adds no value to produce an exact algebraic solution to a discrete system that is only an approximate representation, for instance, or to overly refine a discretization within which there are coefficients that are only imperfectly known, or where the underlying physical “laws” are merely approximate correlations. One of the primary and most difficult tasks in computational science is to estimate and balance the errors at each stage, to avoid overinvesting in work that does not ultimately contribute to the accuracy of the desired output. “Validation” and “verification” are two generalized stages of a comprehensive error analysis of a computational science campaign, the former measuring the degree to which the model represents the salient features under investigation and the latter measuring the quality of the solution to the model. The ultimate goal is to get the greatest scientific insight at the lowest “cost.” Error estimation in an individual execution is an essential aspect of insight, but it must be accompanied by judicious selection of cases to run and by performance tuning to run them efficiently.

4.2 Uncertainty Quantification

To be accepted as a means of scientific discovery, engineering design, and decision support, computational science must embrace standards of predictivity and reproducibility. Uncertainty can enter computations in a number of ways, but fundamentally, there are two types: epistemic and aleatoric. Epistemic uncertainties are those that could, in principle, be reduced to zero, leading to accurate deterministic simulations, but for which the modeler simply lacks sufficient knowledge. Aleatoric uncertainties are those that are regarded as unknowable, except in a statistical sense, because of fundamental randomness. Uncertainty in the output of a simulation can enter via the structure of the model itself, via parameters, or via approximations committed by the algorithm. Classical approaches to uncertainty quantification are Monte Carlo in nature: one executes the model for a cloud of inputs distributed according to various assumptions and then performs statistics on the output. This is direct, but it can be wasteful of simulation resources. A more progressive approach is

to derive models for the statistical properties of the distribution and propagate them along with the uncertain solution. Uncertainty quantification has justifiably become an interdisciplinary research area dependent upon mathematical, statistical, and domain knowledge. It is also a driver within computational science that justifies investment in scaling the hardware-software environment, since it greatly increases complexity relative to that of the execution of an individual forward model.

4.3 The Ideal Basis

The quest for the ideal basis in which to represent a problem is a recurring theme in scientific computing, since solving the same problem in an ideal basis can bring a critical improvement in computational complexity, that is, in the number of operations required to reach a solution of given accuracy. Rank, sparsity, and boundary conditions are among the features that allow intelligent choice of basis. Problems arrive at the doors of computational scientists with a choice of basis implicit; they are described by objects and operators that are convenient and natural to the scientific community. However, the best formulation for computation may be quite different. Some algorithms derive their own discrete bases that adapt to the operator, such as harmonic interpolants. Reduced-order models are important at the application level, where physical insight may guide a low-dimensional representation of an apparently high-dimensional system. They are also critical at the algorithmic kernel level, where a more automatically adaptive process may incrementally produce a reduced basis, such as a KRYLOV SUBSPACE [II.23] in linear algebra. Possessing multiple models for the same phenomena can increase algorithmic creativity. For instance, in linear problems, an inexpensive model may be used to construct a preconditioner for an expensive one. In nonlinear problems, the solution to a crude model may provide a more robust starting estimate than is otherwise available.

4.4 A Canonical “Algorithmic Basis”

Though the applications of computational science are very diverse, there are a number of algorithmic paradigms that recur throughout them. Seven of these floating-point algorithms were identified by Phillip Colella in 2004, and he called them the “seven dwarfs.” This set was expanded by six integer algorithms in 2006 by the Berkeley scientific computing group, bringing us up to “13 dwarves”: dense direct solvers, sparse direct

solvers, fast transforms, N -body methods, structured (grid) iterations, unstructured (grid) iterations, Monte Carlo, combinatorial logic, graph traversal, graphical models, finite-state machines, dynamic programming, and backtrack and branch-and-bound. These kernels have been characterized by their amenability to scaling on what are known as “hybrid” or “hierarchical” architectures. In such architectures, cores are proliferated within a node of fixed memory and memory bandwidth resources in a shared-memory manner. The resulting nodes are then proliferated in a distributed-memory manner, being connected by a network that scales with the number of nodes. The fact that so many problems in computational science can be reduced to a relatively small set of similar tasks has profound implications for the scientific software environment and for research and development investment. It is possible for the work of a relatively small number of experts in computational mathematics and computer science to serve a relatively large number of scientists and engineers who are expert in something else, namely their fields of application. Vendors can invest in software libraries with well-defined interfaces (such as ones based on fast Fourier transforms or the basic linear algebra subroutines) that can access their hardware in custom ways. Researchers in numerical analysis can be confident, for instance, that work to improve a dense symmetric eigensolver has the potential to be adopted by thousands of chemists solving the Schrödinger equation or that work to improve a sparse symmetric eigensolver could be used by thousands of mechanical engineers analyzing vibrational modes. The list of “dwarfs/dwarves” is binned into fairly broad categories above and many subcategorizations are required in practice to arrive at a problem specification that leads directly to the selection of software. Many of the dwarfs do not yet have optimal implementations or even weakly scalable implementations. These dwarfs make good targets for ongoing mathematical research.

4.5 Polyalgorithms

While it may be possible to describe many computational science applications with reference to a relatively small number of kernels, each such specification can typically be approached by a large number of algorithms. A polyalgorithm is a set of algorithms that can accomplish the same task(s), together with a set of rules for selecting among the members of the set,

based on the characteristics of the input, the requirements of the output, and the properties of the execution environment. Sometimes, one algorithm offers superior performance in terms of the number of operations, the pattern of memory references, running time, or other metrics over a wide range of inputs, output requirements, and environment, which renders the concept trivial. More typically, each algorithm has a niche in which it is superior to all others, and there is no transitivity with respect to performance metrics across all possible uses. Problem size (discrete dimension) is a fundamental input characteristic. A method that requires, asymptotically, $O(N^2)$ operations may beat a method that requires only $O(N)$ or $O(N \log N)$ operations if N is small and the constant hidden by the order symbol is small compared with the constant for an asymptotically superior method. Between two such algorithms there is therefore a crossover point in N that dictates selection between them. Other input characteristics that are often important include sparsity, symmetry, definiteness, heterogeneity, and isotropy. Output requirements may vary dramatically from one application to another. For instance, in an eigenanalysis scenario, are all eigenvalues required, or just the largest, the smallest, or those closest to an interior value? Are eigenvectors required? Environmental characteristics may include the number of processing elements, the availability of built-in floating-point precisions, the relative cost of communication versus computation, and the size of various memories, caches, or buffers. It is therefore beneficial to have access to a variety of well-characterized approaches to accomplish each kernel task.

4.6 Space-Time Trade-Offs

Often, scientific computing algorithms are parametrizable in ways that allow one to make space-time complexity trade-offs. If memory is limited, one may store less and compute more. If extra memory is available, one may store more and compute less. This principle has many manifestations in practical implementations and algorithmic tunings. Classical examples are the size of windows of past vectors to retain in a Krylov-style iterative method or a quasi-Newton iterative method. Contemporary examples emerge from the different latencies that different levels of computer memory possess from fast registers (which are essentially one cycle away), to caches of various levels, to main memory (thousands of cycles away), to disk files

(millions of cycles away), to data distributed over the Internet. It may be cheaper to recompute some data than to store and retrieve them. On the other hand, as in modified Newton iterative methods, it may be cheaper and/or faster to reuse old data (in this case a Jacobian) than to constantly refresh them. In performance-oriented computing it may even be advantageous, on average, to assume values (on the basis of experience or rational assumption) for data that are not available when they appear on the critical path as an input for one process and to “roll back” the computation when they arrive if they are too far from the assumed values. Under the heading of space-time trade-offs, one may also employ multiple precisions of floating-point arithmetic, as in classical ITERATIVE REFINEMENT [IV.10 §2] for linear systems. In this algorithm, one stores simultaneously and manipulates both high- and low-precision forms of some objects, doing the bulk of the arithmetic on the low-precision objects in order to refine the high-precision ones.

4.7 Continuum–Discrete Duality

In computational science it is frequently convenient to have multiple views of the same object. Nature is fundamentally discrete but at a scale typically too fine for digital computers. We therefore work through idealized continuous models, such as Navier-Stokes PDEs to calculate momentum transfer in fluids with small mean free paths between molecular collisions. The continuous fields are then integrated over control volumes, parametrized by finite elements, or represented by pointwise values in finite differences, returning the model to finite cardinality, typically a much smaller cardinality than that of the original molecular model. However, adaptive error analyses for refining the spatial resolution or approximation order of the discretization reemploy the underlying continuous model. The optimal complexity solver known as the multigrid method makes simultaneous use of *several* different discrete approximations to the underlying continuum through recursive coarsening. Ordering multidimensional and possibly irregularly spaced coordinate data into the linear address space of computer memory may take advantage of a discrete analogue to Hilbert’s continuous space-filling curves. Thus, computational mathematics moves fluidly back and forth between the continuous and the discrete. However, continuous properties such as conservation or zero divergence are not necessarily preserved in the dual discrete representation. The computational scientist needs to be aware of

operations, such as variational differentiation or application of boundary conditions, that may not commute with the switch of representations. Thus, for example, “discretize then optimize” may yield a different result from “optimize then discretize” (and famously often does).

4.8 Numerical Conditioning

Numerical conditioning is a primary concern of the computational scientist; it affects the accuracy that can be guaranteed by theory or expected in practice and the convergence rate of many algorithms. It is therefore a key factor in the scientist’s choice of how precise a floating-point arithmetic to employ. In computational science applications, the condition number of a discrete operator is often related to the quality of the discretization in resolving multiscale features in the solution. The continuous operator may have an infinite condition number, so the greater the resolution, the worse the numerical condition number. The progressively worsening conditioning of elliptic operators, in particular, as they better resolve fine-wavelength components in the output, is a bane of iterative methods whose iteration count grows with ill-conditioning. The computational work required to solve the problem to a given accuracy grows superlinearly overall, linearly in the cost per iteration times a factor that depends on the condition number. Optimal algorithms must generally possess a hierarchical structure that handles each component of the error on its own natural scale.

4.9 The Nested-Loop Co-design Process

The classic computational science development paradigm is reflected in figure 1, which is adapted from a figure in a report to the U.S. Department of Energy in 2000. On the left is what could be called a “validation and verification” loop. On the right is a performance tuning loop. The left loop is the province of the computational mathematician, who may make convenient assumptions, such as that memory is flat, in deriving algorithms that deliver bounded error while minimizing floating-point operations or memory capacity. The right loop is the province of computer scientists (and ultimately architects), who inherit a mathematical specification of an algorithm and optimize its implementation for power and runtime. At the time this scheme was introduced in aid of launching the unprecedentedly interdisciplinary SciDAC program, these loops were primarily envisioned to be sequential. First the

validation and verification loop would converge and then the performance tuning loop would, resulting in a computational tool for scientific discovery. “Codesign” is a classic concept from embedded systems that is increasingly being invoked in the general-purpose scientific computing context; it puts an outer loop around these algorithmic and performance loops based on the recognition that isolated design keeps significant performance and efficiency gains off the table. An unstructured grid PDE may not be a good discretization for exploitation of hybrid hardware with significant SIMDization, for instance. Such feedback could lead to consideration of lattice Boltzmann methods in some circumstances, for example.

4.10 From Computing to Understanding

As hardware improves exponentially in performance, computational modeling has the luxury of becoming a science by means of which a simulated system is “poked” intelligently and repeatedly to reveal generalizable insight into behavior. Historically, computational science research was driven by the gap between the capabilities of the hardware and the complexity of the systems intended for modeling. Effort was concentrated on isolating a component of the overall system and improving computational capability thanks to improvements in algorithms, software, and hardware. This inevitably involves invoking assumptions for ignored coupling; for instance, an ocean model may be executed with simple assumptions for atmospheric forcing. Today, highly capable components are being reunified into complex systems that make fewer decoupling compromises. For instance, ocean and atmospheric models drive each other across the interface between them by passing fluxes of mass, momentum, and energy in various forms. With increased computational power and memory, these complex systems can be partially quantified with respect to uncertainty and then subjected to true experiments by being embedded into ensemble runs. “What if” questions can be posed and executed by controlling inputs. This progression is powered at every stage by new mathematics, and sometimes, in turn, it generates new mathematical questions. In building up capability, the focus is on reducing computational complexity. In coupling components, the focus is on balancing error and stability analysis, with a continued premium on complexity reduction. Finally, the focus is on uncertainty quantification and the formulation of hypotheses from observation—

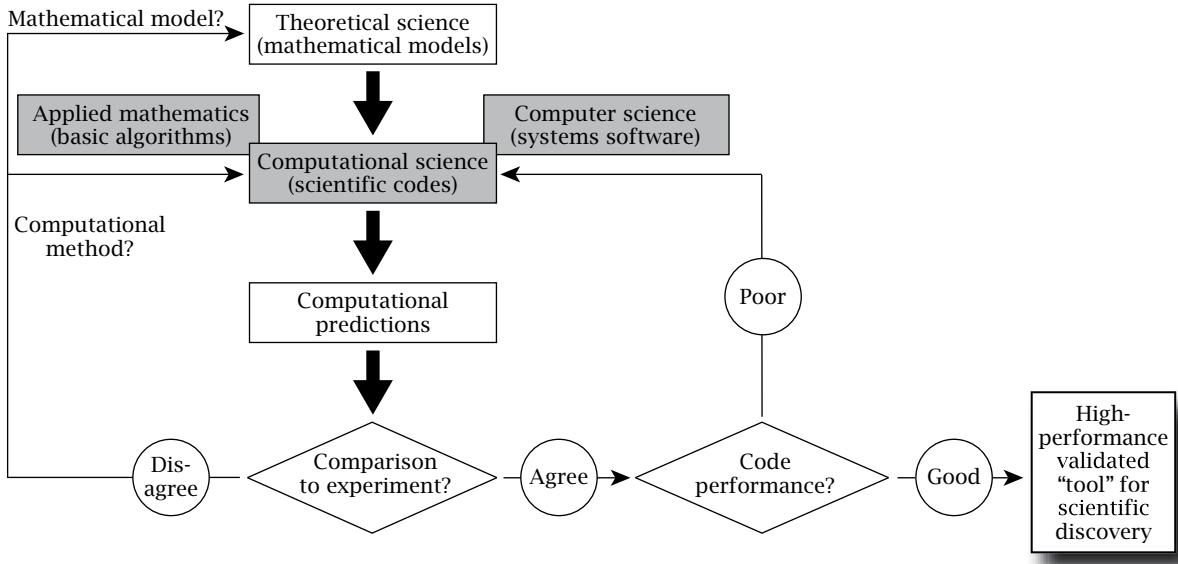

Figure 1 Diagram that launched the SciDAC program in 2000, courtesy of Thom Dunning Jr.

hypotheses that may eventually be provable theoretically or be subject to controlled experimental testing in the real world.

4.11 The “Multis”

The discussion of the cross-cutting themes of computational science can be conveniently and mnemonically encapsulated in the list of the “multis.” Scientific and engineering applications are typically multiphysics, multiscale, and multidimensional in nature. Algorithms to tackle them are typically hierarchical, using interacting multimodels, on multilevels of refinement, in multiprecisions. These then have to be implemented on multinode distributed systems, with multicore nodes, and multiprotocol programming styles, all of which requires a multidisciplinary approach in which the mathematician plays a critical bridging role. We elaborate on multiphysics in the next section.

4.12 Encapsulation in Software

There have been many efforts to respond to the targets presented by one or more of the “dwarfs” and the complexity of the applications and algorithms of computational science with well-engineered software packages. The Portable Extensible Toolkit for Scientific Computing (PETSc), a freely downloadable suite of data structures and routines from Argonne National Laboratory that has been in continuous development since

1992, is an example that incorporates generic parallel programming primitives, matrix and vector interfaces, and solvers for linear, nonlinear, and transient problems. PETSc emphasizes ease of experimentation. Its strong encapsulation design allows users to hierarchically compose methods at runtime for coupled problems. Several relatively recent components have substantially improved composability for multiphysics and multilevel methods. For example, DMComposite manages distributed-memory objects for coupled problems by handling the algebraic aspects of gluing together function spaces, decomposing them for residual evaluation, and setting up linear operators to act on the coupled function spaces. A matrix assembly interface is available that makes it possible for individual physics modules to assemble parts of global matrices without needing global knowledge or committing in advance to matrix format. The **FieldSplit** preconditioner solves linear block systems using either block relaxation or approximate block factorization (as in “physics-based” preconditioners for stiff waves or block preconditioners for incompressible flow). **FieldSplit** can be nested inside other preconditioners, including geometric or algebraic multigrid ones, with construction of the hierarchy and other algorithmic choices exposed as runtime options. Recent enhancements to the TS component support implicit-explicit time integration schemes. Multiphysics applications that have employed

these capabilities include lithosphere dynamics, subduction and mantle convection, ice sheet dynamics, subsurface reactive flow, tokamak fusion, mesoscale materials modeling, and electrical power networks.

5 Multiphysics Modeling

A multiphysics system consists of multiple coupled components, each component governed by its own principle(s) for evolution or equilibrium, typically conservation or constitutive laws. Multiphysics simulation is an area of computational science possessing mathematical richness. Coupling individual simulations may introduce stability, accuracy, or robustness limitations that are more severe than the limitations imposed by the individual components. A major classification in such systems is whether the coupling occurs in the bulk (e.g., through source terms or constitutive relations that are active in the overlapping domains of the individual components) or whether it occurs over an idealized interface that is lower dimensional or over a narrow buffer zone (e.g., through boundary conditions that transmit fluxes, pressures, or displacements). Typical examples of bulk-coupled multiphysics systems that have their own extensively developed literature include radiation with hydrodynamics in astrophysics (radiation-hydrodynamics, or “rad-hydro”), electricity and magnetism with hydrodynamics in plasma physics (magnetohydrodynamics), and chemical reaction with transport in combustion or subsurface flows (reactive transport). Typical examples of interface-coupled multiphysics systems are ocean-atmosphere dynamics in geophysics, fluid-structure dynamics in aeroelasticity, and core-edge coupling in tokamaks. Beyond these classic multiphysics systems are many others that share important structural features.

The two simplest systems that exhibit the crux of a multiphysics problem are the coupled equilibrium problem

$$F_1(u_1, u_2) = 0, \quad (1a)$$

$$F_2(u_1, u_2) = 0 \quad (1b)$$

and the coupled evolution problem

$$\partial_t u_1 = f_1(u_1, u_2), \quad (2a)$$

$$\partial_t u_2 = f_2(u_1, u_2). \quad (2b)$$

When (2a)–(2b) is semidiscretized in time, the evolution problem leads to a set of problems that take the form (1a)–(1b) and that are solved sequentially to obtain values of the solution $u(t_n)$ at a set of discrete

times. Here u refers generically to a multiphysics solution, which has multiple components indicated by subscripts $u = (u_1, \dots, u_{N_c})$; the simplest case of $N_c = 2$ components is indicated here.

Initially, we assume for convenience that the Jacobian $J = \partial(F_1, F_2)/\partial(u_1, u_2)$ is diagonally dominant in some sense and that $\partial F_1/\partial u_1$ and $\partial F_2/\partial u_2$ are nonsingular. These assumptions are natural in the case where the system arises from the coupling of two individually well-posed systems that have historically been solved separately. In the equilibrium problem, we refer to F_1 and F_2 as the component *residuals*; in the evolution problem, we refer to f_1 and f_2 as the component *tendencies*.

The choice of solution approach for these coupled systems relies on a number of considerations. From a practical standpoint, existing codes for component solutions often motivate operator splitting as an expeditious route to a first multiphysics simulation, making use of the separate components. This approach, however, may ignore strong couplings between components. Solution approaches ensuring a tight coupling between components require smoothness, or continuity, of the nonlinear, problem-defining functions, F_i , and their derivatives.

Classic multiphysics algorithms preserve the integrity of the two uniphysics problems, namely, solving the first equation for the first unknown, given the second unknown, and solving the second equation for the second unknown, given the first. Multiphysics coupling is taken into account by iteration over the pair of problems, typically in a Gauss-Seidel manner (see algorithm 1), linearly or nonlinearly, according to context. Here we employ superscripts to denote iterates.

Algorithm 1 (Gauss-Seidel multiphysics coupling).

Given initial iterate $\{u_1^0, u_2^0\}$

for $k = 1, 2, \dots$ until convergence **do**

Solve for v in $F_1(v, u_2^{k-1}) = 0$; set $u_1^k = v$

Solve for w in $F_2(u_1^k, w) = 0$; set $u_2^k = w$

end for

Likewise, the simplest approach to the evolutionary problem employs a field-by-field approach in a way that leaves a first-order-in-time splitting error in the solution. Algorithm 2 gives a high-level description of this process that produces solution values at time nodes $t_0 < t_1 < \dots < t_N$. Here, we use the notation $u(t_0), \dots, u(t_N)$ to denote discrete time steps. An alternative that staggers solution values in time is also possible.

Algorithm 2 (multiphysics operator splitting).

```

Given initial values  $\{u_1(t_0), u_2(t_0)\}$ 
for  $n = 1, 2, \dots, N$  do
    Evolve one time step in  $\partial_t u_1 + f_1(u_1, u_2(t_{n-1})) = 0$ 
    to obtain  $u_1(t_n)$ 
    Evolve one time step in  $\partial_t u_2 + f_2(u_1(t_n), u_2) = 0$ 
    to obtain  $u_2(t_n)$ 
end for

```

If the residuals or tendencies and their derivatives are sufficiently smooth and if one is willing to write a small amount of solver code that goes beyond the legacy component codes, a good algorithm for both the equilibrium problem and the implicitly time-discretized evolution problem is the Jacobian-free Newton-Krylov method (see below). Here, the problem is formulated in terms of a single residual that includes all components in the problems,

$$F(\mathbf{u}) \equiv \begin{bmatrix} F_1(u_1, u_2) \\ F_2(u_1, u_2) \end{bmatrix} = 0, \quad (3)$$

where $\mathbf{u} = (u_1, u_2)$. The basic form of NEWTON'S METHOD [II.28] to solve (3), for either equilibrium or transient problems, is given by algorithm 3. Because of the inclusion of the off-diagonal blocks in the Jacobian, for example,

$$J = \begin{bmatrix} \frac{\partial F_1}{\partial u_1} & \frac{\partial F_1}{\partial u_2} \\ \frac{\partial F_2}{\partial u_1} & \frac{\partial F_2}{\partial u_2} \end{bmatrix},$$

Newton's method is regarded as being "tightly coupled."

Algorithm 3 (Newton's method).

```

Given initial iterate  $\mathbf{u}^0$ 
for  $k = 1, 2, \dots$  until convergence do
    Solve  $J(\mathbf{u}^{k-1})\delta\mathbf{u} = -F(\mathbf{u}^{k-1})$ 
    Update  $\mathbf{u}^k = \mathbf{u}^{k-1} + \delta\mathbf{u}$ 
end for

```

The operator and algebraic framework described here is relevant to many divide and conquer strategies in that it does not "care" (except in the critical matter of devising preconditioners and nonlinear component solvers for good convergence) whether the coupled subproblems are from different equations defined over a common domain, the same equations over different subdomains, or different equations over different subdomains. The general approach involves iterative corrections within subspaces of the global problem. All the methods have in common an amenability to exploiting

a "black-box" solver philosophy that amortizes existing software for individual physics components. The differences are primarily in the nesting and ordering of loops and the introduction of certain low-cost auxiliary operations that transcend the subspaces.

Not all multiphysics problems can be easily or reliably cast into these equilibrium or evolution frameworks, which are primarily useful for deterministic problems with smooth operators for linearization. In formulating multiphysics problems, modelers first apply asymptotics to triangularize or even diagonalize the underlying Jacobian as much as possible, pruning provably insignificant dependences but bearing in mind the conservative rule: "coupled until proven uncoupled." One then applies multiscale analyses to simplify further, eliminating stiffness from mechanisms that are dynamically irrelevant to the goals of the simulation.

Perhaps the simplest approach for solving systems of nonlinear equations (3) is the fixed-point iteration, also known as the Picard or nonlinear Richardson iteration. The root-finding problem (3) is reformulated into a fixed-point problem $\mathbf{u} = G(\mathbf{u})$ by defining a fixed-point iteration function, for example,

$$G(\mathbf{u}) := \mathbf{u} - \alpha F(\mathbf{u}),$$

where $\alpha > 0$ is a fixed-point damping parameter that is typically chosen to be less than 1. Fixed-point methods then proceed through the iteration

$$\mathbf{u}^{k+1} = G(\mathbf{u}^k),$$

with the goal that $\|\mathbf{u}^{k+1} - \mathbf{u}^k\| < \varepsilon$. If the iteration function is a contraction, that is, if there exists some $\gamma \in (0, 1)$ such that

$$\|G(\mathbf{u}) - G(\mathbf{v})\| \leq \gamma \|\mathbf{u} - \mathbf{v}\|$$

for all vectors \mathbf{u} and \mathbf{v} in a closed set containing the fixed-point solution \mathbf{u}^* , then the fixed-point iteration is guaranteed to converge. This convergence is typically linear, however, and can be slow even from a good initial guess.

Newton's method (algorithm 3) offers faster convergence, up to quadratic. However, direct computation of $\delta\mathbf{u}$ in algorithm 3 may be expensive for large-scale problems. *Inexact* Newton methods generalize algorithm 3 by allowing computation of $\delta\mathbf{u}$ with an iterative method, requiring only that $\|J(\mathbf{u}^{k-1})\delta\mathbf{u} + F(\mathbf{u}^{k-1})\| < \varepsilon_k$ for some set of tolerances, ε_k . Newton-Krylov methods are variants of inexact Newton methods in which $\delta\mathbf{u}$ is computed with a Krylov subspace method. This choice is advantageous because the only

information required by the Krylov subspace method is a method for computing Jacobian-vector products $J(u^k)v$. A consequence of this reliance on only matrix-vector products is that these directional derivatives may be approximated and the Jacobian matrix $J(u^k)$ is never itself needed. The Jacobian-free Newton-Krylov method exploits this approach, using a finite-difference approximation to these products:

$$J(u^k)v \approx \frac{F(u^k + \sigma v) - F(u^k)}{\sigma},$$

where σ is a carefully chosen differencing parameter and F is sufficiently smooth. This specialization facilitates use of an inexact Newton method by eliminating the need to identify and implement the Jacobian. Of course, the efficiency of the Jacobian-free Newton-Krylov method depends on preconditioning the inner Krylov subspace method, and the changes in the Jacobian as nonlinear iterations progress place a premium on preconditioners with low setup cost. Implementations of inexact Newton methods are available in several high-performance software libraries, including PETSc, which was mentioned above.

Fixed-point and inexact Newton methods can be used to solve multiphysics problems in a fully coupled manner, but they can also be used to implement coupling strategies such as algorithms 1 and 2. With an implicit method for one of the components, one can directly eliminate it in a linear or nonlinear Schur complement formulation. The direct elimination process for u_1 in the first equation of the equilibrium system (1 a), given u_2 , can be symbolically denoted

$$u_1 = G(u_2),$$

with which the second equation (1 b) is well defined in the form

$$F_2(G(u_2), u_2) = 0.$$

Each iteration thereof requires subiterations to solve (in principle to a high tolerance) the first equation. Unless the first system is much smaller or easier than the second, this is not likely to be an efficient algorithm, but it may have robustness advantages.

If the problem is linear,

$$\begin{aligned} F_1(u_1, u_2) &= f_1 - A_{11}u_1 - A_{12}u_2, \\ F_2(u_1, u_2) &= f_2 - A_{21}u_1 - A_{22}u_2, \end{aligned} \quad (4)$$

then $F_2(G(u_2), u_2) = 0$ involves the traditional Schur complement

$$S = A_{22} - A_{21}A_{11}^{-1}A_{12}.$$

If the problem is nonlinear and if Newton's method is used in the outer iteration, the Jacobian

$$\frac{dF_2}{du_2} = \frac{\partial F_2}{\partial u_1} \frac{\partial G}{\partial u_2} + \frac{\partial F_2}{\partial u_2}$$

is, to within a sign, the same Schur complement.

Similar procedures can be defined for the evolution problem, which, when each phase is implicit, becomes a modified root-finding problem on each time step with the Jacobian augmented with an identity or mass matrix.

If the types of nonlinearities in the two components are different, a better method may be the nonlinear Schwarz method or the additive Schwarz preconditioned inexact Newton (ASPIN) method. In nonlinear Schwarz, one solves component subproblems (by Newton or any other means) for componentwise corrections,

$$\begin{aligned} F_1(u_1^{k-1} + \delta u_1, u_2^{k-1}) &= 0, \\ F_2(u_1^{k-1}, u_2^{k-1} + \delta u_2) &= 0, \end{aligned}$$

and uses these legacy componentwise procedures implicitly to define modified residual functions of the two fields:

$$\begin{aligned} G_1(u_1, u_2) &\equiv \delta u_1, \\ G_2(u_1, u_2) &\equiv \delta u_2. \end{aligned}$$

One then solves the modified root-finding problem

$$\begin{aligned} G_1(u_1, u_2) &= 0, \\ G_2(u_1, u_2) &= 0. \end{aligned}$$

If one uses algorithm 3 to solve the modified problem, the Jacobian is

$$\begin{bmatrix} \frac{\partial G_1}{\partial u_1} & \frac{\partial G_1}{\partial u_2} \\ \frac{\partial G_2}{\partial u_1} & \frac{\partial G_2}{\partial u_2} \end{bmatrix} \approx \begin{bmatrix} I & \left(\frac{\partial F_1}{\partial u_1}\right)^{-1} \frac{\partial F_1}{\partial u_2} \\ \left(\frac{\partial F_2}{\partial u_2}\right)^{-1} \frac{\partial F_2}{\partial u_1} & I \end{bmatrix},$$

which clearly shows the impact of the cross-coupling in the off-diagonals. In practice, the outer Newton method must converge in a few steps for ASPIN to be worthwhile, since the inner iterations can be expensive. In nonlinear Schwarz, the partitioning of the global unknowns into u_1 and u_2 need not be along purely physical lines, as it would be if they came from a pair of legacy codes. The global variables can be partitioned into overlapping subsets, and the decomposition can be applied recursively to obtain a large number of small

Newton problems. The key to the convenience of nonlinear Schwarz is that the outer iteration is Jacobian-free and the inner iterations may involve legacy solvers. (This is also true for the Jacobian-free Newton-Krylov method, where the inner preconditioner may involve legacy solvers.)

Error bounds on linear and nonlinear block Gauss-Seidel solutions of coupled multiphysics problems show how the off-diagonal blocks of the Jacobian enter the analysis. Consider the linear case (4) for which the Jacobian of the physics-blocked preconditioned system is

$$\begin{bmatrix} I & A_{11}^{-1}A_{12} \\ A_{22}^{-1}A_{21} & I \end{bmatrix}.$$

Let the product of the coupling blocks be defined by the square matrix $C \equiv A_{11}^{-1}A_{12}A_{22}^{-1}A_{21}$, the norm of which may be bounded as $\|C\| \leq \|A_{11}^{-1}\| \|A_{12}\| \|A_{22}^{-1}\| \|A_{21}\|$. Provided $\|C\| \leq 1$, any linear functional of the solution (u_1, u_2) of (4) solved by the physics-blocked Gauss-Seidel method (algorithm 1) satisfies conveniently computable bounds in terms of residuals of the individual physics blocks of (4). The cost of evaluating the bound involves the action of the inverse uniphysics operators A_{11}^{-1} and A_{22}^{-1} on vectors coming from the uniphysics residuals and the dual vectors defining the linear functionals of interest. The bounds provide confidence that the block Gauss-Seidel method has been iterated enough to produce sufficiently accurate outputs of interest, be they point values, averages, fluxes, or similar. The required actions of the inverse uniphysics operators are a by-product of an implicit method for each phase. The nonlinear case is similar, except that the Jacobian matrices from each physics phase that comprise C may change on each block Gauss-Seidel iteration.

Preconditioning is essential for efficiency whenever a Krylov subspace method is used. While there has been considerable success in developing black-box algebraic strategies for preconditioning linear systems, preconditioners for multiphysics problems generally need to be designed by hand.

A widely used approach is to use a block-diagonal approximation of the Jacobian of the system. Improved performance can generally be achieved by capturing the strong couplings in the preconditioner and leaving the weak couplings to be resolved by the outer Krylov/Newton iterations. Such approaches generally lead to identification of a Schur complement that embodies the important coupling, and their suc-

cess relies on judicious approximation of the Schur complement.

6 Anatomy of a Large-Scale Simulation

We illustrate many issues in computational science by discussing the multiphysics application of turbulent reacting flows. Fittingly, the first ACM-SIAM Prize in Computational Science and Engineering was awarded in 2003 to two scientists at Lawrence Berkeley National Laboratory who addressed this difficult problem by integrating analytical and numerical techniques. Apart from the scientific richness of the combination of fluid turbulence and chemical reaction, turbulent flames are at the heart of the design of equipment such as reciprocating engines, turbines, furnaces, and incinerators for efficiency and minimal environmental impact. Effective properties of turbulent flame dynamics are also required as model inputs in a broad range of larger-scale simulation challenges, including fire spread in buildings or wildfires, stellar dynamics, and chemical processing.

The first step in such simulations is to specify the models for the reacting flows. The essential feature of reacting flows is the set of chemical reactions at a priori unknown locations in the fluid. As well as chemical products, these reactions produce both temperature and pressure changes, which couple to the dynamics of the flow. Thus, an accurate description of the reactions is critical to predicting the shape and properties of the flame. Simultaneously, it is the fluid flow that transports the reacting chemical species to the reaction zone and transports the products of the reaction and the released energy away from the reaction zone. The location and shape of the reaction zone are determined by a delicate balance of species, energy, and momentum fluxes and are highly sensitive to how these fluxes are specified at the boundaries of the computational domain. Turbulence can wrinkle the reaction zone, giving it a much greater area than it would have in its laminar state, without turbulence. Hence, incorrect prediction of turbulence intensity may under- or over-represent the extent of reaction.

From first principles, the reactions of molecules are described by the SCHRÖDINGER EQUATION [III.26] and fluid flow is described by the NAVIER-STOKES EQUATIONS [III.23]. However, each of these equation sets is too difficult to solve directly, so we must rely on approximations. These approximations define the computational models used to describe the flame. For

the combustion of methane, a selected set of eighty-four reactions involves twenty-one chemical species (methane, oxygen, water, carbon dioxide, and many trace products and reaction intermediates). A particularly useful approximation of the compressible Navier-Stokes model allows detailed consideration of the convection, diffusion, and expansion effects that shape the reaction, but it is filtered to remove sound waves, which pose complications that do not measurably affect combustion in the laboratory regime of the flame. The selection of models such as these requires context-specific expert judgment. For instance, in a jet turbine simulation, sound waves might represent a nonnegligible portion of the energy budget of the problem and would need to be modeled. However, in a jet, it might be valid (and very cost-effective) to use a less intricate chemical reaction mechanism to answer the questions concerning flame stability, thrust, noise, and the like. If atmospheric pollution were the main subject of the investigation, on the other hand, an even more detailed chemical model involving more photosensitive trace species might be required. (Development of the chemistry model and validation of the predictions of the simulation make an interesting scientific story, but one that is too long to be told here.)

The computations that led to the first ACM-SIAM Prize in Computational Science and Engineering were performed on an IBM SP supercomputer named “Seaborg” at the National Energy Research Scientific Computing Center, using as many as 2048 processors. At the time, they were among the most demanding combustion simulations ever performed, though they have since been eclipsed in terms of both complexity and computational resources by orders of magnitude. The ability to perform them was not, however, merely (or even mainly) a result of improvements in computer technology. Improvements in algorithm technology were even more instrumental in making the computations feasible. As mentioned above, mathematical analysis was used to reformulate the equations describing the fluid flow so that high-speed acoustic transients were removed analytically while compressibility effects due to chemical reactions were retained. The resulting model of the fluid flow was discretized using high-resolution finite-difference methods, combined with local adaptive mesh refinement by which regions of the finite-difference grid were automatically refined or coarsened in a structured manner to maximize overall computational efficiency. The implementation used an object-oriented, message-passing software

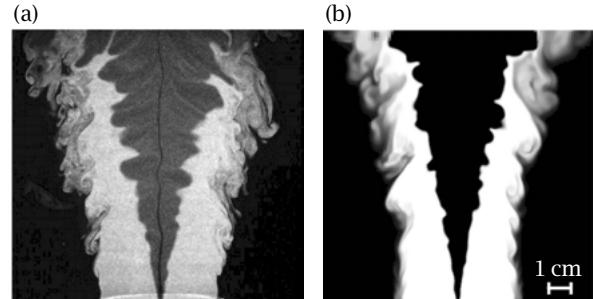

Figure 2 A comparison of (a) the experimental particle image velocimetry crossview of the turbulent V flame and (b) a simulation. Reproduced from “Numerical simulation of a laboratory-scale turbulent V-flame” by J. B. Bell et al. (*Proceedings of the National Academy of Sciences of the USA* 102:10,009 (2005)).

framework that handled the complex data distribution and dynamic load balancing needed to effectively exploit thousandfold parallelism. The data analysis framework used to explore the results of the simulation and create visual images that lead to understanding is based on recent developments in “scripting languages” from computer science. The combination of these algorithmic innovations reduced the computational cost by a factor of 10 000 for the same effective resolution compared with a standard uniform-grid approach. (See figure 2 for a side-by-side comparison of a slotted V-flame experiment and a realization of a three-dimensional time-dependent simulation prepared for the same conditions.)

As the reaction zone shifts, the refinement automatically tracks it, adding and removing resolution dynamically. Unfortunately, the adaptivity and mathematical filtering employed to save memory and reduce the number of operations complicate the software and throw the execution of the code into a regime of computation that processes fewer operations per second and uses thousands of processors less uniformly than a “business as usual” algorithm would. As a result, the scientifically effective simulation runs at a small percentage of the theoretical peak rate of the hardware. In this case, a simplistic efficiency metric like “percentage of theoretical peak” is misleading.

Software of this complexity and versatility could never be assembled in the traditional mode of development whereby individual researchers with separate concerns asynchronously toss software written to *a priori* specifications “over the transom.” Behind any

simulation as complex as this stands a tightly coordinated, vertically integrated multidisciplinary team.

7 The Grand Challenge of Computational Science

Many “grand challenges” of computational science, in simulating complex multiscale multiphysics systems, await the increasing power of high-performance computing and insight and innovation in mathematics. It can be argued that any system that can deterministically and reproducibly simulate another system must be at least as “complex” as the system being simulated. Therefore, the high-performance computational environment itself is the most complex system to model. The grandest challenge of computational science is making this complex simulation system sufficiently manageable to use that scientists who are expert in something else (e.g., combustion, reservoir modeling, magnetically confined fusion) can employ it effectively. In over six decades of computational science, humans have so far bridged the gap between the complexity of the system being modeled and machine complexity, with von Neumann as an exemplar of an individual who made contributions at all levels, from the modeling of the physics to the construction of computer hardware. After all of the components of the chain are delivered, the remaining challenge is the vertical integration of models and technology, leading to a hardware–software instrument that can be manipulated to perform the theoretical experiments of computational science.

Glossary

Computational science (and engineering): the vertically integrated multidisciplinary process of exploring scientific hypotheses using computers.

Computational “X” (where “X” is a particular natural or engineering science, such as physics, chemistry, biology, geophysics, fluid dynamics, structural mechanics, or electromagnetodynamics): a specialized subset of computational science concentrating on models, problems, techniques, and practices particular to problems from “X.”

Scientific computing: an intersection of tools and techniques in the pursuit of different types of computational “X.”

Strong/weak coupling of physical models: strong (respectively, weak) coupling refers to strong (respectively, weak) interactions between different physics

models that are intrinsic in a natural process. Mathematically, the off-diagonal blocks of the Jacobian matrix of a strongly coupled multiphysics model may be full or sparse but contain relatively large entries. In contrast, a weakly coupled multiphysics model contains relatively small off-diagonal entries.

Tight/loose coupling of numerical models: tight (respectively, loose) coupling refers to a high (respectively, low) degree of synchronization of the state variables across different physical models. A tightly coupled scheme (sometimes referred to as a strongly coupled scheme) keeps all the state variables as synchronized as possible across different models at all times, whereas a loosely coupled scheme might allow the state variables to be shifted by one time step or be staggered by a fraction of the time step.

IV.17 Data Mining and Analysis

Chandrika Kamath

1 The Need for Data Analysis

Technological advances are enabling us to acquire ever-increasing amounts of data. The amount of data, now routinely measured in petabytes, is matched only by its complexity, with the data available in the form of images, sequences of images, multivariate time series, unstructured text documents, graphs, sensor streams, and mesh data, sometimes all in the context of a single problem. Mathematical techniques from the fields of machine learning, optimization, pattern recognition, and statistics play an important role as we analyze

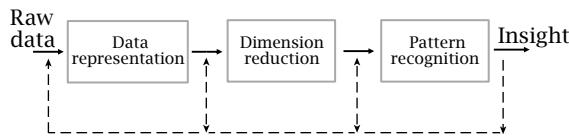

Figure 1 A schematic showing the overall process of data analysis.

these data to gain insight and exploit the information present in them.

The types of analysis that can be done are often as varied as the data themselves. One of the best-known examples occurs in the task of searching, or information retrieval, where we want to identify documents containing a given phrase, retrieve images similar to a query image, or find the answer to a question from a repository of facts. In other analysis tasks, the focus is prediction, where, given historical data that relate input variables to output variables, we want to determine the outputs that result from a given set of inputs. For example, given examples of malignant and benign tumors in medical images, we may want to build a model that will identify the type of tumor in an image. Or we could analyze credit card transactions to build models that identify fraudulent use of a card. In other problems the focus is on building descriptive models. For example, we want to group chemicals with similar behavior to understand what might cause that behavior, or we may cluster users who like similar movies so we can recommend other movies to them.

Data mining is the semiautomatic process of discovering associations, anomalies, patterns, and statistically significant structures in data. At the risk of oversimplification, we can consider data mining, or data analysis, to have three phases, as shown in figure 1: the representation of the data, dimension reduction, and the identification of patterns.

First, the raw data are processed to bring them into a form more suitable for analysis. This is especially true when the data are in the form of images, text documents, or other formats that require us to identify the objects in the raw data and find appropriate representations for them. A common way of representing data is in the form of a table (see table 1) in which each row represents a data item (which could be a document, an image, a galaxy, or a chemical compound) and in which the columns are the features, or descriptors, that characterize the data item. These features are chosen to reflect the analysis task and could include the frequency of different words in a document, the tex-

Table 1 Table data, with each data item I_i characterized by d features, and potentially an output O_i .

	f_1	f_2	\cdots	f_d	O
I_1	f_{11}	f_{12}	\cdots	f_{1d}	O_1
I_2	f_{21}	f_{22}	\cdots	f_{2d}	O_2
\vdots	\cdots	\cdots	\cdots	\cdots	\cdots
I_n	f_{n1}	f_{n2}	\cdots	f_{nd}	O_n

ture of an image, the shape of the objects in an image, or the properties of the atomic species that constitute a chemical compound. Sometimes a data item may be associated with an output variable, which could be discrete (e.g., indicating if a transaction is valid or fraudulent) or continuous (such as the formation enthalpy of a chemical compound). This table, viewed as a matrix, could be sparse if not all features are available for a given data item, for example, words that do not occur in a document.

Each data item in the table can be considered as a point in a space spanned by the features; if the number of features is high, that is, the point is in a high-dimensional space, it can make the analysis challenging. This requires dimension reduction techniques to identify the key features in the data.

The final step of pattern recognition is often seen as the focus of analysis. However, its success is strongly dependent on how well the previous steps have been performed. Not identifying the data items correctly or representing them using inappropriate features can result in inaccurate insights into the data.

The process of data analysis is iterative: the representation of the data is refined and the dimension reduction and pattern recognition steps repeated until the desired accuracy is obtained. Data analysis is also interactive, with the domain experts providing input at each step to ensure the relevance of the process to the problem being addressed. Depending on the type of data being analyzed and the problem being addressed, these three phases of data representation, dimension reduction, and pattern recognition can be implemented using a host of mathematical techniques. In the remainder of this article we review some of these techniques, identify their relationship with methods in other domains, and discuss future trends.

2 History

Data analysis has a long history. We could say that it started with the ancient civilizations, which, observing the motions of celestial objects, identified patterns that

led to the laws of celestial mechanics. Some of the early ideas in statistics arose when governments collected demographic and economic data to help them manage their populations better, while probability played an important role in the study of games of chance and the analysis of random phenomena. The field of statistics, as we know it today, goes back at least a couple of hundred years. By modern standards, the data sets being analyzed then were tiny, composed of a few hundred numbers. However, given that this analysis was done before the advent of computers, it was a remarkable achievement. The field has evolved considerably since then, prompted by new sources of data, a broader range of questions being addressed through the analysis, and different fields contributing different insights into the data.

The recent surge in both the size and the complexity of data started in the 1970s as technology enabled us to generate, store, and process vast amounts of data. Sensors provided some of the richest sources of data, ranging from those used in medicine, such as POSITRON EMISSION TOMOGRAPHY [VII.9] (PET) and MAGNETIC RESONANCE IMAGING [VII.10 §4.1] (MRI) scanning, to sensors monitoring equipment, such as cars and scientific experiments, and sensors observing the world around us through telescopes and satellites. Computers not only enabled the analysis of these data, they contributed to this data deluge as well. Numerical simulations are increasingly being used to model complex phenomena in problems where experiments are infeasible or expensive. The resulting spatiotemporal data, often in the form of variables at grid points, are analyzed to gain insight into the phenomena. The Internet, connecting computers worldwide, is one of the newest sources of data, providing insight into how the world is connected. These data are generated by sensors that observe network traffic, by web services that monitor the online browsing patterns of users, and by the network itself, which changes dynamically as connections are made or broken.

The tasks in data analysis have also evolved to handle the new types of data, the new questions being asked of the data, and the new ways in which users interact with the data. For example, network data, images, mesh data from simulations, and text documents are not in a form that can be directly used for pattern identification; they all have to be converted to an appropriate representation first. The high dimensionality of many data sets has led to the development of dimension reduction techniques, which shed light on the important features

of the objects in a data set. The desire to improve the accuracy of predictions by analyzing many different modalities of data simultaneously has led to data fusion techniques. More recently, a recognition that the analysis of the data should be closely coupled with their generation has resulted in the reemergence of ideas from the field of design of experiments. Further, as data analysis gains acceptance and the results are used in making decisions, techniques to address missing and uncertain features have become important, and tools to reason under uncertainty are playing a greater role, especially when the risks and rewards associated with the decisions can be so high.

Along with these new sources of data and the novel questions that are being asked of the data, different fields have started to contribute to the broad area of data analysis. In addition to statistics, advances in the field of pattern recognition have focused on patterns in signals and images, while work in artificial intelligence and machine learning have tried to mimic human reasoning, and developments in rule-based systems have been used to extract meaningful rules from data. The more recent field of data mining was originally motivated by the need to make better use of databases, though it too is evolving into specialized topics such as web mining, scientific data mining, text mining, and graph mining. Domain scientists have also contributed their ideas for analyzing data. As a result, data analysis is replete with examples where the same algorithm is known by different names in different domains, and a technique proposed in one domain is found to be a special case of a technique from a different domain. The process of inference from data has benefited immensely from the contributions of these different fields, with each providing its own perspective on the data and, in the process, making data analysis a field rich in the diversity of mathematical techniques employed.

3 Data Representation

Many pattern recognition algorithms require the data to be in a tabular form, as shown in table 1. However, this is rarely the form in which the data are given to a data analyst, especially when the raw data are available as images, time series, documents, or network data. Converting the data into a representation suitable for analysis is a crucial first step in any analysis endeavor. However, this task is difficult as the representation is very dependent on the problem, the type of

data, and the quality of the data. Domain- and problem-dependent methods are often used, and the representation is iteratively refined until the analysis results are acceptable.

Consider the problem of improving the quality of images, which are often corrupted by noise, making it difficult to identify the objects in the data. A simple solution is to apply a *mean filter*. In the case of a 3×3 filter, this would imply convolving an image with

$$\frac{1}{9} \begin{pmatrix} 1 & 1 & 1 \\ 1 & 1 & 1 \\ 1 & 1 & 1 \end{pmatrix},$$

thus replacing each image pixel by the weighted average of the pixel and its eight neighbors. While a mean filter assigns equal weight to all pixels within its support, a two-dimensional *Gaussian filter* with standard deviation σ_d ,

$$w_d(p_i, p_j) = \frac{1}{2\pi\sigma_d^2} \exp\left(-\frac{\|p_i - p_j\|^2}{2\sigma_d^2}\right),$$

assigns a lower weight when the pixel p_j is farther from the pixel p_i . A more recent development, the *bilateral filter*, applies this idea in both the domain and the range of the neighborhood around each pixel. Each weight in the filter is the normalized product of the corresponding weights w_d and w_r :

$$w_r(p_i, p_j) = \frac{1}{2\pi\sigma_r^2} \exp\left(-\frac{\delta(I(p_i) - I(p_j))^2}{2\sigma_r^2}\right),$$

where σ_r is the standard deviation of the range filter and $\delta(I(p_i) - I(p_j))$ is a measure of the distance between the intensities at pixels p_i and p_j . When the intensity difference is high—near an edge of an object, for example—less smoothing is done, making it easier to identify the edge in the next step of the analysis.

In 1987 Perona and Malik noted that convolving an image with the Gaussian filter is equivalent to solving the diffusion equation

$$\frac{\partial}{\partial t} I(x, y, t) = \frac{\partial^2}{\partial x^2} I(x, y, t) + \frac{\partial^2}{\partial y^2} I(x, y, t),$$

where $I(x, y, t)$ is the two-dimensional image $I(x, y)$ at time $t = 0.5\sigma_d^2$ and $I(x, y, 0)$ is the original image. This allowed the adoption of ideas from partial differential equations (PDEs) to address the ill-posedness of the original formulation and to enhance de-noising by making suitable choices for the coefficients of the PDEs in order to restrict smoothing near the edges of objects in an image.

There has been similar evolution in the realm of segmentation techniques for identifying objects in images.

Starting with the idea that there is a sharp gradient in the intensity at the boundary of an object, we can use a simple filter, such as the Sobel operators in the x - and y -dimensions,

$$L_x = \begin{pmatrix} -1 & 0 & 1 \\ -2 & 0 & 2 \\ -1 & 0 & 1 \end{pmatrix}, \quad L_y = \begin{pmatrix} 1 & 2 & 1 \\ 0 & 0 & 0 \\ -1 & -2 & -1 \end{pmatrix},$$

to obtain the magnitude and orientation of the gradient. This basic idea is used in the *Canny edge detector*, which, despite its simplicity, performs quite well. It starts by smoothing the image using a Gaussian filter and then applies the Sobel operators. The edges found are thinned to a single pixel by suppressing values that are not maximal in the gradient direction. Finally, a two-parameter hysteresis thresholding retains both strong edge pixels and moderate-intensity edge pixels that are connected to the strong edge pixels. This results in a robust and well-localized detection of edges. However, in regions of low contrast, the gradient detectors may fail to identify any edge pixels, leading to edges that are not closed contours. To address this drawback, we need to use techniques such as snakes and implicit active contours, which again blend ideas from image processing and PDEs. In turn, this allows us to identify objects in mesh data from simulations by using the PDE version of a segmentation algorithm.

Other segmentation techniques, referred to as *region-growing methods*, identify objects in images by exploiting the fact that the pixels in the interior of an object are similar to each other. Starting with the highest intensity pixel, a similarity metric is used to grow a region around it. The process is repeated with the highest intensity pixel among the remaining ones, until all pixels are assigned to a region. Cleanup is often required to merge similar regions that are adjacent to each other or to remove very small regions. This idea of grouping data items based on their similarity is referred to as clustering and is described further in section 5.3. These clustering techniques can be applied to images and mesh data by defining a similarity metric that takes into account both the spatial locations of and the values at the pixels or mesh points.

Once we have identified objects in images, or sequences of images, we can represent them using features such as shape, texture, size, and various moments. There are different ways in which many of these features can be defined. For example, for objects in images, the shape feature can be represented as a linear combination of two-dimensional basis functions

such as shapelets or the angular radial transform described in the MPEG-7 multimedia standard. The coefficients of the linear combination would be the features representing the object. Alternatively, we can focus on the boundary of an object and define the shape features as the coefficients of a Fourier series expansion of the curve that describes the boundary.

The features used to represent the objects in the data are very dependent on the problem and the type of data. It is often challenging to identify and extract features for some types of data, such as images or mesh data. Not only must the features characterize the objects in these data, they must also be invariant to rotation, translation, and scaling, as the patterns in the objects are often invariant to such transformations of the data. Further, if we are analyzing many images of varying quality, each with a variety of objects, it can be difficult to find a single set of algorithms, with a single set of parameters, that can be used to extract the objects and their features.

In contrast, the task of feature extraction is relatively easy for other types of data. For example, in documents it is clear that the features are related to the words or terms in the collection of documents being analyzed. As discussed in TEXT MINING [VII.24], a document can be represented using the term frequency of each term in the document, suitably weighted to reflect its importance in the document or collection of documents. However, representing documents is not without its own challenges, such as the need for word-sense disambiguation for words with multiple meanings, the representation of tables or diagrams in documents, and analysis across documents in different languages.

4 Dimension Reduction

The number of features used to represent the data items in a data set can vary widely, ranging from a handful to thousands. These features can be numeric or categorical. Often, not all the features are relevant to the task at hand, or some features may be correlated, resulting in a duplication of information. Since extracting and storing features can be expensive, and irrelevant features can adversely affect the accuracy of any models built from the data, it is often useful to identify the important features in a data set. This task of dimension reduction maps a data item described in the high-dimensional feature space into a lower-dimensional feature space.

There are two broad categories of dimension reduction methods. In the first category, the features are

transformed, linearly or nonlinearly, into a lower-dimensional space. A popular method for linear transformation is *principal component analysis* (PCA), which has been rediscovered in many domains, ranging from fluid dynamics, climate, signal processing, and linear algebra to text mining, with each contributing different insights into what such techniques reveal about the data. PCA is an orthogonal transform that converts the data into a set of uncorrelated variables called the principal components. The first principal component captures the largest variability in the data; each of the remaining principal components has the highest variance subject to the constraint that it is orthogonal to all the previous principal components. PCA can be calculated by an eigendecomposition of the data covariance or correlation matrix or by the application of the SINGULAR VALUE DECOMPOSITION [II.32] to the data matrix. Usually, the data are first centered by subtracting the mean.

A challenging issue in the practical application of transform-based methods is the selection of the dimension of the lower-dimensional space. Often, a decision on the number of principal components to keep is made using a threshold on the percentage variance explained by the principal components that are retained. This essentially implies that the components that are discarded are considered as noise in the data. Thus, PCA can also be used to reduce the noise in data.

The second category of dimension reduction techniques selects a subset of the original features. These *feature selection techniques* are applicable to prediction tasks, such as classification and regression, where each data item is also associated with an output variable. By identifying important features, such techniques enable us to make judicious use of limited resources available for measuring the features. They can also be invaluable in problems where focusing on just the important variables makes it easier to gain insight into a complex phenomenon.

There are two types of feature selection algorithms: filters, which are not coupled to the prediction task, and wrappers, which are coupled to the prediction task.

As an example of a *filter method*, consider a simple problem where we have data items of two categories, or classes, and we need to find the features that are most useful in discriminating between these classes. For each feature we can build a histogram of the values that the feature takes for each of the two classes. A large distance between the histograms for the two

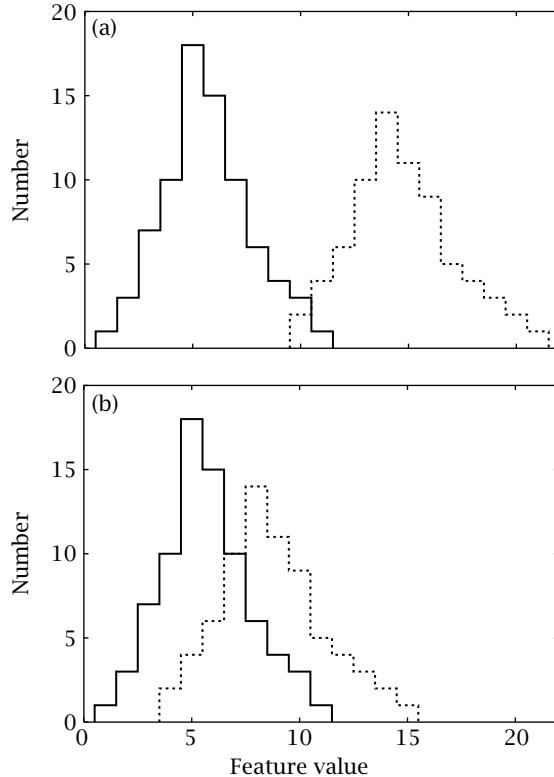

Figure 2 The feature in (a) (with a larger distance between the histograms of feature values for two different classes (solid and dotted lines)) is considered more important than the feature in (b). The large overlap in (b) indicates that there is a larger range of values of the feature for which an object could belong to either of the two classes, making the feature less discriminating.

classes indicates that the feature is likely to be important, but if the histograms overlap, then the feature is unlikely to be helpful in differentiating between the classes (figure 2). The features can be ordered based on the distances between the histograms and the reduced dimension can be determined by placing an appropriate threshold on the distance. Any suitable measure for distances between histograms can be used. For example, we can first convert the histogram for each class into a probability distribution by normalizing it so that the area under the curve is 1. Then, we can either use the Kullback–Leibler divergence

$$d_{\text{KL}}(P, Q) = \sum_{i=1}^b P_i \ln \left(\frac{P_i}{Q_i} \right)$$

as a measure of the difference between two distributions P and Q defined over b bins, or we can create a

symmetric version

$$d(P, Q) = d_{\text{KL}}(P, Q) + d_{\text{KL}}(Q, P),$$

which, unlike the Kullback–Leibler divergence, is a distance metric, as $d(P, Q) = d(Q, P)$. Other distances can also be used, such as the Wasserstein metric, or, as it is referred to in computer science, the earth mover's distance. This intuitively named metric considers the two distributions as two ways of piling dirt on a region, with the distance being defined as the minimum cost of turning one pile into the other. The cost is the amount of dirt moved times the distance over which it is moved.

The *wrapper approach* to feature selection evaluates each subset of features based on the accuracy of prediction using that subset. Suppose we use a decision tree classifier (section 5.2) to build a predictive model for the two-class problem. The forward selection wrapper method starts by selecting the single feature that gives the highest accuracy with the decision tree. It then chooses the next feature to add such that the subset of two features has the highest accuracy. Additional features are included to create larger subsets until the addition of any new feature does not result in an improvement in prediction accuracy. A backward selection approach starts with all the features and progressively removes features. The wrapper approach is more computationally expensive than the filter approach as it involves evaluating the accuracy of a classifier. However, it may identify subsets that are more appropriate when used in conjunction with a specific classifier.

5 Pattern Recognition

In pattern recognition tasks, we use the features that describe each data item to identify patterns among the data items. For example, if we process astronomical images to identify the galaxies in them and extract suitable features for each galaxy, we are then able to use the features in several different ways, as discussed next.

5.1 Information Retrieval

In *information retrieval*, given a query data item, described by its set of features, the task is to retrieve other items that are similar in some sense to the query. Usually, the retrieved items are returned in an order based on the similarity to the query. The similarity metric chosen depends on the problem and the representation of the data item. While Euclidean distance between feature vectors is a common metric, the cosine of the angle between the two vectors is used for document

similarity, and more complex distances could be used if the data items are represented as graphs.

Data sets used in information retrieval are often massive, and a brute-force search by comparing each item with the query item is expensive and will not result in the real-time turnaround often required in such analysis. Ideas from computer science, especially the use of sophisticated data structures that allow for fast nearest-neighbor searches, provide solutions to this problem. As these data structures perform better than a brute-force search only when the data items have a limited number of features, dimension reduction techniques are often applied to the data before storing them in these efficient data structures.

5.2 Classification and Regression

In some pattern recognition tasks we are given examples of patterns, referred to as a training set, and the goal is to identify the pattern associated with a new data item. This is done by using the training set to create a predictive model that is then used to assign the pattern to the new data item. The items in the training set all have an output variable associated with them. If this variable is discrete, the problem is one of *classification*; if it is continuous, the problem is one of *regression*, where, instead of predicting a pattern, we need to predict the value of the continuous variable for the new data item.

Techniques for regression and classification tend to be quite similar. The simplest such technique is the *nearest-neighbor method*, where, given the data item to which we need to assign an output, we identify the nearest neighbors to this item in the feature space and use the outputs of these neighbors to calculate the output for the query. In classification problems we can use the majority class, while in regression problems we can use a weighted average of the outputs of the neighbors. The neighbors are usually identified either by specifying a fixed number of neighbors k , which leads to the k -nearest-neighbor method, or by specifying the neighbors within a radius ϵ , which leads to the ϵ -nearest-neighbor method. While nearest-neighbor techniques are intuitively appealing, it is a challenge to set a value for k or ϵ , and the techniques may not work well if the query data item does not have neighbors in close proximity.

More complex predictive models can be built from a training set using other classification algorithms. *Decision trees* divide the data set into regions using hyperplanes parallel to the axis, such that each region has

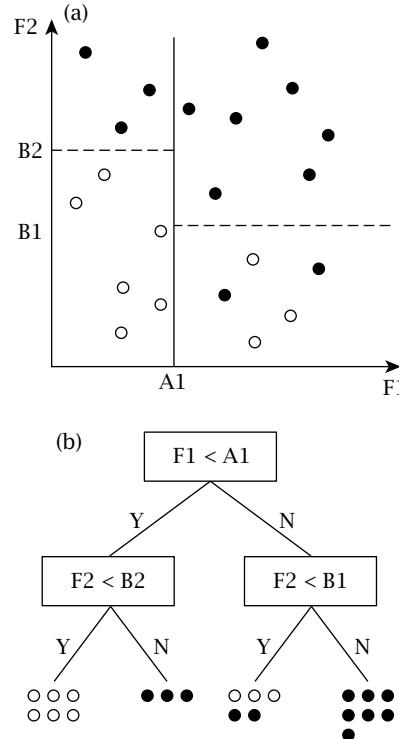

Figure 3 A schematic of a decision tree for a data set with two features: (a) the decision boundaries between open and closed circles; (b) the corresponding decision tree.

data items with the same output value (or similar ones). The tree is a data structure that is either a leaf, which indicates the output, or a decision node that specifies some test to be carried out on a feature, with a branch and subtree for each possible outcome of the test. For example, in figure 3 the open and closed circles are separated by first making the decision $F1 < A1$; data items that satisfy this constraint are next split using $F2 < B2$, while data items that do not satisfy the constraint are split using $F2 < B1$. Then, given a data item with certain values of features ($F1, F2$), we can follow its path down the decision tree and assign it the majority class of the leaf node at which the path ends.

A key task in building a decision tree is the choice of decision at each node of the tree. This is obtained by considering each feature in turn, sorting the values of the feature, and evaluating a quality metric at the midpoints between consecutive values of the feature. This metric is an indication of the suitability of a split using that feature and midpoint value. The feature-midpoint value combination that optimizes the quality

metric across all features is chosen as the decision at the node. For example, in a two-class problem, a split that divides the data items at the node into two groups, each of which has a majority of items of one class, is preferable to a split where each of the two groups has an equal mix of the two classes. A commonly used metric is the Gini index, which finds the split that most reduces the node impurity, where the impurity for a c -class problem with n data items is defined as follows:

$$L_{\text{Gini}} = 1.0 - \sum_{i=1}^c \left(\frac{|L_i|}{|T_L|} \right)^2,$$

$$R_{\text{Gini}} = 1.0 - \sum_{i=1}^c \left(\frac{|R_i|}{|T_R|} \right)^2,$$

$$\text{Impurity} = (|T_L|L_{\text{Gini}} + |T_R|R_{\text{Gini}})/n,$$

where $|T_L|$ and $|T_R|$ are the number of data items, $|L_i|$ and $|R_i|$ are the number of data items of class i , and L_{Gini} and R_{Gini} are the Gini indices on the left- and right-hand side of the split, respectively.

This simple idea of dividing the data items in feature space using decisions parallel to the axes appeared at nearly the same time in the literature relating to both machine learning and statistics, where it was referred to as the decision tree method and the classification tree method, respectively. Both communities have contributed to the advancement of the method. Ideas from machine learning have been used to create more complex decision boundaries by considering a linear combination of the features in the decision at each node. The process of making the decisions at each node of the tree has been related to probabilistic techniques, providing insight into the behavior of decision trees and indicating ways in which they can be improved. In particular, a statistical approach to decision tree modeling takes advantage of the trade-off between bias, which arises when the classifier underfits the data and cannot represent the true function being predicted, and variance, which arises when the classifier overfits the data.

Decision trees are not only simple to create and apply, they are also easy to interpret, providing useful insight into how a pattern is assigned to a data item. Further, the process used in making the decision at each node of the tree indicates which features are important in the data set. This makes the decision tree method a popular first choice for use in classification and regression problems.

Other, more complex, algorithms in common use are neural networks and support vector machines. The simplest *neural network*, called a perceptron, takes a

weighted combination of the input features and outputs a 1 if the combination is greater than a threshold and 0 otherwise, thus acting as a two-class classifier. The task is to use the training set to learn the weights, an adaptive process that starts with random weights, applies the classifier, and modifies the weights whenever the classification is in error. When the two classes are not linearly separable, that is, they cannot be separated using a single line, we need to find the weights using OPTIMIZATION TECHNIQUES [IV.11] such as the gradient descent, conjugate gradient, quasi-Newton, or Levenberg–Marquardt methods.

More complex neural networks include multiple layers (in addition to the first layer, which represents the features) and, instead of a simple thresholding, use a continuously differentiable sigmoid function. This allows neural networks to model complex functions to differentiate among classes. However, they can be difficult to interpret, and designing the architecture of the network—which includes the number of layers, the number of nodes in a layer, and the connectivity among the nodes—can be a challenge.

Another classification algorithm that uses optimization techniques is the *support vector machine*. This uses a nonlinear function to map the input into a higher-dimensional space in which the data are linearly separable. There are many hyperplanes that linearly separate the data. The optimal one, as indicated by statistical learning theory, is the maximum margin solution, where the margin is the distance between the hyperplane and the closest example of each class. These examples are referred to as the support vectors. This solution is obtained by solving a QUADRATIC PROGRAMMING PROBLEM [IV.11] subject to a set of linear inequality constraints. Support vector machines provide some insight into the process of classification through the identification of the support vectors, though it is a challenge to find the nonlinear transformation that linearly separates the data.

A probabilistic approach to inference is provided by Bayesian reasoning, which assumes that quantities of interest are governed by probability distributions. This enables us to make decisions by reasoning about these probabilities in the presence of observed data. *Bayes's theorem*,

$$P(h | D) = P(D | h)P(h)/P(D),$$

is a way of calculating the posterior probability $P(h | D)$, or the probability of hypothesis h given data D , from the prior probability of the hypothesis before we

have seen the data, $P(h)$; the probability $P(D \mid h)$ of seeing the data D in a world where the hypothesis h holds; and the prior probability $p(D)$ of seeing the data D without any knowledge of which hypothesis holds. Bayes's theorem is essentially derived from the two different ways of representing the probability of observing both h and D together by writing it conditional either on D or h .

Given the probabilistic insight provided by Bayes's theorem, it is invaluable in tasks requiring reasoning under uncertainty. The theorem also plays a role in the *naive Bayes classifier*. The new data item is assigned the most probable output value given the values of its features. This most probable output value is obtained by applying Bayes's theorem using probabilities derived from the training data, combined with the added simplifying assumption that the feature values are conditionally independent, given the output.

A recent development in classification techniques is that of *ensemble learning*, where more than one classifier is created from the training data. This is done by introducing randomization into the process, by creating new training sets using sampling with replacement from the original training set, for example, or by selecting a random subset of features or samples to use in making the decision at each node. The class label assigned to a new data item is obtained by using a voting scheme on the labels assigned by each classifier in the ensemble. While ensembles are computationally more expensive as multiple classifiers have to be created, the ensemble prediction is often more accurate.

5.3 Clustering

Clustering is a descriptive technique used when the data items are not associated with an output value. It can be seen as complementary to classification. Instead of using the output value to identify boundaries between items of different classes near each other in feature space, we use the features to identify groups of items in feature space that are similar to, or close to, each other (figure 4). Intuitively, if the features are chosen carefully, two data items with similar features are likely to be similar. Thus, if we know that some chemical compounds, with desirable properties, occur in a certain part of an appropriately defined feature space, other compounds near them might also have the same property. Or, if a customer is interested in a specific movie or book, others that are nearby in feature space could be recommended to them.

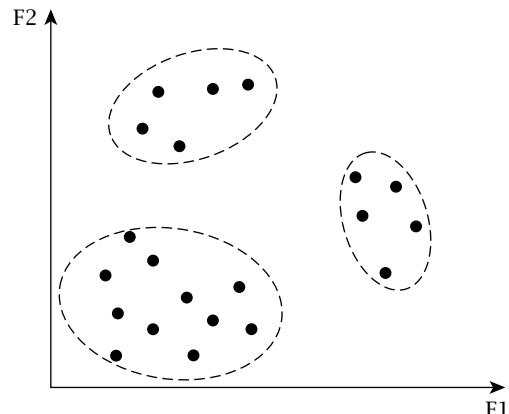

Figure 4 A schematic showing three clusters in a two-dimensional data set.

Clustering techniques broadly fall into one of two categories. In *hierarchical methods* we have two options: start from the bottom, with each item belonging to a singleton cluster, and merge the clusters, two at a time, based on a similarity metric; or start at the top, with all items forming a single cluster, and split that into two, followed by a split of each of the two clusters, and so on. In both methods, we need to determine how many clusters to select in the hierarchy.

In contrast, *partitional methods* start with a predetermined number of clusters and divide the data items into these clusters such that the items within a cluster are more similar to each other than they are to the items in other clusters. The best-known partitional algorithm is the *k-means algorithm*, which divides the data items into k clusters by first randomly selecting k cluster centers. It then assigns each data item to the nearest cluster center. The items in each cluster are then used to update the cluster centers and the process continues until convergence. The *k*-means algorithm is very popular and, despite its simplicity, works well in practice. The main challenge is to determine the number of clusters; this can be done by evaluating a clustering criterion such as the sum of squared errors of each data item from its cluster center and then selecting the k that minimizes this error.

The *k*-means algorithm is related to algorithms in other domains; examples include Voronoi diagrams from computational geometry, the expectation–maximization algorithm from statistics, and vector quantization in signal processing.

There is a third category of clustering algorithms that shares properties of both hierarchical and partitional

methods. These *graph-based algorithms* are related to the reordering methods used in direct solvers and the domain decomposition techniques used in PDEs. Essentially, they represent the data items as nodes in a graph, with the edges weighted according to the similarity between the data items. Clustering is then done either by using graph partitioning algorithms, where clusters are identified by minimizing the weights of the edges that are cut by the partitioning, or by using spectral graph theory and calculating the second eigenvector of the GRAPH LAPLACIAN [V.12 §5]. The nodes of the graph are split into two using the eigenvector components, and the process is then repeated on the two parts.

6 The Future

As data-mining algorithms have gained a foothold in application domains such as astronomy and remote sensing, other domains such as medical imaging, with similar types of data and problems, have started considering data mining as a potential solution to their analysis problems. These new domains have in turn introduced new challenges to the analysis process and posed new questions, prompting the development of new algorithms. And then, when these algorithms are adopted by other communities, the cycle is continued.

There are several key developments from the last decade that will drive the future of data mining and analysis. These developments have been motivated both by the types of data being analyzed and by the requirements of the analysis.

There has been an explosion in the types of data being analyzed. While raw data in a tabular form is still the norm in some problem domains, other types of data—ranging from images and sequences of images to text documents, web pages, links between web pages, chemical compounds, deoxyribonucleic acid (DNA) sequences, mesh data from simulations, and graphs representing social networks—have prompted a new look at algorithms for finding accurate and appropriate representations of such data. This has also prompted greater interest in data fusion, where we analyze multiple modalities of data. For example, we may consider PET scans and MRI scans, as well as clinical data, to treat a patient. Or we may consider not just the links between web pages but also the text, figures, and images on those pages.

Adding to this complexity is the distributed nature of some of the data sets. For example, the use of sensor networks is becoming common in the surveillance

and monitoring of experiments and complex systems. The networks may be autonomous and may reorganize, changing their positions in response to changes in their environment. In some problems, such as when monitoring climate, the sensors may be stationary but geographically scattered over the Earth. In all these cases, the data set to be analyzed is in several pieces that may not be collocated and the size of the data may make it difficult to collocate all the pieces in one place. There is a need for algorithms that analyze distributed data and build a model, or models, to represent the whole data set. In autonomous sensor networks there is an additional requirement that the amount of information exchanged between sensors be small, implying that it is the models and not the data that are exchanged. Such ideas are also relevant in telemedicine, as well as space exploration, where the distances and limited connectivity imply caution in determining what data and information are transferred.

This brings up the need for effective compression techniques: both lossy, for problems which can tolerate the loss of some information, and lossless, where it is important that the data be preserved in their original state. Compression will also play a role as we move to exascale computation, where it is becoming clear that the amount of data generated by simulations run on massively parallel machines will outpace the technology of the input-output system.

The ever-increasing volume of data will increase the need for algorithms that exploit parallel computers; otherwise we run the risk of the data not being analyzed at all. In addition, such algorithms will be invaluable in problems where a real-time or near-real-time response is required.

This short response time is required in the analysis of streaming data, where we analyze data as they are collected to identify untoward incidents, interesting events, or concept drift, where the statistical properties of the data change from one normal state to another. This is prompting the development of new algorithms that yield approximate results, as well as the creation of incremental versions of existing algorithms, where the models being built are constantly being updated to incorporate new data and discard old data. A particular challenge in such analysis is the need to minimize false positives while ensuring that we do not miss any positives, especially in problems where the analysis is used in decision support.

As data analysis comes to be viewed as one step in a closed system in which the data are analyzed and

decisions are made based on the analysis, without a human in the loop, there is an increasing need to understand the uncertainty in the analysis results. Uncertainty can arise as a result of several factors, including the quality of the raw data, the suitability of the chosen analysis algorithms for the data being studied, the sensitivity of the results to the parameters used in the algorithms, a lack of complete understanding of the process or system being analyzed, and so on. Thus, ideas from uncertainty quantification and reasoning under uncertainty become important, especially when the risks associated with the decisions are high.

This brings up the interesting issue of using data analysis techniques to influence the data we collect so that they better meet our needs. So far we have viewed data analysis as a process that starts once the data have been collected, but sometimes we have control over what data to generate, such as which data items to label to create a training set or which input parameters to use for an experiment or a simulation. We can borrow ideas from the field of design of experiments, both physical and computational, to closely couple the generation of the data with their analysis, hopefully improving the quality of that analysis.

This borrowing of ideas from other domains will continue to increase as data analysis evolves to meet new demands. We have already seen how ideas from the traditional data analysis disciplines such as statistics, pattern recognition, and machine learning are being combined with ideas from fields such as image and video processing, mathematical optimization, natural language processing, linear algebra, and PDEs to address challenging problems in data analysis. This cycle involving the development of novel algorithms followed by their application to different problem domains, which in turn generates new analysis requirements, will continue, ensuring that data mining and analysis remain very exciting areas for the foreseeable future. Applied mathematics will remain a cornerstone of the field, not just by contributing to the extraction of insight into the data but also by playing a critical role in convincing the application experts that the insight obtained is based on sound mathematical principles.

IV.18 Network Analysis

Esteban Moro

1 Introduction

Almost 300 years ago Euler posed the problem of finding a walk through the seven bridges of Königsberg and laid the foundations of graph theory. Euler's approach was probably one of the first examples of how to use network analysis to solve a real-world problem. Since then, network analysis has been used in many contexts, from biology to economics and the social sciences. The general approach is to map the constituent units of the system and its interdependencies onto a network and analyze that network in order to understand and predict a given process. For example, buyers and items form a network of purchases that is used in recommendation engines; protein–protein interaction networks are used to unveil functionally coherent families of proteins; social relationships might reveal potential adoption of products and services by social contagion.

The analysis of networks is an old subject in mathematics, and it has its roots in many other disciplines, such as engineering, the social sciences, and computer science. However, in recent times the digital revolution has brought with it easier access to detailed information about phenomena such as biological reactions, economic transactions, social interactions, and human movements. This has allowed us to study networks with an unprecedented level of detail. While this data revolution has produced an enormous boost in the models and applications of network theory, reaching unusual areas such as politics, crime, cooking, and so on, it has also challenged the available analytical methods because of the large size of real networks, which are typically made up of millions or even billions of nodes.

As a consequence, network analysis is a rapidly changing field that attracts many researchers from diverse disciplines. This article discusses the mathematical concepts behind network analysis and also some of the main applications to real-world problems.

2 Definitions

The main mathematical object in network analysis is the network itself. A network (or a graph) is a pair $G = (V, E)$ of a set V of vertices (nodes) together with a set $E \subseteq V \times V$ of edges (links). The numbers of nodes and edges are denoted by $n = |V|$ and $m = |E|$. Any edge is a relation between two vertices of V . Mathematically, a network can be represented by the *adjacency matrix* A , where a_{ij} has the value 1 if there is an edge between vertices i and j and 0 otherwise (see plate 5). If the edge is undirected then $a_{ij} = a_{ji}$, while if the direction of the edge matters then the network is directed and A is in general nonsymmetric. Another variant is a *weighted network*, in which the nonzero elements of A represent the strength of the relationship: $a_{ij} = w_{ij} \in \mathbb{R}$.

Although a complete description of the network is given by the adjacency matrix, we can obtain valuable insights by measuring local (node-centric) and/or global properties of the graph. For example, the *degree* or *connectivity*, k_i , of node i in an undirected network is the number of connections or edges that the node has. The *graph density*, $D = 2m/(n(n - 1))$, measures how sparse or dense a graph is by the ratio of the number of edges to the maximum possible number of edges for an n -node graph. In a *complete graph* every node is connected to every other node, so $D = 1$. A *path* in the network is a sequence of edges that connects a distinct sequence of nodes. The graph is *connected* if one can get from any node to any other node by following a path. The *distance* $\delta(i, j)$ between two nodes i and j is the length of the shortest path (also known as a *geodesic*) between them; if no such path exists, we set $\delta(i, j) = \infty$. Distance can be also defined taking into account the weights of the edges. Finally, the *diameter* ℓ of a graph G is the maximum value of $\delta(i, j)$ over all pairs of $i, j \in V$. Table 1 summarizes some key definitions and notation for easy reference.

One of the most common interests in network analysis is in the “substructures” that may be present in the network. The neighborhood of a node (its ego network), which comprises itself and its k_i neighbors, can be thought of as a substructure. More generally, any subset of the graph is called a subgraph $G' = (E', V')$,

where $E' \subseteq E$ and $V' \subseteq V$. The connected components of a graph are the subgraphs in which any two vertices are connected to each other by paths. We say that there is a *giant component* if there is a component that comprises a large fraction of the nodes. A *clique* in an undirected graph G is a subgraph G' that is complete. A maximal clique in G is a clique of the largest possible size in G . Another measure of the “core” of the network is the *k -core* of G , which is defined as the maximal connected subgraph of G in which all the vertices have degree at least k . Equivalently, it is one of the connected components of the subgraph of G formed by repeatedly deleting all vertices of degree less than k . Finally, *network motifs* are recurrent and statistically significant subgraphs or patterns within a graph. More informal definitions of *clusters* in the network are used in the community-finding problem, in which a graph G is divided into a partition of *dense* subgraphs (see section 3.5).

In some applications the static structure of networks or graphs is not enough to incorporate the dynamical nature of nodes and the interactions between them. For example, if we want to study the phone calls made between the customers of a mobile phone company, we will need to incorporate the fact that calls take place at different times. To this end, we can define *temporal graphs*, $G_t = (V_t, E_t)$, in which we have a different set of nodes and edges for each $t \geq 0$. Time-varying graphs are affected by the temporal aspects of interactions, like causality, which add a new perspective to network analysis. Also, when multiple types of edges are present (multiplexity), we must consider a description in which nodes have a different set of neighbors in each layer (type). For example, one can consider each layer as the different types of social ties among the same set of individuals. Or one could picture each layer as representing a particular time in a temporal graph, or the layers could be the mathematical setup for the bipartite network of users and items in recommendation algorithms.

3 Properties

The German mathematician Dietrich Braess noted that adding extra roads to a traffic network can lead to greater congestion. This paradox shows one of the characteristics of network analysis: namely, that networks have emergent properties that cannot be explained simply by the sum of their components. Here, we review some of the key properties of networks that are found

Table 1 The key definitions and notation for a graph $G = (V, E)$ with n nodes and m edges.

Degree or connectivity	k_i	Number of connections or edges that node i has
Diameter	ℓ	$\max_{i,j \in V} \delta(i, j)$
Degree distribution	p_k	Fraction of nodes in G that have degree k
Average degree	\bar{k}	$\sum_{i=1}^n k_i/n$ or $\sum_k k p_k$
Average degree of neighbors	\bar{k}_{nn}	Average degree of (next-nearest) neighbors of a node in G
Graph density	D	$2m/(n(n - 1))$
Distance	$\delta(i, j)$	Length of the shortest path between nodes i and j
Clustering coefficient	C	Relative frequency of triangles to triplets in G
Individual clustering coefficient	C_i	Relative frequency of triangles to triplets involving node i

in real examples and incorporated in the most representative models. The properties cover most scales of network, from local features like connectivity or clustering to the study of a network's modular structure (motifs, communities).

3.1 Heterogeneity

Many unique properties of networks are due to their heterogeneity. In the simplest approximation, networks are heterogeneous in the connectivity sense: a homogeneous network is one in which each node i has the same degree $k_i \approx \bar{k}$, where \bar{k} is the average degree in the network. However, in real-world networks the distribution of connectivities is highly heterogeneous. In fact, one is very likely to find nodes with $k_i \gg \bar{k}$. A simple way to characterize heterogeneity is by using the degree distribution of the network, p_k , the fraction of nodes in the network that have degree k . In a homogeneous network, p_k peaks around the average value \bar{k} . However, real-world networks are usually heavily skewed, with a long tail of nodes having $k_i \gg \bar{k}$. These high-degree nodes or *hubs* have an important role in many properties of the network. Conversely, the network contains many nodes that are poorly connected. The connectivity description of the network is thus that of “few giants, many dwarves.”

Although measuring the tail of heavily skewed distributions is statistically tricky, recent work has found that some real-world networks have power-law degree distributions $p_k \sim k^{-\alpha}$, where the scaling exponent typically lies in the range $2 < \alpha < 3$. Some instances of this observation are the network structure of the Internet, the network of links between Web pages, the network of citations between papers, phone communication networks, metabolic networks, and financial networks. Networks with power-law degree distributions are usually referred to as *scale-free networks* because p_k lacks a characteristic degree. They have attracted

wide attention in the literature due to their ubiquity in many complex systems and also because of their possible modeling by simple growth models. In other situations, degree distributions seem to be better described by exponentials or power-law distributions with exponential cutoffs. Regardless of which statistical model is best for describing p_k , the large heterogeneity found in networks implies that there is no such thing as typical connectivity in the network. Node degree is not the only network property that shows heterogeneity. For example, the weights (intensity) of edges, the frequency of motifs, and the distribution of community sizes are all described by broad distributions, showing that heterogeneity appears at different scales of the network and in various network descriptions.

3.2 Clustering

As well as being unequally shared among the nodes, edges tend to be clustered in a network. For example, the neighbors of a given node are very likely to themselves be linked by an edge. In the language of social networks, the probability that a friend of your friend is also your friend is very large. A way of measuring network clustering is to calculate the *transitivity* or *clustering coefficient*, $0 \leq C \leq 1$, which measures the relative frequency of triangles (cliques of size 3) in the network with respect to the total number of triplets (three nodes connected by at least two edges). In a fully connected graph, $C = 1$. Clustering can also be measured locally: C_i measures the fraction of neighbors of a node i that are also neighbors of each other. Social and biological networks display large clustering coefficients when compared with random network models, while technological networks like the World Wide Web, the Internet, or power grids have much less clustering. The origin of this difference lies in the potential mechanisms behind clustering or its absence: in social networks people who spend time with a common third

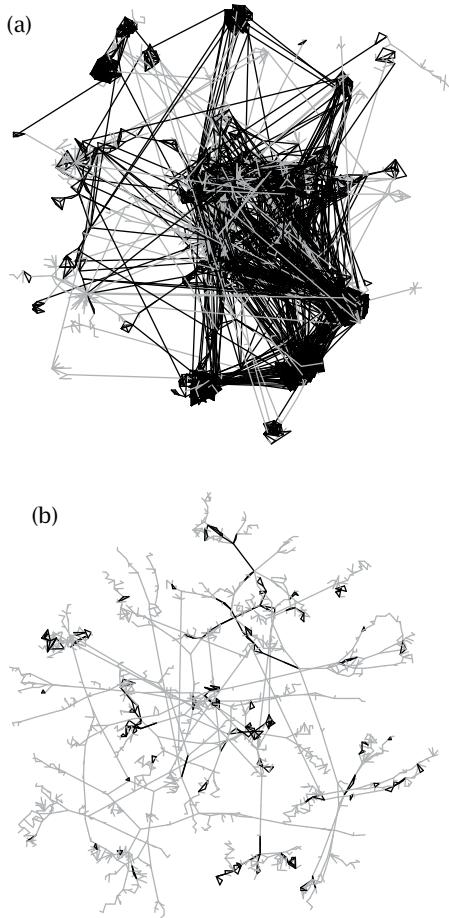

Figure 1 (a) Yeast protein-protein interactions (data from von Mering, C., et al., 2002, *Nature*). (b) The power grid of the western states of the United States (data from Watts, D. J., and S. H. Strogatz, 1998, *Nature*). Links that belong to a triangle are shown in black, with the rest in gray. For reasons of clarity, nodes are removed in both cases. The clustering coefficients are (a) $C = 0.44$ and (b) $C = 0.09$.

person are likely to encounter each other, and thus *triadic closure* is favored by social interactions. Actually, triadic closure is exploited by many online social networks for friend-recommendation algorithms. In biological networks large clustering might be due to concurrent interaction of proteins in biological processes. However, efficiency in technological networks discourages the formation of redundant edges between nodes that are already close in the network, and C is therefore very small (see figure 1).

In some networks C_i decreases with the degree k_i . This means that low-degree nodes are densely

clustered while hubs' neighborhoods are sparsely connected, a result which, together with the existence of densely connected groups of nodes (communities; see section 3.5), reflects the *hierarchical organization* of some networks: low-degree nodes are situated in dense communities, while hubs link different communities.

Triangles are not the only cliques or motifs that are over-represented in networks. For example, some three- or four-node motifs occur in large numbers even in small networks. However, most represented motifs in food webs, for example, are distinct from those found in transcriptional regulatory networks and from those in the World Wide Web, a finding that some authors ascribe to the function of the network. Networks may therefore be classified into distinct functional families based on their typical motifs. At a higher level, the relative size of the maximal clique or the k -core of the graph are also measures of the degree of clustering in the network.

3.3 Small World

Many naturally occurring networks exhibit the *small-world phenomenon*; that is, they have a small graph diameter. This was famously illustrated by the psychologist Stanley Milgram in 1967, who discovered the famous “six degrees of separation” (on average) between two persons in the worldwide social network. The experiment was later reproduced using email and measuring the distance in massive social graphs. The fact that networks are densely connected creates a wealth of short paths between nodes, and the typical distance between nodes is therefore very small. Illustrations of the small-world phenomenon are actors’ “Bacon numbers,” or mathematicians’ Erdős numbers: the distance from Paul Erdős in the graph whose edges represent coauthorship of papers. The average Erdős number is only around 5.

Mathematically speaking, a small-world network refers to a network model in which the diameter increases sufficiently slowly with the number of nodes n in the network—typically, as $\log n$ or slower. However, this property is trivially satisfied in a tree-like network if we assume that the number of nodes at distance d from a given node scales as $d^{\bar{k}}$, where \bar{k} is the average number of neighbors. The small-world property is therefore sometimes accompanied by the condition that the clustering coefficient is bounded away from zero as n increases. In real-world networks, where n is fixed, a small-world network is defined as one in which ℓ is

smaller and C is much bigger than the values found in statistically equivalent random network models.

3.4 Centrality

The concept of the centrality of a network tries to answer the question of which is its most important node. Depending on the nature of the relationships and the process under study, centrality means different things. For example, *degree centrality* approximates the centrality of a node by its degree in the network k_i . In most situations, this is a highly effective measure of centrality. These highly connected nodes, usually called *hubs*, might have a major impact on the robustness of the network if they are removed or damaged.

However, hubs might be located in the periphery of the network. More global and advanced measures of centrality are *eigenvector*, *betweenness*, and *closeness centrality*, which take into account the relative position of one node with respect to the rest.

Eigenvector centrality relies on the idea of centrality propagation: the centrality of a node x_i is a linear function of the centrality of its neighbors $x_i = (1/\lambda) \sum_j a_{ij} x_j$. Writing $\mathbf{x} = (x_1, \dots, x_N)$, we obtain an eigenvector equation $A\mathbf{x} = \lambda\mathbf{x}$. Among all the possible solutions of this equation, the one with the greatest eigenvalue has all entries positive (by the PERRON-FROBENIUS THEOREM [IV.10 §11.1]). The components of the related eigenvector are taken to be the centrality of each node. Several generalizations of this method are possible; for example, a variant of eigenvector centrality is Google's PAGERANK ALGORITHM [VI.9], used to rank the importance of Web pages, which in turn is also used in network analysis to measure the centrality of nodes. Some other centrality measures, such as Katz centrality, the Bonacich power, and the Estrada index, can be obtained as solutions of eigenvalue problems of FUNCTIONS OF THE ADJACENCY MATRIX [II.14].

Another well-known centrality measure is betweenness, introduced by Freeman in 1979, which is defined as the number of times node i appears in the shortest paths between any pair of nodes in the network. Specifically, if g_{jk} is the number of geodesic paths from i to j , and if g_{jik} is the number of these geodesics that pass through node i , then the *betweenness centrality* of node i is given by $b_i = \sum_{j \neq k \neq i} g_{jik}/g_{jk}$. The idea behind betweenness is that it measures the volume of flow through a node of a process that is happening in the network. Finally, closeness centrality (also introduced by Freeman) is defined as the average

distance from one node to the rest of the network, i.e., $c_i = (1/n) \sum_j \delta(i, j)$.

Centrality is widely used to determine the key nodes in the network. For example, it is used to find influential individuals in online social networks, to identify leaders in organizations, as a method for selecting individuals to target in viral marketing campaigns, or to identify central airports in the air transportation network.

3.5 Communities

In most networks (see plate 5 and figure 2) there are groups of nodes that are more densely connected internally than with the rest of the network. This feature of a network is called its *community structure*. Community structure is common in many networks, and its determination yields a mesoscopic description of the network. But primarily it is interesting because it can reveal groups of vertices that share common properties or subgraphs that play different functional roles in the system. In fact, communities in social networks are found to be related to social, economic, or geographical groups; communities in metabolic networks might reflect functional groups; and communities in citation networks are related to research topics.

The hypothesis underneath these findings is that the network itself contains the information needed to reveal the groups and that the communities can be obtained using a graph-partitioning technique that assigns vertices to each group (see figure 2). Mathematically speaking, the problem of identifying graph communities is not well defined. To start with, there is no clear definition of what a community is in a graph. This ambiguity is the reason behind the wealth of algorithms in the literature, each of which implicitly assumes its own mathematical and/or statistical definition of communities and thus produces different partitions in the graph. On top of that, graph-partitioning problems are typically NP-HARD [I.4 §4.1] and their solutions are generally achieved using heuristics and/or approximation algorithms that might not deliver the exact solution or even the same approximate solution. Most of the time, therefore, we need further external information to validate the partition obtained.

Many different methods have been developed and employed for finding communities in graphs. Some of them rely on graph-partitioning techniques (such as the minimum-cut method) or data-clustering analysis (such as hierarchical clustering) borrowed from computer science. Some problems with these methods are

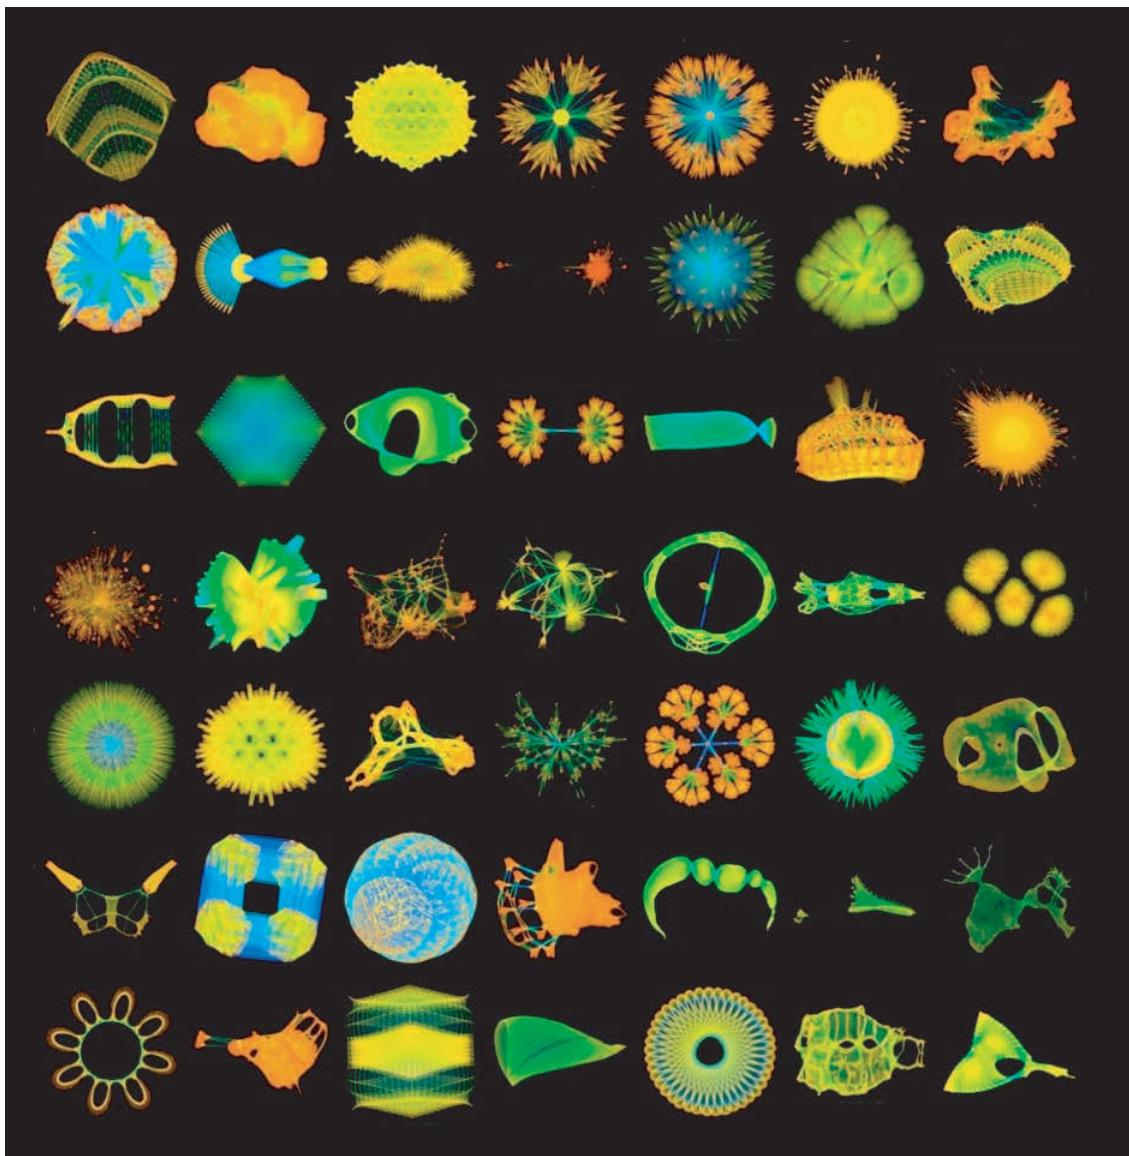

Plate 1 (II.16). Force-directed graph visualizations. A sample of forty-nine graphs from the University of Florida Sparse Matrix Collection. The color is determined by the length of the edges: short ones are red, medium-length edges are green, and long edges are blue.

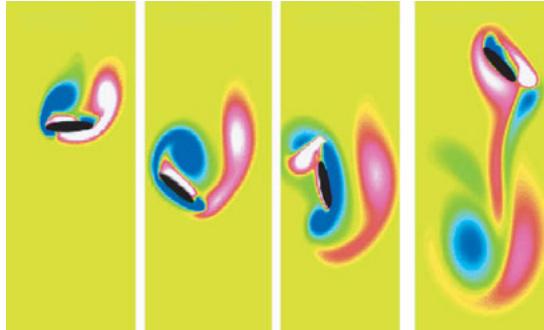

Plate 10 (VI.5). The flow generated by a two-dimensional flapping wing mimicking dragonfly wing motion. The colors indicate the vorticity field, with red and blue representing positive and negative vorticity, respectively. The wing motion creates a downward jet composed of counterrotating vortices. Each vortex pair can be viewed as the cross section of a donut-shaped vortex ring in three dimensions. From Z. J. Wang (2010), Two dimensional mechanism for insect hovering, *Physical Review Letters* 85(10):2216-19.

Plate 11 (VI.5). A fruit fly making a sharp yaw turn of 120° in about 20 wing beats, or 80 ms. The wing hinge acts as if it is a torsional spring. To adjust its wing motion, the wing hinge shifts the equilibrium position of the effective torsional spring, and this leads to a slight shift of the angle of attack of that wing. The asymmetry in the left and right wings creates a drag imbalance that causes the insect to turn. To turn 120° , the asymmetry in the wing angle of attack is only about 5° or so. From A. J. Bergou, L. Ristroph, J. Guckenheimer, I. Cohen, and Z. J. Wang (2010), Fruit flies modulate passive wing pitching to generate in-flight turns, *Physical Review Letters* 104:148101.

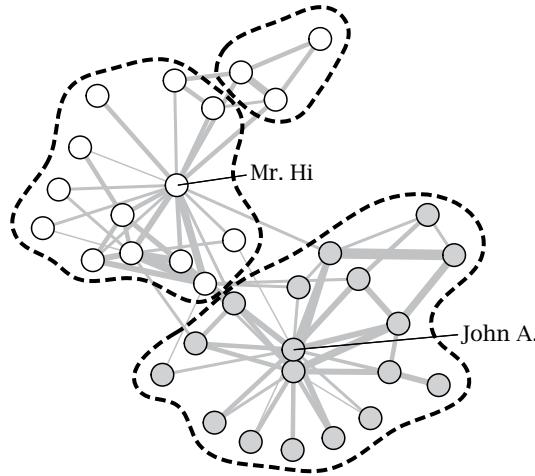

Figure 2 A social network of friendships between thirty-four members of a karate club at a U.S. university in the 1970s. The club was led by president John A. and karate instructor Mr. Hi (pseudonyms). Edge width is proportional to the number of common activities the club members took part in. In 1997 Zachary studied how the club was split into two separate clubs (white and gray symbols) after long disputes between two factions within the club. A community-finding algorithm (label propagation) applied to the network before the split finds three communities (dashed lines) that have a large overlap with the factions after the split.

that the number of communities has to be given by the algorithm and/or there is no way to discriminate between the many possible partitions obtained by the procedure. To circumvent these issues a quality function of the partition has to be given. In a seminal paper, Newman and Girvan introduced the concept of the *modularity* of a partition, which measures the difference between the actual density of edges within communities and the fraction that would be expected if edges were distributed at random:

$$Q = \frac{1}{2m} \sum_{i,j} (a_{ij} - p_{ij})y(c_i, c_j),$$

where the sum runs over all pairs of vertices, $y(c_i, c_j) = 1$ if i and j are in the same community (zero otherwise), and p_{ij} represents the expected number of edges between i and j in a null model, i.e., a model of a random graph with the same number of nodes and edges (see section 4). Given the large heterogeneity of degrees in the network, the most used model is the configuration model in which $p_{ij} = k_i k_j / (2m)$. Despite its limitations, modularity has had a great impact in community-finding algorithms. It gives a quantitative

measure of the partition found, and it can therefore be employed to get the best (maximum-modularity) partition in divisive algorithms. In addition, modularity optimization is itself a popular method for community detection.

Other popular methods include clique-based methods such as the clique-percolation algorithm (which defines a community as percolation clusters of k -cliques), random-walk methods (where a community is a region of the graph in which a random walker spends a long time), and consensus algorithms (where a community is defined as a group of nodes that share common outcomes in a dynamical coordination process). Examples of consensus algorithms are label-propagation algorithms, in which nodes are given unique labels that are then updated by majority voting in the neighborhood of nodes. Labels reached asymptotically by this consensus process are taken as communities in the graph.

Community finding in networks is a computationally complex task. Typically, algorithm times scale with the number of nodes n and edges m , and some methods are therefore not suitable for finding communities in very large networks. In recent years, however, much progress has been made in accelerating the algorithms, and it is possible to efficiently apply algorithms such as the Louvain method, Infomap, or the fast greedy algorithm of Clauset, Newman, and Moore to networks with millions of nodes.

4 Models

Building on the observations of real-world networks and their common properties found in many systems, one can create mathematical models of networks. Models are important for two reasons: the first is that simple null network models can be used to test the statistical significance of the results found in real-world applications. Of course, the very definition of null network models depends on the context and the process to be considered. On the other hand, modeling networks allows us to obtain good mathematical representations of the observed systems, which can then be used for further testing or even to make predictions about the future behavior of a process.

4.1 The Erdős-Rényi Model

The random graph model is the most used model type. In this technique, graphs are generated according to a probability distribution or a random process.

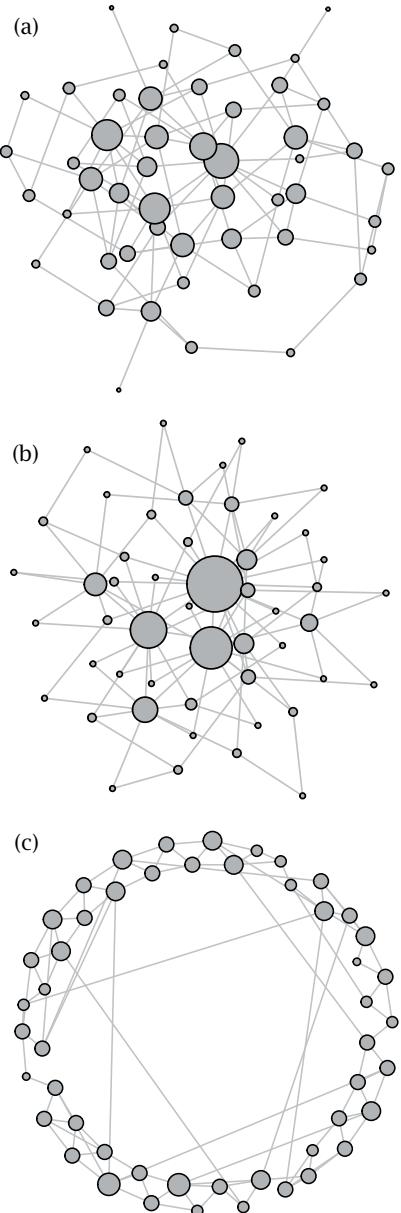

Figure 3 Examples of networks generated by (a) the Erdős-Rényi model, (b) the preferential-attachment model, and (c) the small-world model. All networks have the same number of nodes $n = 50$ and edges $m = 100$. The size of a node is proportional to its connectivity k_i .

Here, we review some of the most popular examples in mathematical studies and applications.

In 1959 Paul Erdős, Alfréd Rényi, and (independently) Edgar Gilbert proposed a simple binomial random

graph model, $G(n, p)$, in which the graph of n nodes is constructed by connecting each pair of nodes with probability p (see figure 3). The distribution of degrees in $G(n, p)$ is given by the binomial distribution, which becomes a Poisson distribution in the limit of large n :

$$p_k = \binom{n-1}{k} p^k (1-p)^{n-1-k} \approx \frac{\bar{k}^k e^{-\bar{k}}}{k!},$$

where $\bar{k} = (n-1)p$ is the mean degree. Thus, p_k does not have heavy tails. Despite this difference from real networks, many properties of $G(n, p)$ are exactly solvable in the limit of large n , and the random graph model has therefore attracted a lot of attention in the mathematics community. For example, the diameter is approximately given by $\ell \sim \log n / \log \bar{k}$, and thus $G(n, p)$ has the small-world property. On the other hand, the clustering coefficient is $C = p = \bar{k}/(n-1)$, which tends to zero in the limit of a large system (for finite \bar{k}), unlike real-world networks where C is finite even for large n . Obviously, $G(n, p)$ does not have any community structure either. Nonetheless, $G(n, p)$ can be used as a zero-information model, providing a benchmark for comparison with other models and data.

4.2 The Configuration Model

To allow for non-Poisson degree distributions, we can generalize the Erdős-Rényi model to the configuration model, which was first given in its simple explicit form by Bollobás. In this model the degree distribution p_k or degree sequence k_1, \dots, k_n is given and a random graph is formed with that particular distribution or degree sequence. A simple algorithm to generate such random graphs is to give each vertex a number of “stubs” of edges, either according to the distribution or from the degree sequence, and then pick stubs in pairs uniformly at random and connect them to form edges. The ensemble of graphs produced in this way is called the *configuration model*. Many properties of the configuration model are known. Molloy and Reed showed that there is almost surely a giant component if $\bar{k}^2 - 2\bar{k} > 0$ (where $\bar{k}^2 = \sum_k k^2 p_k$), and that the probability of finding a loop on the graph decays like n^{-1} , i.e., the graph has a local tree-like structure for large n . This was used by Newman to show in a simple way that the clustering coefficient decays asymptotically like $C \sim n^{-1}$.

One of the most important properties of the configuration model is that the distribution q_k of degrees of nodes obtained following a randomly chosen edge is not given by p_k . Instead, since in choosing a random

edge there are k ways to get to a node with connectivity k , we obtain that $q_k \sim kp_k$. The average degree of (next-nearest) neighbors of a node is therefore

$$\overline{k_{nn}} = \sum_k k q_k \sim \frac{\bar{k}^2}{\bar{k}}.$$

Since real-world networks are very heterogeneous, we usually find that $\bar{k}^2 > \bar{k}$, and the neighbors of a randomly chosen node therefore have more connectivity than the node itself. This fact has a key role in many processes that happen in networks (see section 6). In social networks it is known as the *friendship paradox*, posed by the sociologist Feld in 1991: on average, your friends have more friends than you do. It also has other direct consequences; for example, in scale-free networks with $2 < \alpha < 3$, we find that the diameter $\ell \sim \log \log N$, and, thus, scale-free networks are ultrasmall. For $\alpha > 3$ we recover the small-world behavior $\ell \sim \log N$. Finally, since edges are distributed randomly among nodes, the probability that two nodes with degrees k_i and k_j are connected is given by $k_i k_j / (2m)$, a result used in the definition of modularity Q as a null model approximation for p_{ij} .

5 Other Random Models

Configuration models can be generalized to *exponential random graphs*, also called *p^* models*. These are ensembles of graphs in which the probability of observing a graph G with a given set of properties $\{x_i\}$ is $P(G) = e^{H(G)} / Z$, where $Z = \sum_G e^{H(G)}$ and the network *Hamiltonian* is given by $H(G) = \sum_i \theta_i x_i(G)$, with $\{\theta_i\}$ the ensemble parameters. For example, we could take x_1 to be the number of edges, x_2 to be the number of vertices with a given degree, x_3 to be the number of triangles in the network, and so on. Much of the progress made in this field has come through the use of Monte Carlo simulations of the ensemble and/or by using real network data to estimate the parameters of the model.

Another random graph model is the family of *stochastic block models*, in which nodes are assigned to s different blocks and vertices are placed randomly between nodes of different blocks with a probability that depends only on the blocks of the nodes. Specifically, if z_i denotes the block that the vertex i belongs to, then we can define an $s \times s$ stochastic block matrix M , where m_{ij} gives the probability that a vertex of type z_i is connected to a node of group z_j . Blocks can be

groups of nodes that have similar structural equivalence, have similar demographics, or belong to the same community.

5.1 The Small-World Model

The small-world model was introduced by Watts and Strogatz as a random graph that has two independent structural properties of real networks: a finite clustering coefficient, and the small-world property $\ell \sim \log n$ when n increases. The basic idea of this model is to build a graph embedded in a one-dimensional lattice in which nodes are connected to a local neighborhood of size d and then the edges are “rewired” with probability p (see figure 3). When $p = 0$ we recover a one-dimensional regular graph, while when $p = 1$ we recover a random graph. The local tight neighborhood provides the finite clustering property, while the long-range rewired links are responsible for the low diameter of the network. Specifically, as $n \rightarrow \infty$ the clustering coefficient is $C \sim 3(d-1)/[2(2d-1)](1-p)^3$ and the diameter scales as n and $\log n$ for $p = 0$ and $p = 1$, respectively. One interesting feature of the Watts-Strogatz model is that it interpolates between a regular graph and a completely random graph. A major limitation of the model is that it produces unrealistic degree distributions (p_k decays exponentially). Many variations of the small-world model have been proposed and studied.

5.2 The Preferential-Attachment Model

While the models above incorporate the observed macrofeatures of networks, generative models try to explain those features as an emergent property that is due to microscopic mechanisms. A particularly popular class of models is the network growth model, in which the dynamics of node and edge creation create the observed network properties. Probably the best-known example is the so-called *preferential-attachment model* of Barabási and Albert, which aims to explain the scale-free property of the degree distribution. This is done using the rich-get-richer mechanism in edge creation: nodes are added to the network with a certain number m of edges emerging from them, and those edges are connected to preexisting nodes with connectivity k with probability π_k . This preferential-attachment mechanism has been observed in many growing networks, from citation and collaboration networks to the Internet and online social networks. Simple rate equations can be written for the evolution of the system,

and we find that the degree of each node grows according to a power law $k_i(t) \sim t^\beta$ and that for all t the degree distribution is scale free $p_k \sim k^{-\alpha}$, where the exponents α, β depend on the preferential-attachment probability. In the linear case, where $\pi_k = k$, we obtain that $\alpha = 3$, a value that is similar to those found in real-world networks such as the World Wide Web.

The preferential-attachment model has the small-world property with a double logarithmic correction $\ell \sim \log n / \log \log n$, and numerical results suggest that the cluster coefficient C behaves as $C \sim n^{-0.75}$. Although C vanishes in the limit $n \rightarrow \infty$, it can have large values for finite n . One of the main criticisms of the preferential-attachment mechanism is that it requires global information about the network, which is clearly an unrealistic assumption in many situations. This and other criticisms have been addressed by modifying the original model using local network formation rules, triadic closure, or finite memory of nodes.

6 Processes

Beyond the metrics and models presented in the previous sections, much of our knowledge about networks comes from our ability to explain processes happening on the network by analyzing its structure. For example, we would like to understand whether the node with the largest centrality is also the fastest to become aware of information spreading in the network. Or perhaps we want to know what the relationship is between an Internet network's degree of heterogeneity and its resilience to targeted attacks. Progress in this direction comes from simulating simple models of these processes on real or synthetic models of networks and from the availability of data that is empowering (and sometimes challenging) our understanding of how networks work.

6.1 Spreading

Probably the most-studied process in networks is how things spread around them. In particular, a wealth of work has been done on understanding how network structure (and dynamics) impacts the spreading of information, viruses, diseases, rumors, etc. For example, people have studied how the structure of networks of sexual contacts (or the network of flows of passengers between airports and cities) influences the spread of diseases; others have studied the best way of choosing the people who are initially targeted in a viral marketing campaign on a social network in order to optimize the reach and velocity of the campaign.

Spreading models are typically borrowed from epidemiology: diseases spread to susceptible (noninfected) (S) nodes when they are exposed to infected (I) nodes, and then they can decay into the recovered (R) state. This is the so-called SIR MODEL [V.16], which has a long history in mathematical epidemiology. Although the model is dynamical in nature, Grassberger found that it could be mapped exactly onto bond percolation in the network: outbreaks in the spreading process correspond to clusters in the percolation problem. Percolation is a well-known problem in mathematics; in its bond version it describes the behavior of connected clusters in a random graph in which edges are occupied with probability λ . The question is then whether there is a cluster that "percolates" the whole network, i.e., a connected cluster of a fraction of the network, the so-called giant component. This would correspond to a large disease outbreak in the spreading problem. In most systems there exists a critical λ_c at which the percolation transition, or *epidemic breakout* in epidemiology, happens for $\lambda > \lambda_c$. In viral marketing we would like our campaigns to operate above λ_c , so the spreading "goes viral," while in disease spreading, vaccination and health policies are designed to maintain $\lambda < \lambda_c$. Although λ_c depends on the virulence of the disease, it is also affected by the structure of the network in which disease propagates. For example, in the configuration model with degree distribution p_k , starting from one infected initial seed we have, on average, that $R_0 = \lambda \bar{k}$ of its neighbors are infected. Each of these R_0 infected neighbors goes on to infect an average of $R_1 = \lambda(\bar{k}_{nn} - 1)$ new next-nearest neighbors. The same happens in the following steps. The size of the outbreak is therefore given by

$$\bar{s} = 1 + R_0 + R_0 R_1 + R_0 R_1^2 + \dots = 1 + \frac{R_0}{1 - R_1}. \quad (1)$$

Thus, outbreak size diverges as $R_1 \rightarrow 1$, that is, when $\lambda \rightarrow \lambda_c = 1 / (\bar{k}_{nn} - 1) = \bar{k} / (\bar{k}^2 - \bar{k})$. This is actually the Molloy and Reed criterion for the existence of a giant component applied to the corresponding configuration model in which edges are occupied with probability λ . Since heterogeneity in networks usually implies that $\bar{k}^2 \gg \bar{k}$, the epidemic threshold is always very small. Moreover, in networks that are scale free with exponent $\alpha \leq 3$, we have that \bar{k}^2 diverges. This implies that in highly heterogeneous networks, the critical point vanishes and information or disease spreads all over the network, an interesting result of Pastor-Satorras and Vespignani that has been suggested as an explanation for the prevalence of computer viruses. Although

this result was obtained for a very particular epidemic model in the configurational model, the general understanding is that network heterogeneity favors spreading. Indeed, R_0 and R_1 are widely used in epidemiology to assess epidemic outbreak, where they are known as the *basic reproduction numbers*. Away from the configuration model, epidemic spreading in real networks is controlled by the first eigenvalue σ_1 of the adjacency matrix, so that $\lambda_c = 1/\sigma_1$. Furthermore, network clustering and its community structure tends to reduce the spread of infection, since spreading gets trapped in densely connected areas of the network.

Two related questions are finding the nodes in the network that spread most efficiently and, conversely, finding the ones that are affected by the spreading process earliest. Both of these questions are related to centrality in the network: the more central a node is, the larger the outbreak cluster that can generate from it, and also the faster it becomes aware of the spreading process. This result allows us to strategically target initial spreaders in information spreading or to vaccinate more central people in social networks to stop epidemics. But it also provides a way of choosing a set of central nodes (*sensors*) in the network that can help us detect epidemic outbreaks or information spreading as quickly as possible. For example, Fowler and Christakis and collaborators have found that a set of sensors is highly effective in detecting outbreaks in information and disease spreading, even in massive networks.

6.2 Contagion

Closely related to information diffusion, yet mechanistically different, is behavior contagion, or how exposure to certain individual behavioral characteristics can drive the propagation of those characteristics from individual to individual in a network. The importance of social-network structure in promoting positive or arresting damaging behavior has recently been studied in many contexts, ranging from spreading of health behaviors, to product/service adoption, to political opinion, to participation in time-critical events, to the diffusion of innovations, and so on. Taken together, these studies hint at some generalities regarding behavior contagion: it critically depends on the structural diversity of the network (i.e., from how many different social communities the behavior is exposed) and on social reinforcement (i.e., how additional exposures change the probability of adoption and how clustering in networks promotes it). However, recent work

has highlighted the problem that most of the observed causal influence in social networks could be chiefly due to latent homophily or other assortative confounder variables. For example, an individual might buy a particular product not because she is influenced by the network surrounding her but because she belongs to a group to which that product is appealing. A more refined statistical network would be needed to establish causality in behavior contagion.

6.3 Robustness

In many applications, networks should be robust to small topological or dynamical perturbations. For example, communication networks, power grids, or organizational business processes should be resilient to intentional attacks, random failures in stations, or organizational changes, respectively. In the most simple approximation network, robustness is studied under a random or intentional removal of nodes and/or edges. The question is at which point in this removal process does the network stop operating as intended, e.g., when a significant fraction of nodes in communication networks can no longer communicate with each other. This obviously happens when there is no path between those nodes, and in that case the network becomes disconnected with a number of small components. In this form, the robustness problem is then very similar to percolation, where nodes or edges are unoccupied when they are attacked or they fail. Depending on the removal strategy there will be a critical fraction q_c such that when q nodes are removed with $q > q_c$ the network becomes disconnected, while the removal of $q < q_c$ nodes leaves a large fraction of nodes in a connected component (the *giant component*). For example, if a fraction q of randomly chosen nodes are removed from the configuration model with degree distribution p_k , then each node has $(1 - q)\bar{k}$ neighbors on average and each of the neighbors will itself have $(1 - q)\bar{k}_{nn}$ neighbors. Thus, starting from a node that has not been removed we can form a connected component that has average size given by equation (1), where $R_0 = (1 - q)\bar{k}$ and $R_1 = (1 - q)(\bar{k}_{nn} - 1)$, recovering the Molloy-Reed criterion that $q_c \approx 1 - \bar{k}/\bar{k}^2$. This implies that highly heterogeneous networks (where $\bar{k}^2 \gg \bar{k}$) are very robust against random attacks. Conversely, given the structural importance (centrality) of hubs or bridges, an intentional attack to remove those nodes could disconnect the network very easily. Thus, although the heterogeneous and modular structure of networks makes

them resilient against random attacks, the central role of hubs and bridges between communities makes networks very fragile when it comes to targeted attacks against them.

In some situations failures can propagate in the network like avalanches. This is the case in power transmission grids or the Internet, where the removal or failure of nodes changes the balances of flows and could lead to high loads in other nodes and their possible failure. Another example is cascades of bank failures in financial networks. In this case, the robustness of the network depends both on its topological structure and on how the capacities/tolerance of nodes are distributed over it. Finally, in some technological problems networks are interconnected; for example, in Italy's major 2003 blackout it was found that the coupling between the power grid network and the communication network caused further breakdown of power stations. The effect of heterogeneity in random attacks is the opposite in interconnected networks from the effect in simple networks: a broader distribution of degree increases the vulnerability of interconnected networks.

6.4 Consensus

Repeated information sharing and behavior contagion can lead to the formation of consensus or synchronization in the network. Examples of consensus formation in networks are the problems of opinion formation in society, synchronization of biological neural networks, or protocols in distributed computing. Simple models of consensus formation are the well-known mathematical problems of the voter model or the Kuramoto model of coupled oscillators. Important questions in consensus processes are whether the network structure favors the appearance of consensus and its impact on the time to reach it. The answer to the first question depends on the way in which models or experiments are engineered. For example, in the voter model, consensus is not reached in general in heterogeneous networks, although finite-size fluctuations induce consensus after a time $\tau \sim n$. Since most consensus problems can be written in a diffusion-like framework, the time to consensus can be obtained from the spectral properties of the graph. For example, consider the simple local average consensus problem

$$\dot{x}_i = \sum_{j \in \mathcal{N}_i} (x_j(t) - x_i(t)),$$

where the \mathcal{N}_i are the neighbors of node i , and $x_i(t)$ is the state of node i . The collective dynamics of the agents can be written as $\dot{\mathbf{x}} = -L\mathbf{x}$, where L is the Laplacian matrix $[L]_{ij} = k_i \delta_{ij} - a_{ij}$. Since L always has a zero eigenvalue $\sigma_1 = 0$, the timescale in the consensus problem is given by the second smallest eigenvalue σ_2 , which is usually called the *algebraic connectivity*. The time to achieve consensus is then given by $\tau \sim 1/\sigma_2$. In general, heterogeneity has a large influence on τ : while in the voter model larger heterogeneity (more hubs) favors consensus, synchronization of oscillators is more difficult in highly heterogeneous networks. On the other hand, it appears that community structure has a large influence in reaching consensus. In fact, this is the main idea behind some community-finding algorithms that are based on consensus formation, such as the label-propagation algorithm (see section 3.5)

6.5 Network Prediction/Inference

Networks contain explicit information about the nodes they contain and how they interact, but they might also contain implicit information about interactions that might happen in the future or about the possibility that a given node, edge, or subgraph disappears from the network after some time. For example, in a social context, the fact that two people share a large number of friends indicates that those two people might be friends as well. This kind of analysis is not only useful in predicting how a network might evolve, but it also helps us to make inferences about links that are unobserved or are missing from the data. Most of the processes of link formation and decay can be predicted by looking at the local neighborhood or community of the link: nonconnected nodes that have structural similarity tend to become connected. The simplest similarity measure is the number of shared neighbors in the network (or the embeddedness of an edge), but other dyadic or neighborhood measures have been proposed. Conversely, studying four years' worth of banker relationships in a large organization, Burt found that edges between nodes that are very similar do not decay easily, and therefore network evolution happens mostly at the bridge positions between communities, where nodes are structurally different.

7 Applications

It would be impossible to cover all the applications of network analysis here. Although it has long been used in the social sciences, the last few decades have seen

many technological, engineering, economic, and biological problems being studied using network analysis. Here we review some of those applications.

7.1 Social Networks

The analysis of social networks has a long tradition, and in fact many of the techniques and ideas in network analysis are derived from sociology. Social networks are defined by a set of actors (persons, organizations, etc.) and edges that represent relationships between them (friendships, business relationships, etc.). Traditional social network analysis was devoted to explaining the role of network structures, dyadic properties, or network positions in social processes. At the level of the network, for example, the connectedness or cohesion of a group or of the network itself could be an explanatory variable in consensus formation, shared norms, etc. Dyadic properties of social networks refer to concepts like distance between nodes, structural equivalence (sharing the same relationships to all other nodes), reciprocity (the tendency of nodes to form mutual connections), etc., that can be used to find structural equivalence classes, that is, types of actors in the network. Regarding network positions, the most studied concept is that of the use of centrality to determine the most important actor in a social network with respect to information sharing, economic opportunities, prestige, and so on.

Different social positions also lead to different network roles; for example, bridges are nodes that appear between communities and thus have a large centrality (see figure 4). Bridges are surrounded by structural holes (i.e., the lack of a connection between two nodes in communities connected by a bridge), and thus only bridges can access information from different sources and communities and benefit from their position in the network. The potential benefits that their position in a network could yield to a group or individual are known as social capital theory (introduced by Burt in the 1990s). Intimately related to the concept of bridges and structural holes is Granovetter's theory of weak ties: if strong ties are associated with intimate and intense relationships, Granovetter's theory is that weak ties are associated with bridges, that is, that our strongest edges happen within communities (see figure 4). Weak ties therefore enable people to reach information that is not accessible via strong ties. Granovetter used a survey of job seekers to prove this; he asked people who had found a job through contacts

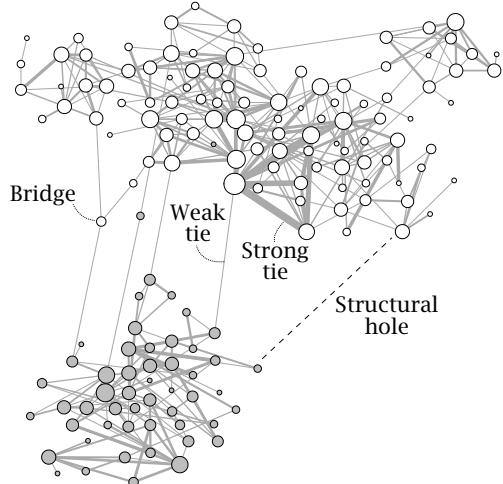

Figure 4 The network of email communication between two departments (white and gray symbols) from plate 5. Most communication happens within departments, and some individuals have special roles as bridges between them. Also, there are a large number of structural holes in the network; weak ties happen between the departments while strong ties occur between people in the same department (the Granovetter hypothesis).

how often they saw the person who had helped them get their job. The majority were acquaintances rather than close friends. In more recent work, Onnela and collaborators measured these social theories quantitatively; using a large graph of mobile phone communications, they found that people with weak ties (those with a smaller number of calls) tend to have larger betweenness than those with strong ties.

Much work has been devoted to understanding when and why information propagates in social networks. Understanding how fast and how far information spreads is important in viral marketing, social mobilizations, innovation spreading, and computer viruses, for example. Although information spreading is affected by many factors, including the value of the content transmitted and exogenous campaigns, the very network structure shapes the speed and reach of information spreading. As we show in section 6, it is possible to study how the structural properties of the network—such as heterogeneity, clustering, and communities—influence the spreading, and to study what structural properties (centrality, degree, k -coreness) of an initial set of nodes are needed to maximize the spreading in the network.

Although behavior contagion is difficult to assess in many contexts, network analysis is widely used in marketing and social media to detect and predict changes of behavior. For example, it is used in the telecommunication industry to predict churn or product/service adoption using the social network of a company's clients obtained through the calls placed between them. The basic idea is that behavior like churning or adoption has a viral component and propagates on the network. Thus, the probability to churn or buy a particular product or service depends on the number of neighbors in the social network that have already done so. The analysis of the social network of clients permits one to identify and target those individuals most likely to make a purchase.

Disease spreading is also influenced by an infected person's social network. Here, the approach is different depending on the scale at which spreading is being studied. At small scale, the study of networks of sexual contacts can help to understand and control the spread of sexually transmitted diseases. These networks show high heterogeneity, modular structure, and small-world phenomena—properties that promote the spread of the disease across the network. In turn, since highly heterogeneous networks are susceptible to intentional attacks, targeted vaccination of superspreaders might be enough to prevent an epidemic, a result that reinforces standard public-health guidelines. At a large scale, we can consider metapopulation network models, in which nodes are populations (groups, patches, cities) and edges account for the probability of transmission between populations. In these examples, human mobility networks play a major role. For example, the worldwide airport transportation network is highly connected; it is a small world, and its structure therefore favors epidemics on a global scale (see figure 5). In 2003 the SARS outbreak took just a few weeks to spread from Hong Kong to thirty-seven countries. Analysis of transportation networks allows us to predict which airports or hubs will be most likely to promote aggressive spatial spreading.

7.2 Economics and Finance

The complexity of interdependencies between different agents, financial instruments, traders, etc., can be also studied using network analysis. In these studies, the main aim is to understand how the network structure impacts the performance of institutions or economies and also the role it plays in economic risks

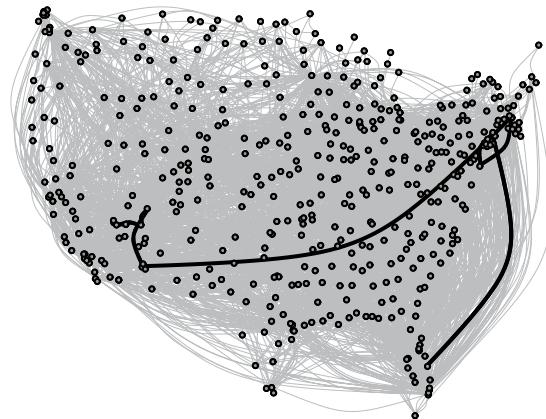

Figure 5 A network of passenger flows among U.S. airports. The network has 489 airports and 5609 different routes between them. The diameter of the network is only 8. The black line shows one of the largest geodesics in the network: that between the airports of Grand Canyon West, AZ, and Fort Pierce, FL.

and their possible mitigation. For example, the 2008 financial crisis has shown that systemic risk can propagate rapidly between interconnected financial structures. A potentially vulnerable market for contagion of financial shocks is the interbank loan market, where banks exchange large amounts of capital for short durations to accommodate temporal fluctuations. Network analysis has shown the important role of the topology of that market in the systemic risk of the system. Specifically, it has been found that contagion of bank failures can be promoted by the heterogeneity and density of the network, and the fragility of the system to external shocks has also been demonstrated. The impact of the structure of financial networks and global markets on their stability has attracted the interest of regulators and central bankers in using network analysis to evaluate systemic risk.

Network analysis is also used to map how organizational environments affect an organization's performance, that is, how market transactions, contracts, mergers, interlocking board directorates, or strategic alliances shape organizations, create innovation, or define the future performance of companies in a particular sector. For example, in 1994 Saxenian hypothesized that the dramatic growth of Silicon Valley in the previous decades could be explained, in part, by the cooperative and informal exchange of information among the organizations in the area. At the world level, the study of the network of international trade allows

us to analyze indirect trade interactions between countries, the effect of globalization on the world economy, or the cascade effect of financial crises in different countries.

7.3 Biology

Many biological problems are intrinsically complex; they include the interaction of a large number of molecules, cells, individuals, or species. Mapping all this information into a network allows us to analyze the common structure of those problems and to develop tools that may prove useful for applications in a wide variety of biological problems.

For example, new noninvasive techniques for measuring brain structure and activity, such as neuroimaging (e.g., MAGNETIC RESONANCE IMAGING [VII.10 §4.1] (MRI), functional MRI, and diffusion tensor imaging) and neurophysiological recordings (e.g., electroencephalography, magnetoencephalography), have allowed us to collect large amounts of spatiotemporal data about brain structure and activity. Analyzing the anatomical and/or functional connectivity of different areas of the brain, researchers have constructed network models of the brain. Brain networks (*connectome*) seem to be organized in communities or modules, have the small-world property, and also present highly influential (hubs) nodes; they even seem to be scale free. Those communities appear to coincide with known cognitive networks or function subdivisions of the human brain, while the small diameter of the network seems to allow for efficient information processing.

The recent development of high-throughput techniques in molecular biology has led to an unprecedented amount of data about the molecular interactions that occur in biological organisms, e.g., the metabolic networks of biochemical reactions between metabolic substrates, the interaction networks between proteins (*interactome*), and the regulatory networks that represent the interactions between genes. A knowledge of the topologies of complex biological networks and their impact on biological processes is needed not only to understand those processes but also to develop more effective treatment strategies for complex diseases. Most of the available analyses are concerned with the application of the concept of centrality, which allows us to determine the *essential* protein or gene (or groups of them) in the organism and then apply the results to drug target identification.

7.4 Other Applications

Network analysis has expanded into many other areas. For example, it is used in sports to understand the style of play and the performance of teams. In football, by analyzing the network of passes between players it was found that a large clustering coefficient, or the diversity of the distribution of passes (entropy), correlates with the performance of the Spanish team that won the 2010 FIFA World Cup. Similar analysis has been done for basketball in the 2010 NBA Playoffs. Another interesting and recent application has been to map and understand the networks of cuisines, recipes, and ingredients in cooking. The availability of online recipe repositories has allowed researchers to find similarities among different regional cuisines in China, and to unveil the flavor network in culinary ingredients.

Since networks shape the information we receive and influence our behavior, a major concern is how much of our private life is encoded in the network structures and dynamics around us. For example, the information we leave behind in social networks can be used for identity disclosure or to unveil private personal traits. Network analysis can be used in this context to understand how to perform privacy-preserving network analysis, typically by graph-modification algorithms in which some edges or nodes are changed and/or removed. The idea is that these modifications conserve enough of the structure to perform analysis globally while hindering the identification of individuals and/or personal traits.

7.5 Software Tools

Much of the progress in network analysis in recent years is down to the availability of not only data but also the software tools needed to analyze it and visualize it. The most well-known tools are those that include a graphical user interface, such as UCINet, Pajek, Cytoscape, NetMiner, and Gephi. More powerful analyses of large networks can be done using packages such as the igraph package (ported to R, Python, and C) or the NetworkX library for Python, tools that are also widely used in producing high-quality graphics (the figures in this article were produced using igraph).

In the era of large data sets, efficient storage of networks can be achieved using the graph structure of nodes, edges, and the relationships between them. A number of *graph databases* have been developed in which the network structure is used internally to store and query network data. Typically, graph databases

scale more naturally to large graphs and are more powerful for graph-like queries; for example, computing the neighborhood of a node or the shortest path between two nodes in the graph is much easier and faster than in relational databases. Prominent examples of these databases are Neo4j and Sparksee.

8 Outlook

In this article we have introduced the main mathematical tools needed to analyze networks, and we have also illustrated how a large variety of complex systems can be studied by mapping the interdependencies between their constituent units into a network. But network analysis is not just a powerful methodology for analyzing those graphs; it is also a different way of conceiving those systems as collective structures with emergent behaviors that cannot be explained by the sum of their individual parts. For example, the world economy, the biological processes that occur in cells or ecosystems, mass mobilization, and the performance of organizations all depend on the structure and dynamics of the whole network rather than on the sum of individual behaviors. Recent and future technologies will allow us to collect more data more quickly from those systems, allowing us to detect and promote more interdependencies between the units of the system. For example, in the near future it will be possible to completely map the connectome in the brain. Or perhaps we will be able to monitor the activity within cities on an unprecedented scale or reveal the interdependencies between financial and economic activities to help us prevent future economic and societal crises. We might therefore expect that the observation of systems will deliver more and more *networked data*. Network analysis will be the required tool for validating, modeling, and predicting the behavior of those systems.

IV.19 Classical Mechanics

David Tong

Classical mechanics is an ambitious subject. Its purpose is to predict the future and reconstruct the past, to determine the history of every particle in the universe.

The fundamental principles of classical mechanics were laid down by Galileo and Newton in the sixteenth and seventeenth centuries. They provided a framework to explain vast swathes of the natural world, from planets to tides to falling cats. In later centuries the framework of classical mechanics was reformulated, most notably by Lagrange and Hamilton. While this new way of viewing classical mechanics often makes it simpler to solve problems, its main advantage lies in the new mathematical perspective it offers on the subject. In particular, it reveals the door to the quantum world that lies beyond the classical.

This article begins by reviewing the Newtonian framework, providing examples of important physical systems that can be solved. It then goes on to describe the Lagrangian and Hamiltonian frameworks of classical mechanics. Throughout, the emphasis of the article is more on the role that classical mechanics plays in the fundamental laws of physics than on practical engineering applications of the theory.

1 Newtonian Mechanics

Newtonian mechanics describes the motion of *particles*, which are defined to be objects of insignificant size. This means that if we want to say what a particle looks like at a given time t , the only information that we have to give is its position in \mathbb{R}^3 , specified by a 3-vector $\mathbf{r} \equiv (x, y, z)$. The goal of classical dynamics is to determine the vector function $\mathbf{r}(t)$ in any given situation. This, in turn, tells us the velocity $\mathbf{v} = d\mathbf{r}/dt \equiv \dot{\mathbf{r}}$ of the particle.

1.1 Newton's Laws of Motion

The motion of a particle of mass m at the position \mathbf{r} is governed by a second-order differential equation known as *Newton's second law*:

$$\frac{d\mathbf{p}}{dt} = \mathbf{F}(\mathbf{r}, \dot{\mathbf{r}}; t), \quad (1)$$

where $\mathbf{p} = m\dot{\mathbf{r}}$ is the momentum of the particle and \mathbf{F} is the force, an input that must be specified. Examples will be given below. In general, the force can depend on both the position \mathbf{r} and the velocity $\dot{\mathbf{r}}$. It can also depend explicitly on time.

In most situations the mass is independent of time. In this case, Newton's second law reduces to the familiar form $\mathbf{F} = m\mathbf{a}$, where $\mathbf{a} \equiv \ddot{\mathbf{r}}$ is the acceleration. We will not consider phenomena with time-dependent mass in the following.

Because (1) is a *second-order* differential equation, a unique solution exists only if we specify two initial conditions. This has a consequence: if we are given a snapshot of some situation and asked what happens next, then there is no way of knowing the answer. It is not enough to be told only the positions of the particles at some point in time; we need to know their velocities too.

1.1.1 Principle of Relativity

Equation (1) is not quite correct as stated; we must add the caveat that it holds in an *inertial frame*. This is a choice of coordinates appropriate for an observer who sees a free particle travel in a straight line, also known as uniform motion.

The statement that, in the absence of a force, a particle travels in a straight line is sometimes called *Newton's first law*. However, setting $\mathbf{F} = 0$ in (1) already tells us that free particles travel in straight lines. So is the first law nothing more than a special case of the second? In fact, a better formulation of the first law is the statement that inertial frames exist. This then sets the stage for the second law.

Inertial frames are not unique. Indeed, there are infinitely many of them. Let S be an inertial frame in which the position of a particle is measured as \mathbf{r} . There are then $10 = 3 + 3 + 3 + 1$ independent transformations $S \rightarrow S'$ such that S' is also an inertial frame. These transformations are the following.

Spatial translation: $\mathbf{r}' = \mathbf{r} + \mathbf{c}$ for any constant \mathbf{c} .

Rotations: $\mathbf{r}' = O\mathbf{r}$, where O is a 3×3 orthogonal matrix with $O^T O = I$.

Boosts: $\mathbf{r}' = \mathbf{r} + \mathbf{u}t$ for constant velocity \mathbf{u} .

Time translation: $t' = t + d$ for constant d .

If the motion of a particle is uniform in S , then it will also be uniform in S' . These transformations make up the *Galilean group* under which Newton's laws are invariant. The physical meaning of these transformations is that position, direction, and velocity are relative. But acceleration is not. One does not have to accelerate relative to something else. It makes perfect sense to simply say that one is, or is not, accelerating.

1.1.2 Systems of Particles

The discussion above is restricted to the motion of a single particle. It is simple to generalize to many particles; we just add an index to everything in sight. Let particle i have mass m_i and position \mathbf{r}_i , where $i = 1, \dots, N$, with N the number of particles. Newton's law now reads

$$\frac{d\mathbf{p}_i}{dt} = \mathbf{F}_i, \quad (2)$$

where \mathbf{F}_i is the force on the i th particle. The novelty is that forces can now be working between particles. In general, we can decompose the force as

$$\mathbf{F}_i = \sum_{j \neq i} \mathbf{F}_{ij} + \mathbf{F}_i^{\text{ext}},$$

where \mathbf{F}_{ij} is the force acting on the i th particle due to the j th particle, while $\mathbf{F}_i^{\text{ext}}$ is the external force on the i th particle.

The total mass of the system is $M = \sum_i m_i$. We define the *center of mass* as $\mathbf{R} = \sum_i m_i \mathbf{r}_i / M$ and the total momentum as $\mathbf{P} = \sum_i \mathbf{p}_i = M\mathbf{R}$.

The center of mass motion is particularly simple. From (1),

$$\begin{aligned} M\ddot{\mathbf{R}} &= \sum_i \mathbf{F}_i = \sum_i \sum_{j \neq i} \mathbf{F}_{ij} + \sum_i \mathbf{F}_i^{\text{ext}} \\ &= \sum_{i < j} (\mathbf{F}_{ij} + \mathbf{F}_{ji}) + \sum_i \mathbf{F}_i^{\text{ext}}, \end{aligned}$$

where, in the second line, we have rewritten the sum to be over all pairs $i < j$. At this stage we invoke *Newton's third law of motion*: every action has an equal and opposite reaction. Or, in equation form, $\mathbf{F}_{ij} = -\mathbf{F}_{ji}$. We see that the first term vanishes and we are left with

$$M\ddot{\mathbf{R}} = \sum_i \mathbf{F}_i^{\text{ext}}.$$

This is identical in form to Newton's second law (1) for a single particle. This is an important formula. It says that the center of mass of a system of particles acts as if all the mass were concentrated there. In other words,

it does not matter if you throw a tennis ball or a very lively cat; the center of mass of each traces the same path.

1.2 Forces

Newton's second law is not useful until someone else tells us what the force \mathbf{F} is in any given situation. Here we provide several examples of forces.

1.2.1 Conservative Forces and Energy

We start by considering time-independent forces that are a function only of the position of the particle, $\mathbf{F} = \mathbf{F}(\mathbf{r})$. Within this class there is a special class known as *conservative forces*. These can be expressed as

$$\mathbf{F} = -\nabla V(\mathbf{r})$$

for some scalar function $V(\mathbf{r})$. Systems that admit a potential of this form include gravitational, electrostatic, and interatomic forces. The importance of conservative forces lies in the fact that there is a *conserved quantity* called *energy*:

$$E = \frac{1}{2}m\dot{\mathbf{r}} \cdot \dot{\mathbf{r}} + V(\mathbf{r}) \equiv T + V.$$

(Recall that the scalar dot product is defined as $\dot{\mathbf{r}} \cdot \dot{\mathbf{r}} = \dot{x}^2 + \dot{y}^2 + \dot{z}^2$.) The function T is known as the *kinetic energy*; V is known as the *potential energy*. It is simple to show that if the equation of motion (1) is obeyed, then E does not change over time:

$$\frac{dE}{dt} = (m\ddot{\mathbf{r}} + \nabla V) \cdot \dot{\mathbf{r}} = 0.$$

In section 2.3 we prove a result called Noether's theorem, which offers a deep explanation of why a conserved quantity called energy exists.

Example (harmonic oscillator). Perhaps the simplest example of a conservative force is provided by the *harmonic oscillator*, which describes a particle attached to a spring. The particle moves in one dimension, with position $x(t)$ and has potential energy $V = \frac{1}{2}kx^2$, where $k > 0$ is known as the spring constant. The resulting force, $F = -kx$, is known as HOOKE'S LAW [III.15]. The equation of motion $m\ddot{x} = -kx$ has the general solution $x = A \cos \omega_0 t + B \sin \omega_0 t$, where A and B are integration constants. This describes a particle oscillating around the origin with angular frequency $\omega_0 = \sqrt{k/m}$.

The harmonic oscillator is by far the most important system in all of theoretical physics. For any system described by a potential energy V , the stable equilibrium points are the minima of V . This means that

if the particle is placed at an equilibrium point then, by construction, $dV/dx = 0$, ensuring that it remains at the equilibrium point for all time. Moreover, Taylor expanding the potential tells us that small deviations from equilibrium are generically governed by the harmonic oscillator.

1.2.2 Central Forces

Central forces form a subclass of conservative forces in which the potential depends only on the distance to the origin:

$$V(\mathbf{r}) = V(r),$$

where $r = |\mathbf{r}|$. The resulting force always points in the direction of the origin:

$$\mathbf{F}(r) = -\nabla V = -\frac{dV}{dr}\hat{\mathbf{r}}, \quad (3)$$

where $\hat{\mathbf{r}} \equiv \mathbf{r}/r$ is the unit radial vector. In addition to energy, central forces enjoy another conserved quantity, known as *angular momentum*:

$$\mathbf{L} = m\mathbf{r} \times \dot{\mathbf{r}},$$

where \times denotes the CROSS PRODUCT [I.2 §24]. Notice that, in contrast to the linear momentum $\mathbf{p} = m\dot{\mathbf{r}}$, the angular momentum \mathbf{L} depends on the choice of origin. It is perpendicular to both the position and the momentum.

When we take the time derivative of \mathbf{L} we get two terms. But one of these contains $\dot{\mathbf{r}} \times \dot{\mathbf{r}} = \mathbf{0}$, and we are left with

$$\frac{d\mathbf{L}}{dt} = m\mathbf{r} \times \ddot{\mathbf{r}} = \mathbf{r} \times \mathbf{F}.$$

The quantity $\boldsymbol{\tau} = \mathbf{r} \times \mathbf{F}$ is called the *torque*. For a general force \mathbf{F} , we find an equation that is very similar to Newton's law: $d\mathbf{L}/dt = \boldsymbol{\tau}$. However, for central forces (3), \mathbf{F} is parallel to the position \mathbf{r} and the torque vanishes. We find that angular momentum is conserved:

$$\frac{d\mathbf{L}}{dt} = \mathbf{0}.$$

As with energy, we will gain a better understanding of why \mathbf{L} is conserved when we prove Noether's theorem in section 2.3. For now, note that \mathbf{L} is a constant vector and, by construction, $\mathbf{L} \cdot \mathbf{r} = 0$, which means that motion governed by a central potential takes place in a plane perpendicular to the vector \mathbf{L} .

1.2.3 Gravity

To the best of our knowledge, there are four fundamental forces in nature. They are gravity, electromagnetism, the strong nuclear force, and the weak nuclear force.

The two nuclear forces operate only on small scales, comparable with the size of the nucleus of an atom, and it makes little physical sense to discuss them without quantum mechanics. We will discuss the remaining two, starting with Newtonian gravity.

Gravity is a conservative force. Consider a particle of mass M fixed at the origin. A particle of mass m moving in its presence experiences a central potential energy

$$V(r) = -\frac{GMm}{r}. \quad (4)$$

Here G is Newton's constant; it determines the strength of the gravitational force and is given by $G \approx 6.67 \times 10^{-11} \text{ m}^3 \text{ kg}^{-1} \text{ s}^{-2}$. The force on the particle, $\mathbf{F} = -\nabla V$, points toward the origin and is proportional to $1/r^2$. For this reason it is called the *inverse-square law*.

Motion governed by the potential (4) describes the orbits of planets around the sun and is known as the Kepler problem. It is not difficult to solve Newton's equation for this potential, and solutions can be found in all of the references in the further reading section below. Instead, here we present a very slick, but indirect, method to find the orbits of the planets. We have already seen that the conservation of angular momentum ensures that the motion takes place in a plane. However, the potential (4) is special since it admits yet another conserved quantity known as the *Laplace–Runge–Lenz* vector:

$$\mathbf{e} = \frac{\dot{\mathbf{r}} \times \mathbf{L}}{GMm} - \frac{\mathbf{r}}{r}.$$

With a little algebra, one can show that $d\mathbf{e}/dt = 0$. Its magnitude $e = |\mathbf{e}|$ satisfies

$$er \cos \theta = L^2/GMm^2 - r,$$

where θ is the angle between \mathbf{L} and \mathbf{r} . This is the equation for a conic section. The solution with $e < 1$ describes an ellipse, with the origin at one of the foci. For the special case of $e = 0$, the orbit is a circle. Note that these orbits are closed: the particle periodically returns to the same position. This is not generally true for orbits in central potentials other than (4). The solutions with $e > 1$ are not closed orbits; these describe hyperbolas.

The elliptical solutions with $e < 1$ describe the planetary orbits, with the sun sitting at the focus. Nearly all planets in the solar system have $e < 0.1$, which means that their orbits are approximately circular. The only exception is Mercury, the closest planet to the sun, which has $e \approx 0.2$. In contrast, some comets have very eccentric orbits. The most famous, Halley's Comet, has $e \approx 0.97$.

We could try to extend our analysis to the problem of three objects all moving under their mutual gravity, but here things are dramatically harder. No general solution to the three-body problem is known, and to answer any practical questions one must resort to numerical methods. Historically, though, the study of the three-body problem has led to a number of new mathematical developments, including chaos.

1.2.4 Electromagnetism

Throughout the universe, at each point in space there exist two vectors, \mathbf{E} and \mathbf{B} . These are known as the *electric* and *magnetic* fields. The laws governing \mathbf{E} and \mathbf{B} are called MAXWELL'S EQUATIONS [III.22]. An important application of these equations is described in MAGNETOHYDRODYNAMICS [IV.29].

For the purposes of this article, the role of \mathbf{E} and \mathbf{B} is to guide any particle that carries electric charge. The force experienced by a particle with electric charge q is called the *Lorentz force*:

$$\mathbf{F} = q(\mathbf{E}(\mathbf{r}) + \dot{\mathbf{r}} \times \mathbf{B}(\mathbf{r})). \quad (5)$$

Here, the notation $\mathbf{E}(\mathbf{r})$ and $\mathbf{B}(\mathbf{r})$ emphasizes that the electric and magnetic fields are functions of position. The term $\dot{\mathbf{r}} \times \mathbf{B}$ involves the vector cross product.

In principle, both \mathbf{E} and \mathbf{B} can change in time. However, here we will consider only situations in which they are static. In this case, the electric field is always of the form

$$\mathbf{E} = -\nabla \phi$$

for some function $\phi(\mathbf{r})$ called the *electric potential* or the *scalar potential*. This means that a static electric field gives rise to a conservative force. The electric potential is related to the potential energy by $V = q\phi$.

As an example, consider the electric field due to a particle of charge Q fixed at the origin. This is given by

$$\mathbf{E} = -\nabla \left(\frac{Q}{4\pi\epsilon_0 r} \right) = \frac{Q}{4\pi\epsilon_0 r^2} \hat{\mathbf{r}}. \quad (6)$$

The quantity ϵ_0 has the grand name the *permittivity of free space* and is a constant given by $\epsilon_0 \approx 8.85 \times 10^{-12} \text{ m}^{-3} \text{ kg}^{-1} \text{ s}^2 \text{ C}^2$, where C stands for Coulomb, the unit of electric charge. The quantity ϵ_0 should be thought of as characterizing the strength of the electric interaction.

The force between two particles with charges Q and q is $\mathbf{F} = q\mathbf{E}$, with \mathbf{E} given by (6). This is known as the *Coulomb force*. It is a remarkable fact that, mathematically, the force is identical to the Newtonian gravitational force arising from (4): both forces have the

characteristic inverse-square form. This means that the classical solutions describing an electron orbiting a proton, say, are identical to those describing the planets orbiting the sun.

We turn now to magnetic fields. These give rise to a velocity-dependent force (5) with magnitude proportional to the speed of the particle, but with direction perpendicular to that of the particle. The magnetic force does not contribute to the energy of the particle.

For a constant magnetic field $\mathbf{B} = (0, 0, B)$, the equations of motion read

$$m\ddot{x} = qB\dot{y}, \quad m\ddot{y} = -qB\dot{x},$$

together with $\ddot{z} = 0$. This last equation tells us that the particle travels at constant velocity in the z -direction parallel to \mathbf{B} . The equations in the xy -plane, perpendicular to \mathbf{B} , are also easily solved to reveal that a magnetic field causes particles to move in circles:

$$x = \frac{v}{\omega}(\cos \omega t - 1) \quad \text{and} \quad y = -\frac{v}{\omega} \sin \omega t,$$

where v is the speed and $\omega = qB/m$ is the *cyclotron frequency*. The time to undergo a full circle is fixed: $T = 2\pi/\omega$, independent of v . The bigger the circle, the faster the particle moves.

1.2.5 Friction

At a fundamental level, energy is always conserved. However, in many everyday processes this does not appear to be the case. At a microscopic level, the kinetic energy of an object is transferred to the motion of many atoms, where it manifests itself as an increase in temperature. If we do not care about what all these atoms are doing, it is useful to package our ignorance into a single macroscopic force that we call *friction*. In practice, friction forces are important in nearly all applications, not just in questions in fundamental physics.

There are a number of different kinds of friction forces. When two solid objects are in contact they experience dry friction. Experimentally, one finds that the complicated dynamics involved in friction can often be summarized by a single force that opposes the motion. This force has magnitude $F = \mu R$, where R is the component of the reaction force normal to the floor and μ is a constant called the *coefficient of friction*. For steel rubbing against steel, $\mu \approx 0.6$. With a layer of grease added between the metals, it drops to $\mu \approx 0.1$. For steel rubbing against ice, it is as low as $\mu \approx 0.02$.

A somewhat different form of friction, known as *drag*, occurs when an object moves through a fluid,

either a liquid or a gas. The resistive force is opposite to the direction of the velocity and, typically, falls into one of two categories.

Linear drag is described by $\mathbf{F} = -\gamma \mathbf{v}$, where the coefficient of friction, γ , is a constant. This form of drag holds for objects moving slowly through very viscous fluids. For a spherical object of radius L , there is a formula due to Stokes that gives $\gamma = 6\pi\eta L$, where η is the dynamic viscosity of the fluid.

In contrast, quadratic drag is described by $\mathbf{F} = -\gamma|\mathbf{v}|\mathbf{v}$, where, again, γ is a constant. For quadratic friction, γ is usually proportional to the surface area of the object, i.e., $\gamma \propto L^2$. Quadratic drag holds for fast-moving objects in less viscous fluids. This includes objects falling in air.

The kind of drag experienced by an object is determined by the *Reynolds number* $R \equiv \rho v L^2 / \eta$, where ρ is the density of the fluid and η is the viscosity. For $R \ll 1$, linear drag dominates; for $R \gg 1$, quadratic friction dominates.

Systems that suffer any kind of friction are *dissipative*. They do not have a conserved energy.

To illustrate the effect of friction we return to the harmonic oscillator that we met in section 1.2.1. Adding a linear drag term to the equation of motion gives the damped harmonic oscillator:

$$m\ddot{x} = -\gamma\dot{x} - kx.$$

We can look for solutions of the form $x = e^{i\beta t}$. The results fall into one of the following three categories depending on the relative values of the natural frequency $\omega_0^2 = k/m$ and the magnitude of friction $\alpha = \gamma/2m$.

Underdamped: $\omega_0^2 > \alpha^2$. The solution takes the form $x = e^{-\alpha t}(Ae^{i\Omega t} + Be^{-i\Omega t})$, where $\Omega = \sqrt{\omega_0^2 - \alpha^2}$.

Here, the system oscillates with a frequency $\Omega < \omega_0$, while the amplitude of the oscillations decays exponentially.

Overdamped: $\omega_0^2 < \alpha^2$. The general solution is now $x = e^{-\alpha t}(Ae^{\Omega t} + Be^{-\Omega t})$, where $\Omega = \sqrt{\alpha^2 - \omega_0^2}$. There are no oscillations.

Critical damping: $\omega_0^2 = \alpha^2$. For this special case, the general solution is $x = (A + Bt)e^{-\alpha t}$. Again, there are no oscillations, but the system does achieve some mild linear growth for times $t < 1/\alpha$, after which it decays away.

In each of these cases, the solutions tend asymptotically to $x = 0$ at large times. Energy is not conserved.

2 The Lagrangian Formulation

There are two reformulations of Newtonian mechanics: the first is due to Lagrange and the second to Hamilton. These new approaches are not particularly useful in modeling phenomena in which friction plays a dominant role. However, when energy is conserved these reformulations provide a new perspective on classical mechanics, one that is more elegant, is more powerful, and, ultimately, provides the link to more sophisticated theories of physics, such as quantum mechanics. The starting point is one of the most profound ideas in theoretical physics: the *principle of least action*.

2.1 The Principle of Least Action

First, let us get our notation right. Part of the power of the Lagrangian formulation over the Newtonian approach is that it does away with vectors in favor of more general coordinates. We start by doing this trivially. Let us rewrite the positions of N particles with coordinates \mathbf{r}_i as x^a , where $a = 1, \dots, 3N \equiv n$. Newton's equations (2) then read

$$\dot{p}_a = -\frac{\partial V}{\partial x^a}, \quad (7)$$

where $p_a = m_a \dot{x}^a$. The number of *degrees of freedom* of the system is said to be n . These parametrize an n -dimensional space known as the *configuration space* C . Each point in C specifies a configuration of the system (i.e., the positions of all N particles). Time evolution gives rise to a curve in C .

Define the *Lagrangian* to be a function of the positions x^a and the velocities \dot{x}^a of all the particles. It is formulated as follows:

$$L(x^a, \dot{x}^a) = T(\dot{x}^a) - V(x^a), \quad (8)$$

where $T = \frac{1}{2} \sum_a m_a (\dot{x}^a)^2$ is the kinetic energy and $V(x^a)$ is the potential energy. Note the minus sign between T and V . To describe the principle of least action, we consider all smooth paths $x^a(t)$ in C with fixed endpoints such that

$$x^a(t_i) = x_{\text{initial}}^a \quad \text{and} \quad x^a(t_f) = x_{\text{final}}^a.$$

Of all these possible paths, only one is the true path taken by the system. Which one?

To each path let us assign a number called the *action* S , defined as

$$S[x^a(t)] = \int_{t_i}^{t_f} L(x^a(t), \dot{x}^a(t)) dt.$$

The action is a functional (i.e., a function of the path that is itself a function). The principle of least action is the following result.

Theorem (principle of least action). *The actual path taken by the system is an extremum of S .*

Proof. Consider varying a given path slightly:

$$x^a(t) \rightarrow x^a(t) + \delta x^a(t),$$

where we fix the endpoints of the path by demanding that $\delta x^a(t_i) = \delta x^a(t_f) = 0$. Then the change in the action is

$$\begin{aligned} \delta S &= \delta \int_{t_i}^{t_f} L dt \\ &= \int_{t_i}^{t_f} \delta L dt \\ &= \int_{t_i}^{t_f} \left(\frac{\partial L}{\partial x^a} \delta x^a + \frac{\partial L}{\partial \dot{x}^a} \delta \dot{x}^a \right) dt. \end{aligned}$$

In this last equation we are using the *summation convention*, according to which any term with a repeated a or b index is summed. This means that this term, and similar terms in subsequent equations, should be thought of as including an implicit $\sum_{a=1}^{3N}$. The second term above includes $\delta \dot{x}^a \equiv d(\delta x^a)/dt$ and can be integrated by parts to get

$$\delta S = \int_{t_i}^{t_f} \left(\frac{\partial L}{\partial x^a} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{x}^a} \right) \right) \delta x^a dt + \left[\frac{\partial L}{\partial \dot{x}^a} \delta x^a \right]_{t_i}^{t_f}.$$

But the final term vanishes since we have fixed the endpoints of the path so that $\delta x^a(t_i) = \delta x^a(t_f) = 0$. The requirement that the action is an extremum says that $\delta S = 0$ for all changes in the path $\delta x^a(t)$. We see that this holds if and only if

$$\frac{\partial L}{\partial x^a} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{x}^a} \right) = 0 \quad \forall a. \quad (9)$$

These are known as the **EULER-LAGRANGE EQUATIONS** [III.12]. To finish the proof we need only show that these equations are equivalent to Newton's. From the definition of the Lagrangian (8), we have $\partial L / \partial x^a = -\partial V / \partial x^a$, while $\partial L / \partial \dot{x}^a = p_a$. It is then easy to see that equations (9) are indeed equivalent to (7). \square

The principle of least action is an example of a variational principle of the type discussed further in **CALCULUS OF VARIATIONS** [IV.6]. The path of the particle is viewed globally, as a whole rather than at any instance in time. At first this may appear somewhat teleological. Yet, as we have shown above, this perspective is entirely equivalent to the more local Newtonian methodology.

The principle of *least* action is a slight misnomer. The proof requires only that $\delta S = 0$; it does not specify whether it is a maximum or a minimum of S . Since $L = T - V$, we can always increase S by taking a very fast, wiggly path with $T \gg 0$, so the true path is never a

maximum. However, it may be either a minimum or a saddle point. “Principle of stationary action” would be a more accurate, but less catchy, name. It is sometimes called “Hamilton’s principle.”

Somewhat astonishingly, all the fundamental laws of physics can be written in terms of an action principle. This includes electromagnetism, general relativity, the standard model of particle physics, and attempts to go beyond the known laws of physics such as string theory. There is also a beautiful generalization of the action principle to quantum mechanics that is due to Richard Feynman. It is known as the theory of *path integrals*, and in it the particle takes *all paths* with some weight determined by S .

Returning to classical mechanics, there are two very important reasons for working with the Lagrangian formulation. The first is that the Euler-Lagrange equations hold in any coordinate system, while Newton’s laws are restricted to an inertial frame. The second is the ease with which we can deal with certain types of constraints in the Lagrangian system. We discuss the former of these reasons below, but first let us look at an example.

Example (the Lorentz force). A particle with charge q moving in a background electric and magnetic field experiences the Lorentz force law (5). A static electric field $\mathbf{E} = -\nabla\phi$ gives rise to a conservative force and fits naturally into the Lagrangian formulation. But in the presence of a magnetic field \mathbf{B} , it is less obvious that the equation of motion can be written using a Lagrangian. To do so, we first need to introduce the vector potential \mathbf{A} and write (possibly time-dependent) magnetic and electric fields as

$$\mathbf{B} = \nabla \times \mathbf{A}, \quad \mathbf{E} = -\nabla\phi - \frac{1}{c} \frac{\partial \mathbf{A}}{\partial t},$$

where c is the speed of light. One can then check that the Euler-Lagrange equations arising from the Lagrangian

$$L = \frac{1}{2}m\dot{\mathbf{r}} \cdot \dot{\mathbf{r}} - q\left(\phi - \frac{1}{c}\dot{\mathbf{r}} \cdot \mathbf{A}\right) \quad (10)$$

coincide with Newton’s equations for the Lorentz force law (5).

2.2 Changing Coordinate Systems

We stressed in section 1 that Newton’s equation of motion (2) holds only in inertial frames. In contrast, Lagrange’s equations hold in any coordinate system. This means that we could choose to work with any coordinates

$$q^a = q^a(x_1, \dots, x_{3N}; t),$$

where we have included the possibility of using a coordinate system that changes with time t . The Lagrangian can then be written as a function of $L = L(q^a, \dot{q}^a; t)$, and the equations of motion (9) are equivalent to

$$\frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}^a} \right) - \frac{\partial L}{\partial q^a} = 0. \quad (11)$$

One can prove the equivalence of (9) and (11) through application of the chain rule. Alternatively, one can note that the principle of least action is a statement about the path taken and makes no mention of the coordinate used; it must therefore be true in all coordinate systems.

The general variables q^a are called *generalized coordinates*; the variables $p_a = \partial L / \partial \dot{q}^a$ are called *generalized momenta*. These coincide with what we usually call “momenta” only in Cartesian coordinates.

2.2.1 Rotating Coordinate Systems

We can illustrate the flexibility of the Lagrangian approach by deriving the fictitious forces at play in a noninertial, rotating coordinate system. Consider a free particle with Lagrangian

$$L = \frac{1}{2}m\dot{\mathbf{r}} \cdot \dot{\mathbf{r}}.$$

Now measure the motion of the particle with respect to a coordinate system that is rotating with constant angular velocity $\boldsymbol{\omega} = (0, 0, \omega)$ about the z -axis. Denote the coordinates in the rotating frame as $\mathbf{r}' = (x', y', z')$. We have the relationships $z' = z$ and

$$\begin{aligned} x' &= x \cos \omega t + y \sin \omega t, \\ y' &= y \cos \omega t - x \sin \omega t. \end{aligned}$$

These expressions can be substituted directly into the Lagrangian to find L in terms of the rotating coordinates:

$$\begin{aligned} L &= \frac{1}{2}m[(\dot{x}' - \omega y')^2 + (\dot{y}' + \omega x')^2 + \dot{z}^2] \\ &\equiv \frac{1}{2}m(\dot{\mathbf{r}}' + \boldsymbol{\omega} \times \mathbf{r}') \cdot (\dot{\mathbf{r}}' + \boldsymbol{\omega} \times \mathbf{r}'). \end{aligned}$$

We can now derive the Euler-Lagrange equations in the rotating frame, differentiating L with respect to $r^{a'}$ and $\dot{r}^{a'}$. We find that

$$m(\ddot{\mathbf{r}}' + \boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}') + 2\boldsymbol{\omega} \times \dot{\mathbf{r}}') = 0.$$

We learn that in the rotating frame the particle does not follow a straight line with $\ddot{\mathbf{r}}' = 0$. Instead, we find the appearance of two extra terms in the equation of motion.

The term $\boldsymbol{\omega} \times (\boldsymbol{\omega} \times \mathbf{r}')$ is called the *centrifugal force*. It points outward in the plane perpendicular to $\boldsymbol{\omega}$ with

magnitude $m\omega^2|\mathbf{r}'_{\perp}| = m|\mathbf{v}_{\perp}|^2/|\mathbf{r}'_{\perp}|$, where the subscript \perp denotes the projection perpendicular to $\mathbf{\omega}$. This is the force you feel pinning you to the side of a car when you take a corner too fast.

The term $-2\mathbf{\omega} \times \dot{\mathbf{r}}$ is called the *Coriolis force*. Notice that it is mathematically identical to the Lorentz force (5) for a particle moving in a constant magnetic field. In myth the Coriolis force determines the direction in which the water draining from a sink rotates, but in practice it is too small on domestic scales to have a noticeable effect. It is, however, significant on large length scales, where it dictates the circulation of oceans and the atmosphere.

The centrifugal and Coriolis forces are referred to as *fictitious forces* because they are a result of the reference frame rather than any interaction. However, we should not underestimate their importance just because they are “fictitious.” According to Einstein’s theory of general relativity, gravity is also a fictitious force, on the same footing as the Coriolis and centrifugal forces.

2.3 Noether’s Theorem

A *symmetry* of a physical system is an invariance under a transformation. We have already met a number of symmetries in our discussion of inertial frames; the laws of (nonrelativistic) physics are invariant under the Galilean group, composed of rotations and translations in space and time. A beautiful theorem due to Emmy Noether relates these symmetries to conservation laws.

Consider a one-parameter family of maps between generalized coordinates

$$q^a(t) \rightarrow Q^a(s, t), \quad s \in \mathbb{R},$$

such that $Q^a(0, t) = q^a(t)$. This transformation is said to be a continuous *symmetry* of the Lagrangian L if

$$\frac{\partial}{\partial s} L(Q^a(s, t), \dot{Q}^a(s, t); t) = 0.$$

Noether’s theorem states that for each such symmetry there exists a conserved quantity. The proof is straightforward. We compute

$$\frac{\partial L}{\partial s} = \frac{\partial L}{\partial Q^a} \frac{\partial Q^a}{\partial s} + \frac{\partial L}{\partial \dot{Q}^a} \frac{\partial \dot{Q}^a}{\partial s}.$$

Evaluated at $s = 0$, we have

$$\begin{aligned} \frac{\partial L}{\partial s} \Big|_{s=0} &= \frac{\partial L}{\partial Q^a} \frac{\partial Q^a}{\partial s} \Big|_{s=0} + \frac{\partial L}{\partial \dot{Q}^a} \frac{\partial \dot{Q}^a}{\partial s} \Big|_{s=0} \\ &= \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{Q}^a} \right) \frac{\partial Q^a}{\partial s} \Big|_{s=0} + \frac{\partial L}{\partial \dot{Q}^a} \frac{\partial \dot{Q}^a}{\partial s} \Big|_{s=0}, \end{aligned}$$

where we have used the Euler-Lagrange equations. The result is a total derivative:

$$\frac{\partial L}{\partial s} \Big|_{s=0} = \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{Q}^a} \frac{\partial Q^a}{\partial s} \Big|_{s=0} \right) = 0.$$

We learn that the quantity $\sum_a (\partial L / \partial \dot{Q}^a) (\partial Q^a / \partial s)$, evaluated at $s = 0$, is constant for all time whenever the equations of motion are obeyed. Notice that the proof of Noether’s theorem is constructive: it does not just tell us about the existence of a conserved quantity, it also tells us what that quantity is.

Homogeneity of Space

Consider a closed system of N particles interacting through a potential $V(|\mathbf{r}_i - \mathbf{r}_j|)$ that, as the notation suggests, depends only on the relative distances between the particles $i, j = 1, \dots, N$. The Lagrangian

$$L = \frac{1}{2} \sum_i m_i \dot{\mathbf{r}}_i \cdot \dot{\mathbf{r}}_i - V(|\mathbf{r}_i - \mathbf{r}_j|) \quad (12)$$

has the symmetry of translation: $\mathbf{r}_i \rightarrow \mathbf{r}_i + s\mathbf{n}$ for any vector \mathbf{n} and for any real number s , so $L(\mathbf{r}_i, \dot{\mathbf{r}}_i, t) = L(\mathbf{r}_i + s\mathbf{n}, \dot{\mathbf{r}}_i, t)$. This is the statement that space is homogeneous. From Noether’s theorem we can compute the conserved quantity associated with translations. It is $\sum_i \mathbf{p}_i \cdot \mathbf{n}$, which we recognize as the total linear momentum in the direction \mathbf{n} . Since this holds for all \mathbf{n} , we conclude that $\sum_i \mathbf{p}_i$ is conserved. The familiar fact that the total linear momentum is conserved is due to the homogeneity of space.

Homogeneity of Time

The laws of physics are the same today as they were yesterday. This invariance under time translations also gives rise to a conserved quantity. Mathematically, this means that L is invariant under $t \rightarrow t + s$, or, in other words, $\partial L / \partial t = 0$. It is straightforward to check that this condition ensures that

$$H = \sum_a \dot{Q}^a (\partial L / \partial \dot{Q}^a) - L$$

is conserved. This is the *energy* of the system. We learn that time is to energy what space is to momentum, a lesson that resonates into the relativistic world of Einstein. We will meet the quantity H again in the next section, where, viewed from a slightly different perspective, it will be rebranded the Hamiltonian.

One can also show that the isotropy of space, meaning invariance under rotations, gives rise to the conservation of angular momentum. In fact, suitably generalized, it turns out that *all* conservation laws in nature are

related to symmetries through Noether's theorem. This includes the conservation of electric charge and the conservation of particles such as protons and neutrons (known as baryons).

3 The Hamiltonian Formulation

The next step in the formulation of classical mechanics is due to Hamilton. The basic idea is to place the generalized coordinates q^a and the generalized momenta $p_a = \partial L / \partial \dot{q}^a$ on a more symmetric footing.

We can start by thinking pictorially. Recall that the coordinates $\{q^a\}$ define a point in n -dimensional *configuration space* C . Time evolution is a path in C . However, the *state* of the system is defined by $\{q^a\}$ and $\{p_a\}$ in the sense that this information will allow us to determine the state at all times in the future. The pair $\{q^a, p_a\}$ defines a point in $2n$ -dimensional *phase space*. Since a point in phase space is sufficient to determine the future evolution of the system, paths in phase space can never cross. We say that evolution is governed by a *flow* in phase space.

3.1 Hamilton's Equations

The Lagrangian $L(q^a, \dot{q}^a; t)$ is a function of the coordinates q^a , their time derivatives \dot{q}^a , and (possibly) time. We define the *Hamiltonian* to be the Legendre transform of the Lagrangian with respect to the \dot{q}^a variables:

$$H(q^a, p_a; t) = \sum_{a=1}^n p_a \dot{q}^a - L(q^a, \dot{q}^a, t),$$

where \dot{q}^a is eliminated from the right-hand side in favor of p_a by using $p_a = \partial L / \partial \dot{q}^a = p_a(q^a, \dot{q}^a; t)$ and inverting to get $\dot{q}^a = \dot{q}^a(q^a, p_a; t)$. Now we look at the variation of H . Once again employing the summation convention, we have

$$\begin{aligned} \delta H &= (\delta p_a \dot{q}^a + p_a \delta \dot{q}^a) \\ &\quad - \left(\frac{\partial L}{\partial q^a} \delta q^a + \frac{\partial L}{\partial \dot{q}^a} \delta \dot{q}^a + \frac{\partial L}{\partial t} \delta t \right) \\ &= \delta p_a \dot{q}^a - \frac{\partial L}{\partial q^a} \delta q^a - \frac{\partial L}{\partial t} \delta t. \end{aligned}$$

But we know that this can be rewritten as

$$\delta H = \frac{\partial H}{\partial q^a} \delta q^a + \frac{\partial H}{\partial p_a} \delta p_a + \frac{\partial H}{\partial t} \delta t.$$

We now equate terms. We also make use of the Euler-Lagrange equations, which can be written as $\dot{p}_a = \partial L / \partial \dot{q}^a$. The end result is

$$\dot{p}_a = -\frac{\partial H}{\partial q^a}, \quad \dot{q}^a = \frac{\partial H}{\partial p_a}.$$

For Lagrangians with explicit time dependence these are supplemented with $-\partial L / \partial t = \partial H / \partial t$. These are *Hamilton's equations*. We have replaced n second-order differential equations by $2n$ first-order differential equations for q_a and p_a . Recast in this manner, Hamilton's equations are ideally suited for dealing with initial-value problems rather than the boundary-value problems that are more natural in the Lagrangian formulation.

A Particle in a Potential

The simplest example is a single particle moving in a potential. The Lagrangian is $L = \frac{1}{2}m\dot{\mathbf{r}} \cdot \dot{\mathbf{r}} - V(\mathbf{r})$ and the momentum $\mathbf{p} = m\dot{\mathbf{r}}$. The steps above give us the Hamiltonian

$$H = \mathbf{p} \cdot \dot{\mathbf{r}} - L = \frac{1}{2m}\mathbf{p} \cdot \mathbf{p} + V(\mathbf{r}).$$

Hamilton's equations are simply $\dot{\mathbf{r}} = \mathbf{p}/m$ and $\dot{\mathbf{p}} = -\nabla V$, both of which are familiar: the first is the definition of momentum in terms of velocity; the second is Newton's equation for this system.

The Lorentz Force

A charged particle moving in an electric and magnetic field is described by the Lagrangian (10). From this we can compute the momentum, $\mathbf{p} = m\dot{\mathbf{r}} + (q/c)\mathbf{A}$, which now differs from what we usually call momentum by the addition of the vector potential \mathbf{A} . The Hamiltonian is

$$H(\mathbf{p}, \mathbf{r}) = \frac{1}{2m} \left(\mathbf{p} - \frac{q}{c} \mathbf{A} \right) \left(\mathbf{p} - \frac{q}{c} \mathbf{A} \right) + q\phi.$$

One can check that Hamilton's equations reduce to Newton's equations with the Lorentz force law (5).

3.2 Looking Forward

The advantage of the Hamiltonian formulation over the Lagrangian is not really a practical one. Instead, the true value of the formulation lies in what it tells us about the structure of classical mechanics. It is, at heart, a geometric formulation of classical mechanics and can be expressed in more abstract form using the language of symplectic geometry. Moreover, the Hamiltonian framework provides a springboard for later developments, including chaos theory and integrability. (See the article on CHAOS [II.3] in this book.) Perhaps most importantly, the Hamiltonian offers the most direct link to more fundamental theories of physics and particularly to quantum mechanics.

Further Reading

This article is based on two lecture courses given by the author to undergraduates at the University of Cambridge. Full lecture notes for both courses can be downloaded from the author's Web page: www.damtp.cam.ac.uk/user/tong/teaching.html.

Lev Landau and Evgeny Lifshitz's *Mechanics* (Butterworth-Heinemann, Oxford, 3rd edn, 1982) is one of the most concise, elegant, and conceptually gorgeous textbooks ever written.

A more modern, pedagogical approach to Newtonian mechanics can be found in Mary Lunn's *A First Course in Mechanics* (Oxford Science Publications, Oxford, 1991).

A good introduction to the Lagrangian and Hamiltonian formulation is Louis Hand and Janet Finch's *Analytic Mechanics* (Cambridge University Press, Cambridge, 1998).

IV.20 Dynamical Systems

Philip Holmes

1 Introduction

The theory of dynamical systems describes the construction and analysis of models for things that move or evolve over time and space. It combines analytical, geometrical, topological, and numerical methods for studying differential equations and iterated mappings. These methods stem from the work of Newton and his successors, the great natural philosophers of the eighteenth and nineteenth centuries, and in particular from Henri Poincaré. As such, the study of dynamical systems is normal mathematics rather than the paradigm shift that some popular accounts have claimed for CHAOS THEORY [II.3]. Nonetheless, problems from the applied sciences have continued to strongly influence and motivate it, especially over the past half century (see Aubin and Dahan Dalmedico (2002) for a socio-historical discussion of developments in the turbulent decade around 1970).

It is a capacious field, implying different things to different people, including deterministic and stochastic systems of finite or infinite dimensions, ERGODIC THEORY [II.3], and holomorphic dynamics (the study of iterated functions on the complex plane). I shall focus on ordinary differential equations (ODEs) and iterated maps defined on Euclidean space \mathbb{R}^n , but note that the theory generalizes to manifolds, much of it generalizes to infinite dimensions, and some of it generalizes to stochastic systems. In contrast to classical ODE

theory, which focuses on specific initial or boundary-value problems, dynamical systems theory brings a qualitative and geometrical approach to the analysis of nonlinear ODEs, addressing the existence, stability, and global behavior of sets of solutions, rather than seeking exact or approximate expressions for individual solutions (see ORDINARY DIFFERENTIAL EQUATIONS [IV.2]).

We consider systems of ODEs (1) and discrete mappings (2):

$$\dot{x}_j = f_j(x_1, x_2, \dots, x_n; \mu), \quad (1)$$

$$x_j(l+1) = F_j(x_1(l), \dots, x_n(l); \mu), \quad (2)$$

where $j = 1, \dots, n$; \dot{x}_j denotes the time derivative; f_j and F_j are smooth, real-valued functions; the x_j are *state variables*; and μ is a *control parameter*. In solving (1) or (2) with given initial conditions $\mathbf{x}(0)$ to obtain orbits $\mathbf{x}(t) = (x_1(t), \dots, x_n(t))$ or $\{\mathbf{x}(l)\}_{l=0}^\infty$, μ is kept fixed.

In studying the ODE (1), one seeks to describe the behavior of the *flow map*

$$\mathbf{x}(t, \mathbf{x}(0)) = \phi_t(\mathbf{x}(0)) \quad \text{or} \quad \phi_t: U \rightarrow \mathbb{R}^n, \quad (3)$$

generated by the *vector field* $\mathbf{f}(\mathbf{x}) = (f_1(\mathbf{x}), \dots, f_n(\mathbf{x}))$, which transports initial points $\mathbf{x}(0) \in U \subseteq \mathbb{R}^n$ to their images at time t : $\phi_t(\mathbf{x}(0))$. If ϕ_t can be found, then, fixing a time interval $t = T$, (1) reduces to (2), but explicit formulas can be derived only in exceptional cases, and in any case the study of iterated maps is no less complicated than that of ODEs. Of course, numerical algorithms for ODEs can provide excellent approximations of ϕ_T (see NUMERICAL SOLUTION OF ORDINARY DIFFERENTIAL EQUATIONS [IV.12]).

Before describing the theory, I sketch some historical threads through the work of A. A. Andronov, V. I. Arnold, G. D. Birkhoff, A. N. Kolmogorov, S. Smale, and other key figures. Two motivating examples are then introduced: one physical and one mathematical.

2 A Brief History

Dynamical systems theory began with Poincaré's work on differential equations and celestial mechanics from 1879 to 1912. In addition to special methods for two-dimensional ODEs, many other central concepts first appeared in Poincaré's work, including *invariant manifolds* (smooth hypersurfaces composed of families of orbits), *first-return (Poincaré) maps* for the study of periodic motions, *bifurcations*, coordinate changes to *normal forms* that simplify analyses, and *perturbation methods*. Notably, Poincaré realized that, due to the

presence of “doubly asymptotic” points or *homoclinic and heteroclinic orbits*, certain differential equations describing mechanical systems with $N \geq 2$ degrees of freedom were not integrable. More precisely, they do not possess enough independent, analytic functions of \mathbf{x} that remain constant on solutions, which would imply that the geometry of invariant manifolds is relatively simple. During this period A. M. Lyapunov also made important contributions to stability theory.

Birkhoff extended Poincaré’s work, in particular proving that maps from an annulus to itself having two periodic orbits with different periods also contain complicated limit sets that separate the domains of attraction of those orbits. This prepared the way for Cartwright and Littlewood’s proof that the van der Pol equation—a periodically forced nonlinear oscillator—possesses infinitely many periodic orbits and a set of nonperiodic orbits “of the power of the continuum.” N. Levinson subsequently drew this to Smale’s attention, prompting his construction of the *horseshoe map*: a prototypical example with an unstable chaotic set, which is nonetheless *structurally stable*, implying that the flows of the original and perturbed systems are topologically equivalent (homeomorphic). The qualitative behavior of structurally stable vector fields and maps survives small perturbations.

Structural stability had been introduced by Andronov and L. S. Pontryagin in 1937 under the name “systèmes grossières” (coarse systems). From this perspective, a bifurcation occurs when a system becomes structurally unstable as a parameter varies; its behavior changes as one passes through the bifurcation point. Andronov’s group in Gorky (now Nizhni Novgorod) also did important work in bifurcation theory. M. M. Peixoto’s characterization of structurally stable flows on two-dimensional manifolds required that they possess only finitely many fixed points and periodic orbits, leading to Smale’s conjecture that the same should hold in higher dimensions. The horseshoe map, with its infinite set of periodic points, can be seen as a return map for a three-dimensional flow and thus provided a counterexample to this conjecture. Moreover, it showed that the chaos glimpsed by Poincaré was prevalent in ODEs of dimensions $n \geq 3$ as well as in maps of dimensions $n \geq 2$. Smale’s influential work in the 1960s introduced mathematicians to the field, but these ideas did not reach the applied mathematical mainstream for some time.

As was common in the Soviet Union, Andronov’s group maintained strong connections between abstract

theory and applications, in its case, nonlinear oscillators and waves, electronic circuits, and control theory. In Moscow, Kolmogorov and his students (including D. V. Anosov, Ya. G. Sinai, and Arnold) did foundational work on ergodic theory, billiards, and geodesic flows, with links to mathematical physics. Smale’s visits in 1961 and during the International Congress of Mathematicians in 1966 helped introduce their work to the wider mathematical world.

Lorenz’s paper on a three-dimensional ODE modeling Rayleigh–Bénard convection was done almost independently of the work described above, although in presenting his discovery of *sensitive dependence on initial conditions* in 1963, Lorenz appealed to Birkhoff’s work. An earlier, extra-mathematical, discovery had taken place in 1961 when Ueda, a graduate student in electrical engineering at Kyoto University, observed irregular motions in analogue computer simulations of a periodically forced van der Pol–Duffing equation.

3 Two Dynamical Systems

To motivate the theory described below, we first introduce a problem from classical mechanics and then a mathematical toy that is, perhaps surprisingly, related to it.

3.1 The Double Pendulum

Consider a pendulum comprising two rigid links, the first rotating about a fixed pivot, the second pivoting about the end of the first (see figure 1(a)). Under Newtonian mechanics, the four angles and angular velocities $\theta_1, \theta_2, \dot{\theta}_1, \dot{\theta}_2$ describe the pendulum’s *state space*, and neglecting air resistance and friction, conservation of energy implies that all motions started with given potential and kinetic energy lie on a three-dimensional subset of state space (typically, a smooth manifold). However, unlike the one-link pendulum, its motions are not generally periodic, and small changes in initial conditions yield orbits that rapidly diverge. Part (b) of figure 1 illustrates this sensitive dependence.

3.2 The Doubling Machine

Next we describe a piecewise-linear mapping defined on the interval $[0, 1]$ by the rule

$$h(x) = \begin{cases} 2x & \text{if } 0 \leq x < \frac{1}{2}, \\ 2x - 1 & \text{if } \frac{1}{2} < x \leq 1 \end{cases} \quad (4)$$

(see figure 2). An orbit of h is the sequence $\{x_n\}_{n=0}^{\infty}$ obtained by repeatedly doubling the initial value x_0 and

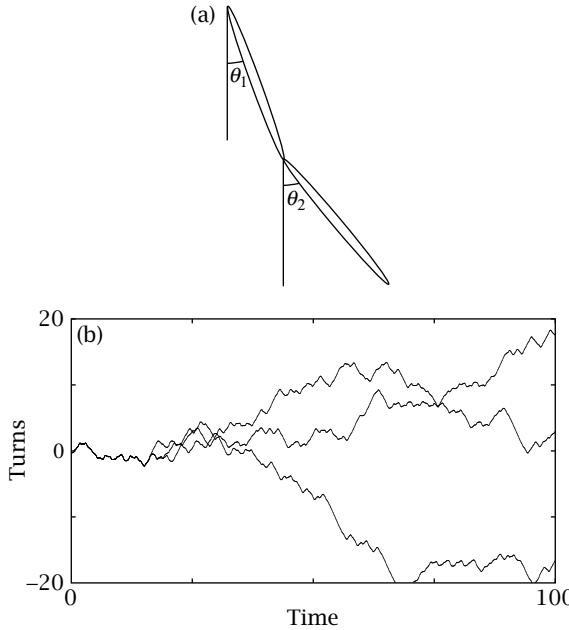

Figure 1 (a) The double pendulum. (b) The numbers of full turns, θ_2 , executed by three different orbits released from rest with $\theta_1(0) = 90^\circ$, $\theta_2(0) = -90^\circ$, and $\theta_2(0) = -(90 \pm 10^{-6})^\circ$.

subtracting the integer part at each step:

$$0.2753 \rightarrow 0.5506 \rightarrow 1.1012 = 0.1012 \rightarrow 0.2024 \rightarrow \dots$$

To understand the sensitive dependence on initial conditions and its consequences, we represent the numbers between 0 and 1 in binary form:

$$x_0 = \frac{a_1}{2} + \frac{a_2}{2^2} + \frac{a_3}{2^3} + \dots + \frac{a_j}{2^j} + \dots,$$

where each coefficient a_j is either 0 or 1. Thus,

$$x_1 = h(x_0) = 2 \sum_{j=1}^{\infty} \frac{a_j}{2^j} = a_1 + \frac{a_2}{2} + \frac{a_3}{2^2} + \dots,$$

but since the integer part is removed on every iteration, we have

$$x_1 = \frac{a_2}{2} + \frac{a_3}{2^2} + \frac{a_4}{2^3} + \dots,$$

and in general,

$$x_k = \frac{a_{k+1}}{2} + \frac{a_{k+2}}{2^2} + \dots = \sum_{j=1}^{\infty} \frac{a_{j+k}}{2^j}.$$

Applying h is equivalent to shifting the “binary point” and dropping the leading coefficient,

$$(a_1 a_2 a_3 a_4 \dots) \rightarrow (a_2 a_3 a_4 \dots),$$

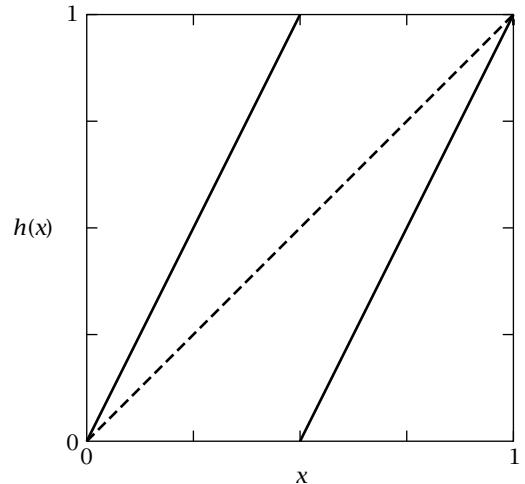

Figure 2 The doubling map, h .

just as multiplication by 10 shifts a decimal point. Were x_0 known to infinite accuracy, with *all* the a_k specified, the current state, x_k , at each step would also be known exactly. But given only the first N coefficients (a_1, a_2, \dots, a_N) , after N iterations, one cannot even determine whether x_{N+1} lies above or below $\frac{1}{2}$. Moreover, if two points differ only at the N th binary place and thus lie within $(\frac{1}{2})^{N-1}$, after N iterations they lie on opposite sides of $\frac{1}{2}$ and thereafter behave essentially independently. Repeated doubling amplifies small differences.

The binary representation exemplifies symbolic dynamics. To *every* infinite sequence of zeros and ones there corresponds a point in $[0, 1]$, and vice versa. Hence, any random sequence corresponds to a state $x_0 \in [0, 1]$ whose orbit $h^k(x_0)$ realizes that sequence; the map h has infinitely many orbits whose itineraries are indistinguishable from random sequences. It also has infinitely many periodic orbits, corresponding to periodic sequences. These can be enumerated by listing all distinct sequences of lengths 1, 2, 3, ... that contain no subsequences of smaller period, showing that there are approximately $2^N/N$ orbits of period N and a countable infinity in all. Nonetheless, since numbers picked at random are almost always irrational (they form a set of full measure), almost all orbits are nonperiodic (see section 4.5).

4 Dynamical Systems Theory

As noted above, dynamical systems theory emphasizes the study of the global orbit structure or *phase portrait*,

its dependence on parameters, and the description of qualitative properties such as the existence of closed orbits (periodic solutions). We start by describing some important tools and concepts.

4.1 Judicious Linearization

While few nonlinear systems can be “solved” completely, much can be deduced from linear analysis. The linearization of the ODE (1) near a *fixed point* or *equilibrium* \mathbf{x}^e , where $\mathbf{f}(\mathbf{x}^e) = 0$, is obtained by substituting $\mathbf{x} = \mathbf{x}^e + \xi$ into (1), expanding in a Taylor series, and neglecting quadratic and higher-order terms to obtain

$$\dot{\xi} = D\mathbf{f}(\mathbf{x}^e)\xi \quad \text{for } |\xi| \ll 1. \quad (5)$$

Here, $D\mathbf{f}(\mathbf{x}^e)$ is the $n \times n$ Jacobian matrix of first partial derivatives $\partial f_i / \partial x_j$ evaluated at \mathbf{x}^e .

Linear ODEs with constant coefficients, like (5), are completely soluble in terms of elementary functions. One assumes the exponential form

$$\xi = \sum_{j=1}^n \mathbf{v}_j \exp(\lambda_j t)$$

and computes the eigenvalues λ_j and eigenvectors \mathbf{v}_j of $D\mathbf{f}(\mathbf{x}^e)$. If $D\mathbf{f}(\mathbf{x}^e)$ has n linearly independent eigenvectors, then any solution may be expressed as a linear combination $\mathbf{x}(t) = \sum_{j=1}^n c_j \mathbf{v}_j \exp(\lambda_j t)$, and the c_j can be uniquely determined by initial conditions. Eigenvalues and eigenvectors can, of course, be complex numbers and vectors, but using Euler’s formula $\exp(\pm it) = \cos t \pm i \sin t$, and allowing complex c_j , solutions to real-valued ODEs can be written as combinations of exponential and trigonometrical functions. (If $D\mathbf{f}(\mathbf{x}^e)$ has fewer than n linearly independent eigenvectors, generalized eigenvectors are required and terms of the form $t^k \exp(\lambda_j t)$ appear.)

If every eigenvalue of $D\mathbf{f}(\mathbf{x}^e)$ has nonzero real part, \mathbf{x}^e is called a *hyperbolic* or *nondegenerate* fixed point. Excepting special cases, like the energy-conserving pendulum, fixed points are typically hyperbolic, and their stability in the original nonlinear system (1) can be deduced from the linearized system.

A fixed point \mathbf{x}^e of (1) is *Lyapunov* or *neutrally stable* if for every neighborhood $U \ni \mathbf{x}^e$ there is a neighborhood $V \subseteq U$, also containing \mathbf{x}^e , such that every solution $\mathbf{x}(t)$ of (1) starting in V remains in U for all $t \geq 0$. If $\mathbf{x}(t) \rightarrow \mathbf{x}^e$ as $t \rightarrow \infty$ for all $\mathbf{x}(0) \in V$, then \mathbf{x}^e is *asymptotically stable*. If \mathbf{x}^e is not stable, it is *unstable*. More descriptively, if all nearby orbits approach \mathbf{x}^e , it is called a *sink*; if all recede from it, it is a *source*; and

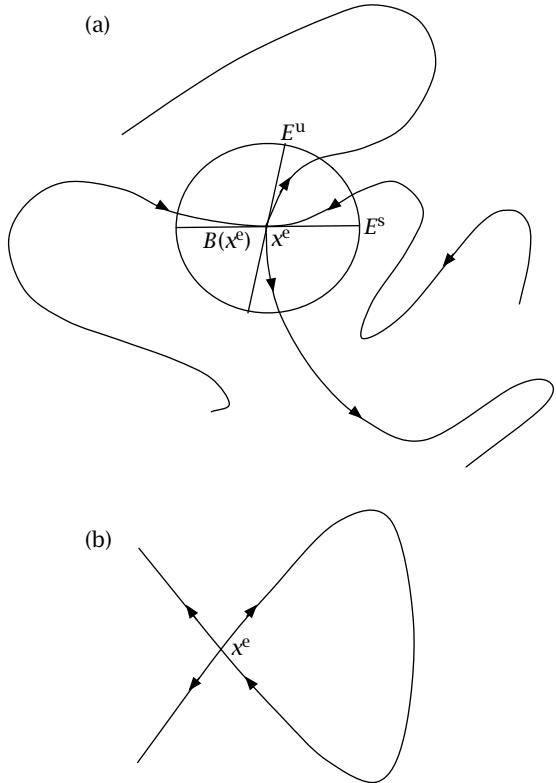

Figure 3 Stable and unstable manifolds. (a) Near \mathbf{x}^e the local manifolds can be expressed as graphs, as in (7). (b) Globally, stable and unstable manifolds may intersect, forming a homoclinic orbit.

if some approach and some recede, it is a *saddle point*. Sinks are the simplest *attractors*: see section 4.5.

Choosing the neighborhood V small enough that the linear part $D\mathbf{f}(\mathbf{x}^e)\xi$ dominates the higher-order terms that were ignored in (5), it follows that, if all the eigenvalues of $D\mathbf{f}(\mathbf{x}^e)$ have strictly negative real parts, then \mathbf{x}^e is asymptotically stable but, if at least one eigenvalue has strictly positive real part, then \mathbf{x}^e is unstable. When one or more eigenvalues have zero real part, the local behavior is determined by the leading nonlinear terms, as described in section 4.3, but if \mathbf{x}^e is hyperbolic, then the entire orbit structure nearby is topologically equivalent to that of the nonlinear ODE (1). Similar results hold for the discrete mapping (2), and systems can also be linearized near periodic and other orbits.

4.2 Invariant Manifolds

Remarkably, the decomposition of the state space into invariant subspaces for the linearized system (5)

also holds for the nonlinear system near \mathbf{x}^e . Suppose that $D\mathbf{f}(\mathbf{x}^e)$ has $s \leq n$ and $u = n - s$ eigenvalues $\lambda_1, \dots, \lambda_s$ and $\lambda_{s+1}, \dots, \lambda_{s+u}$ with strictly negative and strictly positive real parts, respectively, and define the linear subspaces $E^s = \text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_s\}$ and $E^u = \text{span}\{\mathbf{v}_{s+1}, \dots, \mathbf{v}_{s+u}\}$ spanned by their (generalized) eigenvectors. As t increases, orbits of (5) in the stable subspace E^s decay exponentially, while those in the unstable subspace E^u grow.

The *stable manifold theorem* states that, near a hyperbolic fixed point \mathbf{x}^e , equations (1) and (2) possess *local stable and unstable manifolds* $W_{\text{loc}}^s(\mathbf{x}^e), W_{\text{loc}}^u(\mathbf{x}^e)$ of dimensions s and u , respectively, tangent at \mathbf{x}^e to E^s and E^u . The former consists of all orbits that start and remain near \mathbf{x}^e for all future time and approach it as $t \rightarrow \infty$:

$$W_{\text{loc}}^s(\mathbf{x}^e) = \{\mathbf{x} \in V \mid \phi_t(\mathbf{x}) \rightarrow \mathbf{x}^e \text{ as } t \rightarrow \infty \text{ and } \phi_t(\mathbf{x}) \in V \text{ for all } t \geq 0\}; \quad (6)$$

the unstable manifold $W_{\text{loc}}^u(\mathbf{x}^e)$ is defined similarly, with the substitutions “past time” and “ $t \rightarrow -\infty$.” These smooth, curved subspaces locally resemble their linear counterparts E^s and E^u (see figure 3(a)).

Near \mathbf{x}^e the local stable and unstable manifolds can be expressed as graphs over E^s and E^u , respectively. Letting $E^{s\perp}$ denote the $(n - s)$ -dimensional orthogonal complement to E^s and letting $\mathbf{y} \in E^s$ and $\mathbf{z} \in E^{s\perp}$ be local coordinates, we can write

$$W_{\text{loc}}^s(\mathbf{x}^e) = \{(\mathbf{y}, \mathbf{z}) \mid (\mathbf{y}, \mathbf{z}) \in B(\mathbf{0}), \mathbf{z} = \mathbf{g}(\mathbf{y})\} \quad (7)$$

for a smooth function $\mathbf{g}: E^s \rightarrow E^{s\perp}$. We cannot generally compute \mathbf{g} , but it can be approximated as described in section 4.3.

The *global* stable and unstable manifolds are defined as the unions of backward and forward images of the local manifolds under the flow map: $W^s(\mathbf{x}^e)$ is the set of *all* points whose orbits approach \mathbf{x}^e as $t \rightarrow +\infty$, even if they leave $B(\mathbf{x}^e)$ for a while, and $W^u(\mathbf{x}^e)$ is defined analogously for $t \rightarrow -\infty$. Stable manifolds can intersect neither themselves nor the stable manifolds of other fixed points, since this would violate uniqueness of solutions (the intersection point would lead to more than one future). The same is true of unstable manifolds, but intersections of stable and unstable manifolds can and do occur; they lie on solutions that lead from one fixed point to another. Intersection points of manifolds that belong to the same fixed point are called *homoclinic*, while those for manifolds that belong to different fixed points are called *heteroclinic* (see figure 3(b)).

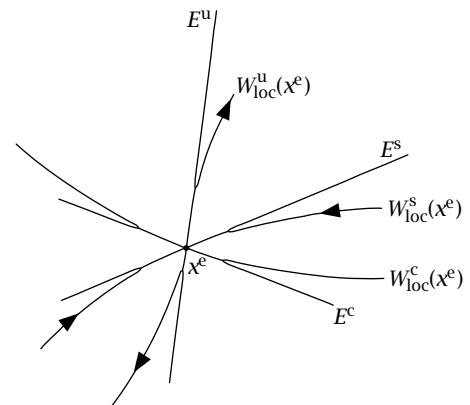

Figure 4 The stable, center, and unstable manifolds.

4.3 Center Manifolds, Local Bifurcations, and Normal Forms

As parameters change, so do phase portraits and the resulting dynamics. New fixed points can appear, the stability of existing ones can change, and homoclinic and heteroclinic orbits can form and vanish. **BIFURCATION THEORY** [IV.21] addresses such questions, and it relies on three further ideas: structural instability, dimension reduction, and nonlinear coordinate changes.

As noted in section 2, a structurally stable system survives small perturbations of its defining vector field \mathbf{f} or map F in the following sense. The phase portraits of the original and perturbed systems are *topologically equivalent*; they can be transformed into each other by a continuous coordinate change that preserves the sense of time, so that sinks remain sinks and sources. Since eigenvalues of the Jacobian matrix determine stability, both the values and the derivatives of the perturbing functions must be small.

There are many ways in which structural stability can be lost, but the simplest is when a single (simple) eigenvalue passes through zero or when the real parts of a complex conjugate pair do the same. More generally, suppose that, in addition to s and u eigenvalues with negative and positive real parts, the Jacobian $D\mathbf{f}(\mathbf{x}^e)$ also has c eigenvalues with zero real part ($s + c + u = n$).

The *center manifold theorem* asserts that, along with the s - and u -dimensional stable and unstable manifolds, a smooth c -dimensional local center manifold W_{loc}^c exists, tangent to the subspace E^c spanned by the eigenvectors belonging to the eigenvalues with zero real part. As figure 4 suggests, this allows one to

separate the locally stable and unstable directions from the structurally unstable ones and thus to reduce the analysis to that of a c -dimensional system restricted to the center manifold, a considerable simplification when $c \ll n$.

To describe the reduction process we assume that coordinates have been chosen with the degenerate equilibrium \mathbf{x}^e at the origin and such that the matrix $D\mathbf{f}(\mathbf{x}^e)$ is block diagonalized. Then (1) can be written in the form

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{f}(\mathbf{x}, \mathbf{y}), \quad \dot{\mathbf{y}} = \mathbf{B}\mathbf{y} + \mathbf{g}(\mathbf{x}, \mathbf{y}), \quad (8)$$

where $\mathbf{x} \in E^c$ and $\mathbf{y} \in E^s \oplus E^u$, the span of the stable and unstable subspaces (explicit reference to the parameter μ is dropped). All eigenvalues of the $c \times c$ matrix \mathbf{A} have zero real parts and the $(s+u) \times (s+u)$ matrix \mathbf{B} has only eigenvalues with nonzero real parts. The center manifold can be expressed as a graph $\mathbf{y} = \mathbf{h}(\mathbf{x})$ over E^c , and hence, as long as solutions remain on W_{loc}^c , the state (\mathbf{x}, \mathbf{y}) of the system is specified by the \mathbf{x} variables alone. The *reduced system* is the projection of the vector field on W_{loc}^c onto the linear subspace E^c :

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{f}(\mathbf{x}, \mathbf{h}(\mathbf{x})). \quad (9)$$

The graph \mathbf{h} is found by substituting $\mathbf{y} = \mathbf{h}(\mathbf{x})$ into the second component of (8) and using the chain rule and the first component of (8) to obtain a (partial) differential equation:

$$\mathbf{D}\mathbf{h}(\mathbf{x})[\mathbf{A}\mathbf{x} + \mathbf{f}(\mathbf{x}, \mathbf{h}(\mathbf{x}))] = \mathbf{B}\mathbf{h}(\mathbf{x}) + \mathbf{g}(\mathbf{x}, \mathbf{h}(\mathbf{x})) \\ \text{with } \mathbf{h}(\mathbf{0}) = \mathbf{0}, \mathbf{D}\mathbf{h}(\mathbf{0}) = \mathbf{0}. \quad (10)$$

The latter conditions are due to the tangency of W_{loc}^c to E^c at $\mathbf{x}^e = \mathbf{0}$. Solutions of (10) can be approximated as a Taylor series in \mathbf{x} , and stability and bifurcation behavior near the nonhyperbolic fixed point can be deduced from the resulting approximation to the reduced system (9).

The third idea—to choose a coordinate system that simplifies the nonlinear terms of the reduced system—effectively extends the use of similarity transformations to diagonalize and decouple components in linear systems. *Normal form theory* simplifies the Taylor series by iteratively performing nonlinear coordinate changes that successively remove, at each order, *non-resonant* terms that do not influence the qualitative behavior. Lie algebra provides bookkeeping methods, and the computations can be (semi-) automated using computer algebra.

To illustrate the resulting simplification, consider a two-dimensional ODE of the form

$$\dot{\mathbf{x}} = \mathbf{A}\mathbf{x} + \mathbf{f}(\mathbf{x}), \quad \mathbf{A} = \begin{bmatrix} 0 & -1 \\ 1 & 0 \end{bmatrix}, \quad (11)$$

the linear part of which is a harmonic oscillator whose phase plane is filled with periodic orbits surrounding a neutrally stable fixed point (a center). Asymptotic stability or instability of $\mathbf{x}^e = \mathbf{0}$ depends on the nonlinear function $\mathbf{f}(\mathbf{x})$, and in particular on the leading terms in its Taylor series. There are six quadratic terms, eight cubic terms, and in general $2(k+1)$ terms of order k , but normal form transformations can successively remove all the even terms and all but two terms of each odd order, at the expense of modifying those terms. After such a transformation and written in polar coordinates ($x_1 = r \cos \theta$, $x_2 = r \sin \theta$), equation (11) becomes

$$\left. \begin{aligned} \dot{r} &= \alpha_3 r^3 + \alpha_5 r^5 + \mathcal{O}(r^7), \\ \dot{\theta} &= 1 + \beta_3 r^2 + \beta_5 r^4 + \mathcal{O}(r^6). \end{aligned} \right\} \quad (12)$$

Not only is the number of coefficients greatly reduced, but the circular symmetry implicit in the localized linear system is extended to higher order, uncoupling the azimuthal θ dynamics from the radial dynamics. Since the latter alone govern decay or growth of orbits, stability is determined by the first nonzero α_k , explicit formulas for which emerge from the transformation.

Normal forms not only simplify the functions defining degenerate vector fields, they also allow the systematic introduction of parameters that *unfold* the bifurcation point to reveal the variety of structurally stable systems in its neighborhood, much as one can perturb a matrix to split a real eigenvalue of multiplicity 2 into a pair of distinct ones by adding a parameter. Equation (12), for example, is unfolded by the addition of a linear term μr to the first component; as μ passes through zero, a Hopf bifurcation occurs, giving rise to a limit cycle (see **BIFURCATION THEORY** [IV.21]).

4.4 Limit Cycles and Poincaré Maps

The van der Pol equation—mentioned in section 2 as a motivating example in the study of chaotic orbits—also illustrates a simpler and more pervasive tool: the *first return* or *Poincaré map*. Without external forcing, this self-excited oscillator possesses a stable limit cycle, an isolated periodic orbit that attracts all nearby orbits. The ODE is

$$\dot{x}_1 = x_2 + \mu x_1 - \frac{1}{3}x_1^3, \quad \dot{x}_2 = -x_1, \quad (13)$$

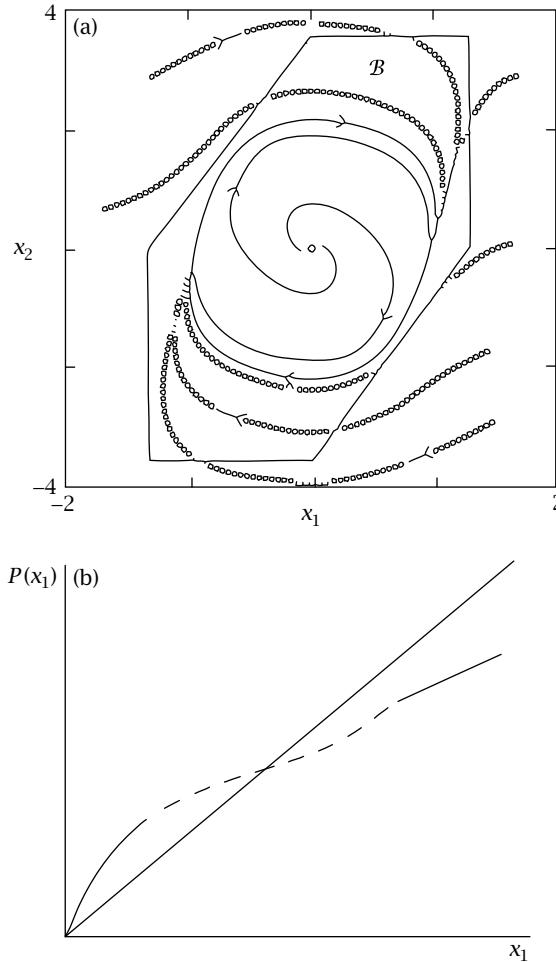

Figure 5 (a) An annular trapping region \mathcal{B} and the limit cycle of the van der Pol equation (13) with $\mu = 1$. (b) The Poincaré map for equation (13) expands lengths for x_1 small and contracts them for x_1 large, implying the existence of at least one fixed point corresponding to a periodic orbit.

and linearization reveals that, for $\mu > 0$, this planar system has a source at $(x_1, x_2) = (0, 0)$. It can, moreover, be shown that all orbits eventually enter and remain within an annular *trapping region* \mathcal{B} surrounding the source. Since no fixed points lie in \mathcal{B} , the Poincaré-Bendixson theorem implies that it contains at least one periodic orbit (see figure 5(a)). As indicated at the end of section 4.3, one can also show that a stable periodic orbit appears in a Hopf bifurcation as μ passes through zero.

More generally, if γ is a periodic orbit in an ODE of dimension $n \geq 2$, we may construct a *cross section* Σ , a

subset of an $(n - 1)$ -dimensional manifold pierced by γ at a point \mathbf{p} and *transverse to the flow* in that all orbits cross Σ with nonzero speed. Thus, by continuity, orbits starting at $\mathbf{q} \in \Sigma$ sufficiently close to \mathbf{p} remain near γ and next intersect Σ again at a point $\mathbf{q}' \in \Sigma$, defining a Poincaré map

$$P: \Sigma \rightarrow \Sigma \quad \text{or} \quad \mathbf{q} \mapsto \mathbf{q}' = P(\mathbf{q}). \quad (14)$$

Evidently, \mathbf{p} is a fixed point for the map P .

The positive x_1 -axis is a suitable cross section for equation (13), and the instability of the fixed point $(0, 0)$ and the attractivity of the trapping region \mathcal{B} from outside imply that $P(x_1)$ takes the form sketched in figure 5(b). Since P is continuous, it must intersect the diagonal at least once in a fixed point $p > 0$, corresponding to the limit cycle. In fact, p is unique and the linearized map satisfies $0 < (dP/dx_1)|_{x_1=p} < 1$, implying asymptotic stability of both p and the limit cycle. In general, if all the eigenvalues of the linearized map $D\mathbf{P}(\mathbf{p})$ have moduli strictly less than 1, then \mathbf{p} and its associated periodic orbit are asymptotically stable; if at least one eigenvalue has modulus greater than 1, they are unstable.

This parallels the eigenvalue criteria for flows described in section 4.1, and the Poincaré map provides a second connection between ODEs and iterated maps (cf. the time T flow map ϕ_T of section 1). Conversely, a mapping $F: U \subset \mathbb{R}^n \rightarrow \mathbb{R}^n$ can be suspended to produce a T -periodic vector field on the $(n + 1)$ -dimensional space $\mathbb{R}^n \times S^1$. Analyses of the ODE (1) and the mapping (2) are therefore closely related, and analogs of the stable, unstable, and center manifold theorems hold for iterated maps.

4.5 Chaos and Strange Attractors

Several definitions of chaos have been advanced, but the following captures its key properties. A set of differential equations or an iterated map is called *chaotic*, or is said to have *chaotic solutions*, if it possesses a set S of orbits such that (1) almost all pairs of orbits in S display sensitive dependence on initial conditions; (2) there is an infinite set of periodic orbits that is dense in S ; and (3) there is a dense orbit in S (see CHAOS [II.3]).

Sensitive dependence means that, for any preassigned number $\beta < |S|$, any point x_0 in S , and any neighborhood U of x_0 , no matter how small, there exists a point $y_0 \in U$ and a time T such that the orbits $x(T)$ and $y(T)$ starting at x_0 and y_0 are separated by at least β ; almost all solutions diverge locally. An orbit $x(t)$ is

dense in S if, given any point z in S and any neighborhood U of z , no matter how small, there exists a time t_z such that $x(t_z)$ lies inside U : $x(t)$ passes arbitrarily close to all points in S .

For the doubling map, a binary sequence \mathbf{a}^* corresponding to a dense orbit x^* can be built by concatenating *all subsequences* of lengths 1, 2, 3, etc.: $\mathbf{a}^* = 0\ 1\ 0\ 0\ 0\ 1\ 10\ 11\ 000\ 001\ \dots$. As one iterates and drops leading symbols, *every* subsequence appears at its head, implying that the orbit of x^* contains points that lie arbitrarily close to every point in $[0, 1]$. Hence $\{h^k(x^*)\}_{k=0}^\infty$ is dense and h satisfies the definition, where $S = [0, 1]$ is the entire state space.

Positive topological entropy also implies that typical orbits explore S , and there are examples of maps with this property that have *no* periodic orbits, so this definition is sometimes preferred. However, topological entropy (roughly speaking, the growth rate of distinct orbits as one progressively refines a discretization of S) is technically complicated, and the above definition will suffice here.

4.5.1 Smale's Horseshoe

The doubling map may seem to be a purely mathematical construct, but as promised in sections 2–3, it is related to the double pendulum and to forced nonlinear oscillators. To understand this, we now describe Smale's construction. Consider a piecewise-linear mapping \mathbf{G} defined on the unit square $Q = [0, 1] \times [0, 1]$ by means of its action on two horizontal strips $H_0 = [0, 1] \times [0, 1/\mu]$ and $H_1 = [1 - 1/\mu, 1] \times [0, 1]$ with images $V_0 = \mathbf{G}(H_0) = [0, \lambda] \times [0, 1]$ and $V_1 = \mathbf{G}(H_1) = [1 - \lambda, 1] \times [0, 1]$, and having Jacobians

$$\mathbf{D}\mathbf{G}|_{H_0} = \begin{bmatrix} \lambda & 0 \\ 0 & \mu \end{bmatrix}, \quad \mathbf{D}\mathbf{G}|_{H_1} = \begin{bmatrix} -\lambda & 0 \\ 0 & -\mu \end{bmatrix} \quad (15)$$

for $0 < \lambda < \frac{1}{2}$ and $\mu > 2$ (so that the images fit within Q as defined). To make \mathbf{G} continuous, the image of the central strip between H_0 and H_1 is taken as a semicircular arch joining V_0 to V_1 . \mathbf{G} can be thought of as the Poincaré map of a flow that compresses Q horizontally, then stretches it vertically, and finally bends its middle to form the eponymous horseshoe (see figure 6).

The invariant set Λ of \mathbf{G} consists of points that remain in Q under all forward and backward iterates: $\Lambda = \bigcap_{j=-\infty}^{+\infty} \mathbf{G}^j(Q)$. We construct Λ step by step. Points that remain in Q for one *backward* iteration occupy two vertical strips V_0 and V_1 , the images of H_0 and H_1 . $\mathbf{G}^{-2}(Q) \cap Q$ is obtained by considering the second iterates $\mathbf{G}(V_0)$ and $\mathbf{G}(V_1)$ of H_0 and H_1 , which form

nested arches standing on pillars, each of width λ^2 , lying within V_0 and V_1 . At each step, vertical distances are expanded by μ and horizontal distances shrunk by λ , and the middle $(1 - 2\lambda)$ fraction of the strips is removed. Continuing, $\Lambda_{-n} = \bigcap_{j=-n}^0 \mathbf{G}^j(Q)$ is 2^n vertical strips, each of width λ^n , and passing to the limit, $\Lambda_{-\infty} = \bigcap_{j=-\infty}^0 \mathbf{G}^j(Q)$ is a Cantor set of vertical line intervals. Similarly, $\Lambda_{+\infty} = \bigcap_{j=0}^{+\infty} \mathbf{G}^j(Q)$ is a Cantor set of horizontal intervals, and since any vertical and any horizontal segment intersect at a point, $\Lambda = \Lambda_{-\infty} \cap \Lambda_{+\infty}$ is a Cantor set of points.

A Cantor set is uncountable, closed, and contains no interior or isolated points; every point is an accumulation point. Cantor sets are examples of *fractals*, sets having fractional dimension.

Orbits of \mathbf{G} can be described by *symbolic dynamics*, which codes points $\mathbf{x} \in \Lambda$ as binary sequences based on their visits to H_0 and H_1 . A mapping $\mathbf{a}: \Lambda \rightarrow \{0, 1\}^\mathbb{Z}$, where $\mathbf{a} = \{\mathbf{a}_j\}_{j=-\infty}^{+\infty}$ and $\{0, 1\}^\mathbb{Z}$ denotes the space of bi-infinite sequences with entries 0 or 1, is defined as follows:

$$\mathbf{a}_j(\mathbf{x}) = \begin{cases} 0 & \text{if } \mathbf{G}(\mathbf{x}) \in H_0, \\ 1 & \text{if } \mathbf{G}(\mathbf{x}) \in H_1. \end{cases} \quad (16)$$

Given a suitable metric on $\{0, 1\}^\mathbb{Z}$, it can be shown that \mathbf{a} is a one-to-one, continuous, invertible map, a homeomorphism. Every point in Λ is faithfully coded by a sequence in $\{0, 1\}^\mathbb{Z}$, and, via equation (16), the action of \mathbf{G} on Λ becomes the shift map

$$\sigma: \{0, 1\}^\mathbb{Z} \rightarrow \{0, 1\}^\mathbb{Z}, \quad \text{with } \mathbf{a}_j = \sigma(\mathbf{a}_{j+1}). \quad (17)$$

This generalizes the binary representation of section 3.2 because \mathbf{G} is invertible and points have past orbits as well as future orbits. The countably infinite set of periodic orbits is coded as before (for such an orbit, future and past are the same), but homoclinic and heteroclinic orbits to any periodic orbit or pair of orbits can now be formed by connecting semi-infinite periodic tails with an arbitrary central sequence. A dense orbit can be built by growing the sequence $0\ 1\ 0\ 0\ 0\ 1\ 10\ 11\ 000\ 001\dots$ forward and backward, and since all possible finite sequences appear in the set of all periodic orbits, this latter set is also dense in Λ .

\mathbf{G} is linear on $H_0 \cup H_1$ with eigenvalues $\pm\lambda$ and $\pm\mu$ and $\lambda < 1 < \mu$, so Λ is a hyperbolic set in which almost all pairs of orbits separate exponentially quickly and \mathbf{G} is chaotic in the above sense. Moreover, it is structurally stable, so the chaos survives small perturbations, and Smale also proved that horseshoes appear in *any* smooth map that possesses a transverse homoclinic point.

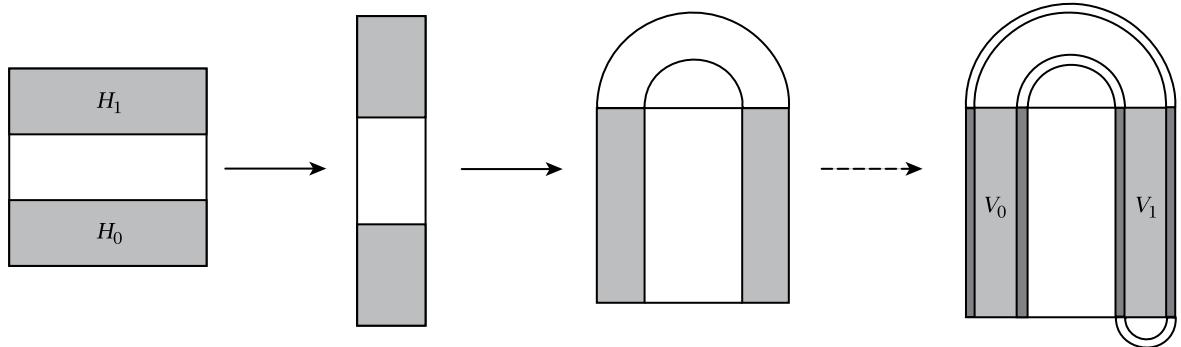

Figure 6 Smale's horseshoe, showing the square Q (left) and its images $G(Q)$ (center right) and $G^2(Q)$ (far right), with the strips H_j and their images $V_j = G(H_j)$ shaded.

There are computable conditions that detect homoclinic points for rather general classes of weakly perturbed systems. Applying these to the ODEs describing a double pendulum, like that of figure 1 but with a heavy upper link and a light lower one, allows one to prove that, given any alternating sequence of positive and negative integers $s_1, -s_2, s_3, \dots$, an orbit exists on which the lower link first turns s_1 times clockwise, then s_2 times counterclockwise, then s_3 times clockwise, and so on. Since any sequence chosen from a suitable probability distribution corresponds to an orbit, one cannot tell whether the motion is deterministic or stochastic.

The horseshoe Λ is a set of saddle type; almost all orbits that approach it eventually leave, so its presence does not necessarily imply physically observable chaos. However, its stable manifold can form a *fractal boundary* separating orbits that have different fates, as in the forced van der Pol equation. To observe persistent chaos, one requires strange attractors.

4.5.2 Strange Attractors

Again there are subtle issues and competing definitions, but to convey the main ideas we define an *attracting set* \mathcal{A} as the intersection of all forward images of a trapping region \mathcal{B} ,

$$\mathcal{A} = \bigcap_{t \geq 0} \phi_t(\mathcal{B}), \quad (18)$$

and an *attractor* as an attracting set that contains a dense orbit. Sinks and asymptotically stable limit cycles provide simple examples, as do stable invariant tori that carry quasiperiodic, and hence densely winding, motions. A *strange attractor* additionally exhibits sensitive dependence and chaos. The following exam-

ple further emphasizes the geometrical viewpoint of dynamical systems theory.

The LORENZ EQUATIONS [III.20] are a (very) low-dimensional projection of the coupled Navier-Stokes and heat equations modeling convection in a fluid layer:

$$\left. \begin{aligned} \dot{x}_1 &= \sigma(x_2 - x_1), \\ \dot{x}_2 &= \rho x_1 - x_2 - x_1 x_3, \\ \dot{x}_3 &= -\beta x_3 + x_1 x_2. \end{aligned} \right\} \quad (19)$$

The parameters σ and β are fixed and ρ is proportional to the temperature difference across the layer. The origin is always a fixed point, representing stationary fluid and heat transport by conduction. For $\rho > 1$, $\mathbf{x} = \mathbf{0}$ is a saddle point with one positive and two negative real eigenvalues; two further fixed points \mathbf{q}^\pm , corresponding to steadily rotating convection cells, also exist. For $\sigma = 10$, $\rho = 28$, $\beta = \frac{8}{3}$ (the values used by Lorenz), these are also saddles, but a trapping region exists and (19) has an attracting set \mathcal{A} containing the unstable fixed points.

Lorenz, who had studied with Birkhoff, realized that \mathcal{A} has infinitely many “sheets.” He also generated a one-dimensional return map related to the doubling map of section 3.2 and gave a symbolic description of its orbits. We adopt the geometric model of Guckenheimer and Williams here, defining a cross section Σ lying above the origin. In suitable nonlinear coordinates, Σ is a square $[-1, 1] \times [-1, 1]$ whose boundaries $\pm 1 \times [-1, 1]$ contain \mathbf{q}^\pm and their local stable manifolds, and whose centerline $0 \times [-1, 1]$ lies in the stable manifold of $\mathbf{0}$. Assuming that all orbits leaving Σ circulate around $\pm 1 \times [-1, 1]$ (except those in $0 \times [-1, 1]$, which flow into $\mathbf{x} = \mathbf{0}$), a Poincaré map F can be defined (see figure 7(a)).

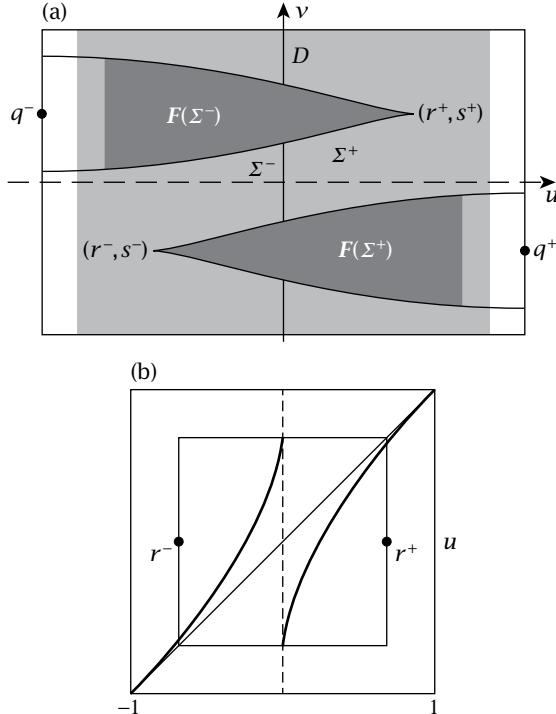

Figure 7 The Poincaré map of the geometric Lorenz attractor. (a) A cross section Σ showing Σ^\pm and their images $F(\Sigma^\pm)$, and the subset V (light gray) and its image $F(V)$ (dark gray). (b) The one-dimensional map $f(u)$.

More precisely, Guckenheimer and Williams assert that coordinates (u, v) can be chosen in which the horizontal (u) dynamics decouples and F takes the form

$$F(u, v) = (f(u), g(u, v)), \quad (20)$$

where g contracts in the v -direction, f expands by a factor greater than or equal to $\sqrt{2}$ in the u -direction, and $F(-u, -v) = -F(u, v)$ respects the symmetry $(x_1, x_2, x_3) \rightarrow (-x_1, -x_2, x_3)$ of (19). Thus, F maps the open rectangles $\Sigma^- = (-1, 0) \times (-1, 1)$ and $\Sigma^+ = (0, 1) \times (-1, 1)$ into the interior of Σ , and since orbits starting near $u = 0$ pass close to $\mathbf{0}$, the strong stable eigenvalue of $\mathbf{0}$ pinches the images of Σ^\pm at their endpoints $(r^\pm, s^\pm) = \lim_{u \rightarrow 0} F(u, v)$. Continuing to iterate, a complicated attracting set appears: at the second step, $F(\Sigma^\pm)$ comprises 4 thinner strips, 2 each inside $F(\Sigma^-)$ and $F(\Sigma^+)$, then 8, 16, etc., as in the Cantor set of Smale's horseshoe, but pinched together at their ends. Defining a subset $V \subset \Sigma$ (shaded in figure 7), it can be shown that $\mathcal{A} = \bigcap_{n \geq 0} F^n(V)$ contains a dense orbit

and so \mathcal{A} is an attractor. Due to the expansive nature of f (figure 7(b)), which resembles the doubling map of section 3.2, F has sensitive dependence and \mathcal{A} is therefore strange.

The geometric picture has been verified by W. Tucker for equation (19) using a computer-assisted proof showing that a *stable foliation* exists, a continuous family of curves \mathcal{F} such that, if $C \in \mathcal{F}$, then $F(C) \in \mathcal{F}$ (here, \mathcal{F} is composed of vertical line segments $u = \text{const.}$).

The key properties necessary for strange attractors are (1) stretching in some state-space directions and (2) contraction in others, so that volumes decrease, coupled with (3) bending (the horseshoe) or discontinuous cutting (the Lorenz example) to place forward images under the flow map ϕ_t into a trapping region. There are now many examples, and smooth maps like that of the horseshoe, which often arise in applications, can produce very complicated dynamics, including infinite sequences of homoclinic bifurcations.

5 Conclusion

I have sketched some central ideas and themes in dynamical systems theory but have necessarily omitted much. In closing, here are some important topics and connections to other concepts, areas, and problems described in this volume.

Chaotic orbits admit statistical descriptions, and there is a flourishing *ergodic theory* of dynamical systems, describing, for example, invariant measures supported on strange attractors and decay of correlations along orbits. Stochastic ODEs are also treated probabilistically (see APPLICATIONS OF STOCHASTIC ANALYSIS [IV.14]). Interest in HYBRID SYSTEMS [II.18], with nonsmooth vector fields and discontinuous jumps, is growing, and the classification of their bifurcations proceeds (see SLIPPING, SLIDING, RATTLING, AND IMPACT: NONSMOOTH DYNAMICS AND ITS APPLICATIONS [VI.15]).

Many equations inherit symmetries from the phenomena they model, and *equivariant dynamical systems* is an important area. Symmetries can both constrain behaviors and stabilize objects that typically lack structural stability in nonsymmetric systems (e.g., heteroclinic cycles). Symmetries also profoundly affect normal forms and their unfoldings (see SYMMETRY IN APPLIED MATHEMATICS [IV.22]).

The Lorenz and other examples show that steady three-dimensional velocity fields of fluids or other continua can exhibit chaotic mixing, which dramatically enhances transport of heat, pollutants, and reactants in such flows (see CONTINUUM MECHANICS [IV.26]).

IV.21 Bifurcation Theory

Paul Glendinning

1 Introduction

Bifurcation theory describes the qualitative changes in the dynamics of systems caused by small changes of parameters in the model. It uses DYNAMICAL SYSTEMS THEORY [IV.20] to determine the different conditions that lead to changes, and to describe the dynamics as a function of the parameter. This leads to a theoretical list of typical changes that can be used to understand the existence and stability of different solutions in a problem. Parameters are present in most applications. They are quantities that are constant in any realization of the system but that may take different values in different realizations depending on the details of the situation being modeled. Examples include the Raleigh and Reynolds numbers in fluid dynamics, virulence in disease models, and reaction rates in chemistry.

The “tipping points” that generate so much interest in economics, say, or climate change are good examples of the idea of a bifurcation: if the parameters satisfy some condition then the associated dynamics is of one type, but if they stray above a threshold, even by a small amount, then the resultant dynamics can change drastically.

There are two types of bifurcation, though the two can be mixed in more complicated problems. One involves changes in the spectrum of the linearization of a system about some solution; this type is an extension of the classical linear stability analysis that dominated so much of applied mathematics in the 1950s and 1960s. This leads to *local bifurcation theory*. The second type of bifurcation builds on Poincaré’s qualitative analysis of dynamical systems to look at global features of the system, and in particular homoclinic and heteroclinic orbits (a homoclinic orbit approaches the same solution in forward and backward time, while a heteroclinic orbit is a solution that tends to one solution in forward time and another in backward time). The analysis of perturbations of these solutions is the basis of *global bifurcation theory*.

Although bifurcation theory can be applied to more general systems, we will restrict ourselves to the cases of autonomous ordinary differential equations in continuous time, which generate flows, and maps in discrete time, which generate sequences, i.e.,

$$\begin{aligned}\dot{x} &= f(x, \mu) && (\text{flow}), \\ x_{n+1} &= f(x_n, \mu) && (\text{map}),\end{aligned}\tag{1}$$

where $x \in \mathbb{R}^p$ are the dependent variables and $\mu \in \mathbb{R}^m$ are the parameters. The simplest solutions are those that are constant. For flows, this implies that $\dot{x} = 0$, so $f(x, \mu) = 0$. These solutions are called stationary points. For maps, a constant solution is called a fixed point. Fixed points satisfy $x_{n+1} = x_n$, or $x = f(x, \mu)$. Since periodic orbits of flows can be analyzed using a RETURN MAP [IV.20], the discrete-time case can describe behavior near periodic orbits of flows.

In some sense, then, bifurcation theory for the simplest dynamical objects is about the variation in the number of solutions of equations such as $f(x, \mu) = 0$ as the parameters vary. This leads to an approach through singularity theory. The linear stability of solutions is determined by the eigenvalues of the linearization (the Jacobian matrix) of the flow or map. In continuous time, simple eigenvalues of the Jacobian matrix λ lead to solutions that are proportional to $e^{\lambda t}$ and

eigenvalues with negative real parts are therefore stable while those with positive real parts are unstable. In the discrete-time case, solutions are proportional to λ^n , so the role of the imaginary axis is replaced by the unit circle since $\lambda^n \rightarrow 0$ as $n \rightarrow \infty$ if $|\lambda| < 1$. The power of local bifurcation theory lies in its ability to go beyond this linear approach.

Linearization determines the local behavior near stationary points and fixed points provided the eigenvalues of the Jacobian matrix are not on the imaginary axis (for continuous-time flows) or the unit circle (for discrete-time maps). Such solutions are called *hyperbolic*, and no local bifurcations can occur at hyperbolic solutions. Local bifurcation theory therefore considers behavior near nonhyperbolic solutions; local in both phase space and parameter space.

One further term that is used in bifurcation theory needs explanation before we move on to examples. The *codimension* of a bifurcation is essentially the number of parameters required to be able to observe the bifurcation in typical systems. Codimension-one bifurcations are therefore observed in one-parameter families of systems, while higher-codimension bifurcations are observed by varying more parameters. These can often act as organizing centers for bifurcations with lower codimension.

2 Five Canonical Examples

The “typical” local bifurcations can be classified using their Taylor series expansions. In section 3 we discuss why the changes in dynamics described here are actually more general, but first we simply describe the different possibilities using examples.

The first is the *saddle-node* or *tangent* bifurcation. Consider the following scalar equations, with $p = m = 1$ in (1):

$$\begin{aligned}\dot{x} &= \mu - x^2 && \text{(flow),} \\ x_{n+1} &= x_n + \mu - x_n^2 && \text{(map).}\end{aligned}$$

Looking for stationary points of the continuous-time system ($\dot{x} = 0$) and fixed points of the discrete-time system ($x_{n+1} = x_n$) gives $x^2 = \mu$, so if $\mu < 0$ there are no such points, while if $\mu > 0$ there are two, $x_{\pm} = \pm\sqrt{\mu}$. Stability is determined by the 1×1 Jacobian matrix of derivatives. For the flow this is $-2x_{\pm}$, so x_+ is stable (negative eigenvalue) and x_- is unstable. For the map the Jacobian is $1 - 2x_{\pm}$, which has modulus less than one at x_+ (for small μ), indicating stability, while x_-

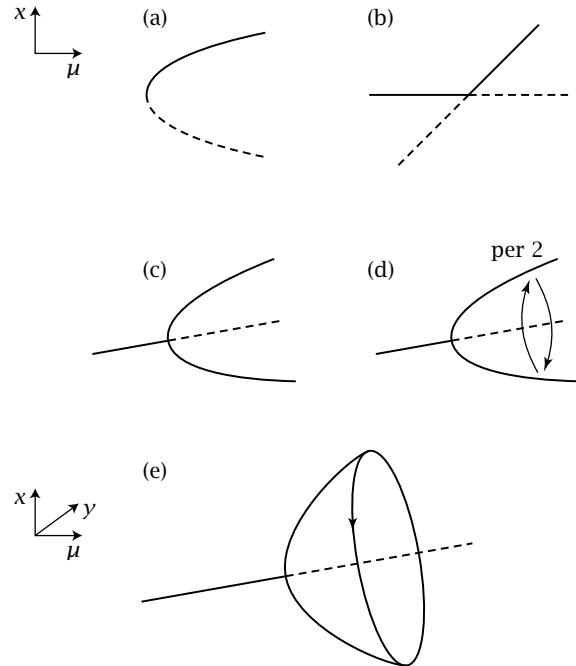

Figure 1 The simple bifurcations.

is unstable. The existence and stability of stationary points or fixed points are represented in the *bifurcation diagram* of figure 1(a), which shows the locus of stationary points and periodic orbits on the vertical axis as a function of the parameter (on the horizontal axis). By convention, the stability of solutions is indicated by plotting stable solutions with solid lines and unstable solutions with dotted lines.

If the origin is constrained to be a solution for all μ , or if the linear term in the parameter of the Taylor series of the function $f(x, \mu)$ of (1) vanishes at the bifurcation point, then a simple scalar model is

$$\begin{aligned}\dot{x} &= \mu x - x^2 && \text{(flow),} \\ x_{n+1} &= (1 + \mu)x_n - x_n^2 && \text{(map).}\end{aligned}$$

In these cases the stationary points are at $x = 0$ and $x = \mu$, and for small $|\mu|$ the origin is stable if $\mu < 0$ and unstable if $\mu > 0$, while the nontrivial solution has the opposite stability properties. This is called a *transcritical bifurcation* or *exchange of stability*, since the two branches of solutions cross and exchange their stability properties, as shown in figure 1(b).

If there is symmetry in the problem or if additional coefficients in the Taylor expansion of the map are zero,

then the quadratic part may vanish identically, leaving

$$\begin{aligned}\dot{x} &= \mu x - x^3 && (\text{flow}), \\ x_{n+1} &= (1 + \mu)x_n - x_n^3 && (\text{map}).\end{aligned}$$

This leads to a *pitchfork* bifurcation. If $|\mu|$ is sufficiently small, then the origin is stable if $\mu < 0$ and unstable if $\mu > 0$. If $\mu > 0$, a pair of new stable stationary solutions with $x^2 = \mu$ also exists. This is a *supercritical* pitchfork bifurcation: the pair of bifurcating solutions are stable (see figure 1(c)). If these solutions are unstable, then the bifurcation is said to be *subcritical*.

For maps there is another way in which a fixed point can lose stability in one-dimensional systems: the eigenvalue of the linearization can pass through -1 . In this case the canonical example is

$$x_{n+1} = -(1 + \mu)x_n + x_n^3,$$

which has a unique local fixed point at $x = 0$ that is stable if $\mu < 0$ and unstable if $\mu > 0$ (with $|\mu|$ sufficiently small). Due to the symmetry of the equations it is easy to see that there are two nontrivial solutions to the equation $x_{n+1} = -x_n$ if $\mu > 0$. These lie on a stable orbit of period two ($x \rightarrow -x \rightarrow x$), and this is therefore called a *period-doubling* bifurcation (see figure 1(d)). To indicate that the bifurcating period-two orbit is stable, it is called a supercritical period-doubling bifurcation; if the new orbit is unstable, coexisting with the stable fixed point, it is called subcritical. These bifurcations do not have a direct analogue for stationary points of flows, but they can occur as bifurcations of periodic orbits of flows, where the map represents a Poincaré map of the flow.

Another local bifurcation, shown in figure 1(e), occurs only in maps or flows with a phase space of dimension greater than one: a pair of complex conjugate eigenvalues pass through the imaginary axis for flows, or the unit circle for maps. Using polar coordinates (r, θ) for the flow and complex coordinates $z = x + iy$ for the map, the canonical examples are

$$\begin{aligned}\dot{r} &= \mu r - r^3, & \dot{\theta} &= \omega && (\text{flow}), \\ z_{n+1} &= (1 + \mu)e^{2\pi i \omega} z_n - |z_n|^2 z_n && (\text{map}).\end{aligned}$$

The origin is stable once again if $\mu < 0$ and $|\mu|$ is sufficiently small, but if $\mu > 0$ there is an attracting circle with radius $\sqrt{\mu}$. In the continuous case, this is a stable periodic orbit, and the bifurcation is called a supercritical *Hopf* bifurcation. In the discrete case, the dynamics on the invariant circle is more complicated: solutions are periodic if ω is rational, and nonperiodic and dense on the circle if ω is irrational. With more general nonlinear terms, this Hopf (or *Neimark-Sacker*) bifurcation of

maps has more cases. The rational case usually breaks up into a finite collection of stable and unstable periodic orbits, and these exist over intervals of parameters in a phenomenon called *mode locking*.

3 Dimension Reduction

The examples above are relevant more generally because there is a (local) dimension reduction possible near nonhyperbolic fixed points. Intuitively, this can be described by noting that, in eigenspaces corresponding to eigenvalues that are not on the imaginary axis (for flows) or the unit circle (for maps), the dynamics is determined by the linearization and decays to zero in forward time for stable directions or backward time for unstable directions. The only interesting directions in which changes can occur are, therefore, the “central” directions associated with zero or purely imaginary eigenvalues (flows) or eigenvalues with modulus one (maps).

It turns out that this observation can be made rigorous in at least two ways. These are the *CENTER MANIFOLD THEOREM* [IV.20 §4.3] and Lyapunov-Schmidt reduction. These describe how to construct projections onto the nonhyperbolic directions (valid for parameters close to the values at which the nonhyperbolic solution exists) such that any change in dynamics occurs in this projection. In particular, if there is a simple nonhyperbolic eigenvalue (the “typical” case), then the analysis reduces to a system with the same dimension as the corresponding eigenspace, i.e., dimension one for a real eigenvalue and dimension two for a complex conjugate pair of eigenvalues.

On these projections the leading terms of the Taylor series expansion of the projected equations are essentially the examples of the previous section. In the Hopf bifurcation for maps there are some extra subtleties that are admirably described in Arrowsmith and Place’s book *An Introduction to Dynamical Systems*.

The mathematical analysis of the bifurcations described above then follows using the dimension reduction and further analysis, e.g., by using the implicit function theorem to describe all possible local fixed points or periodic orbits. This produces a set of *genericity (or nondegeneracy) conditions* in terms of higher-order derivatives of the function f of (1) at the bifurcation point that need to be satisfied in addition to the existence of a neutral direction if the corresponding bifurcation is to be observed.

Although the center manifold theorem and Lyapunov-Schmidt reduction lead to the same conclusions

about dimension reduction, they use quite different methods. The center manifold theorem is established using invariant manifold theory for dynamical systems, e.g., by following the invariant manifold from the trivial linear case into the nonlinear regime. Lyapunov-Schmidt reduction relies on projection techniques onto linear eigendirections.

4 Global Bifurcations

Many global bifurcations involve homoclinic orbits. A homoclinic orbit to a stationary point of a flow is an orbit that approaches the stationary point in forward and backward time. This is a codimension-one phenomenon in typical families of differential equations, and so there is a straightforward bifurcation in which a given homoclinic orbit exists at an isolated value of the parameter. For periodic orbits the situation is rather different because homoclinic orbits typically persist over a range of parameter values, and the interest is therefore in how homoclinic orbits are created or destroyed as the parameter varies.

4.1 Homoclinic Bifurcations to Stationary Points: Planar Flows

Suppose an autonomous flow in the plane is defined by a differential equation that can be written (after a change of coordinates) as

$$\dot{x} = \lambda_1 x + f_1(x, y; \mu), \quad \dot{y} = -\lambda_2 y + f_2(x, y; \mu), \quad (2)$$

where the functions f_i vanish at the origin for all μ and denote nonlinear terms. The direction of time has been chosen such that $\lambda_2 > \lambda_1 > 0$, so locally the stationary point at the origin has a saddle structure as shown in figure 2. There is a one-dimensional stable manifold of solutions that tend to the origin as $t \rightarrow \infty$ that is tangential to the y -axis at the origin, and there is a one-dimensional unstable manifold of solutions that tend to the origin as $t \rightarrow -\infty$ that is tangential to the x -axis at the origin. Can these stable and unstable manifolds intersect?

Typically, one-dimensional sets can intersect transversely in two dimensions, so it might be expected that it is fairly easy for such intersections to occur and that these would be persistent under small changes of the parameters. However, if the two manifolds intersect at a point, then the trajectory through the intersection point must also be in the intersection of the manifolds. In other words, the intersection cannot be transverse, and a fairly straightforward argument shows that

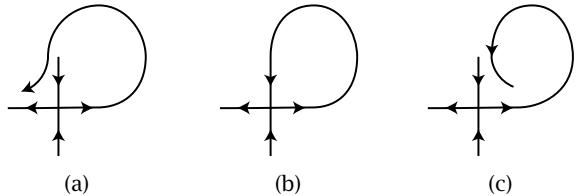

Figure 2 The unstable manifold of a planar homoclinic bifurcation: (a) $\mu < 0$; (b) $\mu = 0$, showing the return planes used in the construction of the return map; and (c) $\mu > 0$.

such intersections typically occur on codimension-one manifolds in parameter space.

Now suppose that if $\mu = 0$ there is a homoclinic orbit, as shown in figure 2(b). Then as μ passes through zero we can expect that the arrangements of the stable and unstable manifolds vary as shown in parts (a) and (c) of figure 2. The local change in behavior can be determined using a return map approach. Close to the stationary point, the flow is approximated by the linear part of (2), as nonlinear terms are much smaller, so approximate solutions are

$$x = x_0 e^{\lambda_1 t}, \quad y = y_0 e^{-\lambda_2 t}.$$

Thus if $h > 0$ is a small constant, solutions that start at (x_0, h) with $x_0 > 0$ intersect $x = h$ after time T , where $h \approx x_0 e^{\lambda_1 T}$ or $T \approx (1/\lambda_1) \log(h/x_0)$. At this intersection, $y = y_1 \approx h e^{-\lambda_2 T} \approx h(x_0/h)^{\lambda_2/\lambda_1}$. In other words, a solution starting at (x_0, h) with $x_0 > 0$ intersects $x = h$ at (h, y_1) and then evolves close to the unstable manifold away from the stationary point until it returns to $y = h$. If we choose the parametrization so that the unstable manifold of the stationary point first strikes $y = h$ at (μ, h) , then the solution starting at (h, y_1) with $y_1 > 0$ small enough will intersect $y = h$ at (x_1, h) close to (μ, h) . Since this flow is bounded away from stationary points, the return map is smooth and can be approximated by a Taylor series: $x_1 = \mu + A y_1 + \dots$. Composing these two maps, the linear approximation near the origin and the return map close to the homoclinic orbit outside a neighborhood of the origin, we find that the full flow close to the homoclinic orbit for $|\mu|$ sufficiently small is modeled by the approximate return map

$$x_{n+1} \approx \mu + a x_n^\delta, \quad x_n > 0, \quad \delta = \lambda_2/\lambda_1,$$

with a constant, and the map is undefined if $x_n \leq 0$ (if $x_n = 0$ the solution returns on the stable manifold and tends to the stationary point, while if $x_n < 0$ we have no information about the behavior of the unstable manifold). Since $\delta > 1$, there is a simple fixed point if

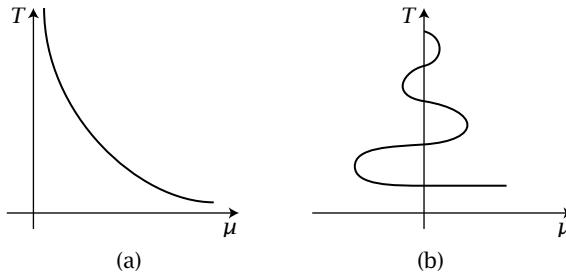

Figure 3 Parameter (μ) versus period (T) plots of the simple periodic orbit as it approaches the homoclinic orbit at $\mu = 0$ with $T \rightarrow \infty$. (a) Real eigenvalues, or a saddle-focus, with $\rho/\lambda > 1$. (b) A saddle-focus with $\rho/\lambda < 1$ (the Shilnikov case).

$\mu > 0$ at $x^* \approx \mu$ that is stable since the slope of the map is small, of order $x^{\delta-1}$. Most of the time is spent in the neighborhood of the stationary point, and so as μ tends to zero from above, the period scales like

$$T \sim -\frac{1}{\lambda_1} \log \mu,$$

i.e., it tends to infinity and approaches the homoclinic orbit itself. If $\mu < 0$ then there is no periodic solution locally. The effect of the bifurcation is to destroy or create a stable periodic orbit. The period of this orbit as a function of the parameter is sketched in figure 3(a).

4.2 Homoclinic Bifurcations to Stationary Points: Lorenz-Like Flows

In \mathbb{R}^3 , the bifurcation of a homoclinic orbit to a stationary point with a Jacobian matrix that has real eigenvalues is typically similar to the planar case. A periodic orbit is created or destroyed by the bifurcation. An interesting exception occurs if the system has the symmetry $(x, y, z) \rightarrow (-x, -y, z)$ with linearization

$$\begin{aligned}\dot{x} &= \lambda_1 x + f_1(x, y, z; \mu), \\ \dot{y} &= -\lambda_2 y + f_2(x, y, z; \mu), \\ \dot{z} &= -\lambda_3 z + f_3(x, y, z; \mu),\end{aligned}$$

with $\lambda_2 > \lambda_3 > \lambda_1 > 0$, and again the functions f_i vanish at the origin for all μ and denote nonlinear terms. In this case the second branch of the unstable manifold (the branch in $x < 0$) is the symmetric image of the branch in $x > 0$, and analysis similar to that of the previous subsection implies that the return map is defined in both $x > 0$ and $x < 0$ by symmetry:

$$x_{n+1} \approx \begin{cases} \mu + ax_n^\delta, & x_n > 0, \\ -\mu - a|x_n|^\delta, & x_n < 0, \end{cases}$$

with $\delta = \lambda_3/\lambda_1 < 1$. If $a > 0$ then the slope of the map tends to infinity as x tends to 0 from above or below, so there are no stable periodic orbits. In fact, if $\mu > 0$ all solutions leave a neighborhood of $x = 0$. However, if $\mu < 0$ then there is an unstable chaotic set of solutions similar to the chaotic set for the map $2x \pmod{1}$ in the article on DYNAMICAL SYSTEMS [IV.20 §3.2]. It is this chaotic set, or more accurately a subset of this set, that stabilizes at higher parameter values to become the LORENZ ATTRACTOR [III.20].

4.3 Homoclinic Bifurcations to Stationary Points: Shilnikov Flows

In generic systems a homoclinic orbit will approach the stationary point tangential to the eigenspace associated with the eigenvalue of the Jacobian matrix with smallest positive real part as $t \rightarrow -\infty$ and the eigenvalue with negative real part having the smallest modulus as $t \rightarrow \infty$. These are called the leading eigenvalues of the stationary point. In higher dimensions it is only the leading eigenvalues that determine the behavior of generic systems. The results can be phrased for general flows in \mathbb{R}^p , but for simplicity we consider only $p = 3$ and $p = 4$.

This means that there are two extra cases: the *saddle-focus*,

$$\begin{aligned}\dot{x} &= \lambda x + f_1(x, y, z; \mu), \\ \dot{y} &= -\rho y + \omega z + f_2(x, y, z; \mu), \\ \dot{z} &= -\omega y - \rho z + f_3(x, y, z; \mu),\end{aligned}$$

where ρ and λ are positive; and the *focus-focus*

$$\begin{aligned}\dot{x} &= \rho x + \omega y + f_1(x, y, z, w; \mu), \\ \dot{y} &= -\omega x + \rho y + f_2(x, y, z, w; \mu), \\ \dot{z} &= -Rz + \Omega w + f_3(x, y, z, w; \mu), \\ \dot{w} &= -\Omega z - R w + f_4(x, y, z, w; \mu),\end{aligned}$$

with $R, \rho > 0$, and Ω and ω nonzero. In both sets of equations the functions f_i are nonlinear and vanish at the origin for all μ .

The dynamics associated with the existence of homoclinic orbits to stationary points described locally by the saddle-focus or focus-focus was analyzed by Leonid Shilnikov in the mid-to-late 1960s. For the saddle-focus with $\rho/\lambda > 1$, the situation is similar to the planar case: a periodic orbit can be continued with changing parameter and approaches the homoclinic orbit monotonically as in figure 3(a). In the remaining cases the situation is more exotic. Shilnikov proved that at the parameter value for which the homoclinic

orbit exists there are a countable number of (unstable) periodic orbits and the dynamics contains horseshoes (and therefore unstable chaotic sets: see dynamical systems). Concentrating on the simplest periodic orbits—those that visit a neighborhood of the origin once in each period—it is possible to show that in the saddle-focus case with $\rho/\lambda < 1$ these exist with period T at parameters μ , where (to lowest order)

$$\mu \sim Ae^{-\rho T} \cos(\omega T + \phi),$$

which is an oscillatory approach to $\mu = 0$ as $T \rightarrow \infty$, as shown in figure 3(b). The turning points here correspond to saddle-node bifurcations, and on every branch involving stable orbits in the saddle-node bifurcations the orbit loses stability via period doubling before it reaches $\mu = 0$. Moreover, there are infinite sequences of more complicated homoclinic orbits accumulating on $\mu = 0$; these homoclinic orbits pass through a neighborhood of the stationary point more than once before tending to that point, and they are called *multipulse* homoclinic orbits. The focus-focus case is similar, but the accumulations can be more complicated.

4.4 Homoclinic Tangles

Whereas the intersection of stable and unstable manifolds is generally a codimension-one phenomenon for flows, it is persistent for maps. This is because the intersection must be at least one dimensional for flows, whereas for maps the existence of a point of intersection implies the existence of only a countable set of intersections. If a point p is on the intersection of the stable and unstable manifolds of a fixed point of a smooth invertible map f , then so are its preimages $f^{-n}(p)$, $n = 1, 2, 3, \dots$, which accumulate on the fixed point along its unstable manifold, and its images $f^n(x)$, which accumulate on the fixed point along its stable manifold. This gives rise to *homoclinic tangles*, as illustrated in figure 4(a). Transverse intersections of stable and unstable manifolds imply that chaotic sets exist, although the chaotic dynamics is not stable. This phenomenon also occurs in periodically forced systems, which can be analyzed via stroboscopic (or Poincaré) maps and provides one of the few ways of proving that a system has chaotic solutions. A range of techniques, known as Melnikov methods, have been developed to prove the existence of intersections between stable and unstable manifolds.

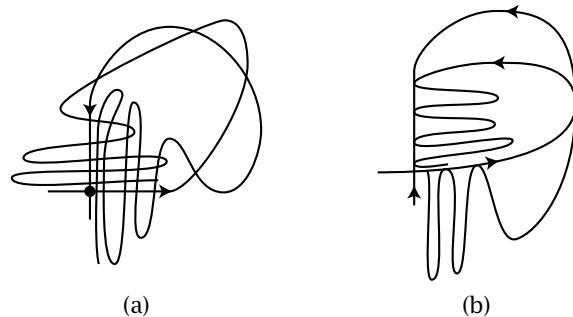

Figure 4 (a) Homoclinic tangles for maps.
(b) Homoclinic tangency.

4.5 Homoclinic Tangencies

The creation of persistent transverse intersections of stable and unstable manifolds as a parameter varies involves the existence of homoclinic tangencies at a critical parameter value as illustrated in figure 4(b). On one side of this value of the parameter there is no intersection locally, and on the other there is a transverse intersection. The existence of a homoclinic tangency implies all sorts of exotic dynamics at nearby parameters. In the 1970s Sheldon Newhouse proved that there are parameters close to the bifurcation point at which the system has a countably infinite number of *stable* periodic orbits, “infinitely many sinks,” and by the end of the 1990s it had been established that there are nearby parameter values (a positive measure of them) at which the system has a strange attractor. Moreover, the existence of a homoclinic tangency implies the existence of homoclinic tangencies for higher iterates of the map at nearby parameter values at which the same analysis holds, so the whole picture repeats for higher periods.

5 Cascades of Bifurcations

By the mid-1970s numerical simulations had shown that simple families of maps such as the quadratic (or logistic) map

$$x_{n+1} = \mu x_n (1 - x_n)$$

can have many complicated bifurcations (see THE LOGISTIC EQUATION [III.19]). Mitchell Feigenbaum showed that a much stronger and more precise statement is possible. For smooth families of maps there are infinite sequences (cascades) of period-doubling bifurcations. Thus there are parameter values μ_n at which an orbit of period 2^n has a period-doubling bifurcation, creating an orbit of period 2^{n+1} , $n = 0, 1, 2, \dots$, and these

accumulate on a limit μ_* at a rate

$$\lim_{n \rightarrow \infty} \frac{\mu_{n-1} - \mu_n}{\mu_n - \mu_{n+1}} = \delta$$

or $|\mu_n - \mu_*| \sim C\delta^{-n}$. Most remarkably, δ is a constant independent of the details of the map, a property referred to as quantitative universality. In fact, this “Feigenbaum constant” δ should really be thought of as a function of the order of the turning point of the map; if it behaves like $|x|^\alpha$ with $\alpha > 1$, then the rate is a function of α . For the typical quadratic turning point,

$$\delta \approx 4.669201609 \dots$$

This quantitative universality also manifests itself in the phase space as a sort of self-similarity under scaling. Feigenbaum was able to understand this by appealing to arguments based on renormalization analysis from statistical physics. At the accumulation point μ_* , the second iterate of the map, restricted to a smaller interval and suitably rescaled, behaves in almost exactly the same way as the map itself: they both have periodic orbits of period 2^n for all $n = 0, 1, 2, 3, \dots$. This idea can be exploited by defining a map \mathcal{T} on unimodal functions $f: [-1, 1] \rightarrow [-1, 1]$ with a maximum at $x = 0$ and with $f(0) = 1$:

$$\mathcal{T}f(x) = -\frac{1}{\alpha}f \circ f(-\alpha x),$$

where $\alpha = -f'(1)$. Seen as a map on an appropriately defined function space, it turns out that \mathcal{T} has a fixed point f_* (so $\mathcal{T}f_* = f_*$) with a codimension-one stable manifold consisting of maps corresponding to the special accumulation values of parameters μ_* for some family, and a one-dimensional unstable manifold with eigenvalue $\delta > 1$ (it is actually a little more complicated than this, but this statement contains the essential structure). The universal accumulation rate δ is therefore the unstable eigenvalue of a map in function space, and the universal scaling is due to the fact that under renormalization, maps on the stable manifold of f_* accumulate on f_* and so the spatial scaling α tends to $-f_*(1)$.

These period-doubling cascades are not limited to the doubling of fixed points. They can also be associated with periodic orbits of any period, creating cascades of period $2^n p$ for some fixed p . Period-doubling cascades also occur in higher dimensions and have been observed numerically in simulations of partial differential equations and experimentally in, for example, the changing convection patterns of liquid helium. The Lorenz maps of section 4.2 can also display cascades of homoclinic bifurcations if the saddle index λ_3/λ_1

is greater than one due to a simple correspondence between the Lorenz maps and unimodal maps based on the symmetry of the system.

Many codimension-two bifurcations involve the existence of infinitely many bifurcation curves, and these again can lead to cascades of bifurcations along appropriately chosen paths in parameter space. The special role played by period-doubling of orbits of period 2^n is that it is a natural route to chaos: on one side of the accumulation point of the period-doubling sequence associated with a fixed point of the map the map is simple, in the sense that it has only a finite number of periodic orbits, while on the other side it is chaotic with infinitely many periodic orbits of different periods (this is not true of cascades associated with other periods in general).

6 Codimension-Two Bifurcations

Codimension-two bifurcations are associated with special properties of a flow that can be observed in two-parameter systems but not (typically) in one-parameter families. Since there is often scope to vary more than one parameter in systems of interest, and because they act as useful organizing centers for describing the dynamics of one-parameter families and are the obvious next step after the codimension-one cases, many codimension-two bifurcations have been catalogued. Here we give two representative examples. One, the Takens-Bogdanov bifurcation, involves two zero eigenvalues at a stationary point and therefore generalizes the idea of local bifurcations to two-parameter systems. The other, a gluing bifurcation, occurs when there is a special value in parameter space at which two homoclinic orbits exist without a symmetry. This provides an example with an infinite set of bifurcations but no chaos.

6.1 Takens-Bogdanov Bifurcations

If a stationary point of a flow has two zero eigenvalues, then the linear part of the differential equation on the center manifold in appropriate coordinates will typically have the form

$$\begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix} \quad (3)$$

after a linear change of coordinates (there is obviously another possibility with every coefficient zero but this is more complicated and nongeneric). A natural way

to unfold this singularity is to introduce two small parameters, μ and ν , and consider the linear part

$$\begin{pmatrix} 0 & 1 \\ \mu & \nu \end{pmatrix}$$

with characteristic equation $s^2 - \nu s - \mu = 0$. If $\mu = 0$ there is a simple root (so a bifurcation such as a saddle node or pitchfork), and if $\nu = 0$ and $\mu < 0$ there is a purely imaginary pair of eigenvalues, suggesting a Hopf bifurcation (see section 2). By considering the nonlinear terms of lowest order after successive near-identity changes of coordinates, it is possible to show that the local behavior is typically modeled by the normal form

$$\dot{x} = y, \quad \dot{y} = \mu + \nu y + x^2 + bxy,$$

where we treat μ and ν as small parameters and, after scaling, $b = \pm 1$. In what follows we treat the case $b = 1$ as an example. If $\mu = \nu = 0$ then the origin is a stationary point and the Jacobian is (3). The bifurcation at $\mu = 0$ is a saddle node (except in the degenerate case $\nu = 0$), and if $\mu = -\nu^2$ ($\mu < 0$), there is a Hopf bifurcation creating a periodic orbit that exists in $\nu^2 < -\mu$ immediately after the bifurcation. Thinking about a circular path in parameter space enclosing the origin, it is clear that there must be another bifurcation (the periodic orbit is created but never destroyed), and in fact there is a homoclinic bifurcation on a curve starting at the origin given to leading order by $\mu = -\frac{49}{25}\nu^2$ that creates/destroys the periodic orbit as expected.

6.2 A Gluing Bifurcation

Suppose that at some parameter a system has a pair of homoclinic orbits in the same configuration as the Lorenz equations but without the symmetry and with saddle index $\lambda_3/\lambda_1 = \delta > 1$ (see section 4.2). There is then a natural two-parameter unfolding locally such that if one parameter is zero, one of the homoclinic orbits persists, and if the other parameter is zero, then the other homoclinic orbit exists, with both therefore existing at the intersection of the two axes. In the same way that an approximate return map was derived for the Lorenz-type flows of section 4.2, the analysis of this more general configuration leads to the approximate map

$$x_{n+1} \approx \begin{cases} -\mu + ax_n^\delta, & x_n > 0, \\ v - a|x_n|^\delta, & x_n < 0, \end{cases}$$

with $\delta > 1$ and $a > 0$. There are now two small parameters, μ and v , and since $\delta > 1$ the derivative of the map is small if $|x|$ is small and nonzero. These maps

have many similarities with maps of the circle that can be exploited to show that as the parameter varies in a path from $(\mu, v) = (\varepsilon, 0)$ to $(\varepsilon, 0)$ for some small $\varepsilon > 0$, the proportion of points of the attractor varies continuously from zero to one, and if it is rational then there is a stable periodic orbit with that proportion of points in $x > 0$. These stable periodic orbits exist on small intervals of the parameters in a form of mode locking.

7 Bits and Pieces

There are many other areas that could be covered in a review such as this, and in this final section we summarize just four of them.

7.1 Saddle-Node on Invariant Circle

Suppose that a saddle-node bifurcation of a stationary point occurs on a periodic orbit for a flow. At first sight this might appear to be a codimension-two bifurcation: one parameter for the saddle node and the other to locate it on a periodic orbit. However, if the periodic orbit is stable, then at the point of saddle-node bifurcation the connection between the weakly unstable direction and the stable manifold is persistent, so it is in fact codimension one. These bifurcations, called SNICs (saddle-node on invariant circle), create a stable periodic orbit from a stable-saddle pair of stationary points. The period of the orbit tends to infinity as the bifurcation point is approached like the inverse of the square root of the parameter (cf., the logarithmic divergence for homoclinic bifurcations in section 4).

The SNIC in discrete-time systems is again of codimension one, but this time chaotic solutions exist in a neighborhood of the bifurcation and there are complex foldings of the unstable manifold as it approaches the fixed point. This was described in detail by Newhouse, Palis, and Takens in the early 1980s.

7.2 Intermittency

Intermittency describes motion that is close to being periodic for a long time, called the laminar phase, and that then has a chaotic burst before returning to the laminar, almost periodic, phase. It can also be seen as a prototype for the more general mixed-mode oscillations observed in neuroscience and elsewhere. Although not strictly a bifurcation, the phenomenon of intermittency is seen as parameters vary and this makes it worth mentioning here. There are several different types of intermittency. The simplest case can

be observed in the quadratic (or logistic) map $x_{n+1} = \mu x_n(1 - x_n)$. There are parameter values with stable periodic orbits that can lose stability via saddle-node bifurcations as the parameter is decreased through a critical value μ_c . Just before the saddle-node bifurcation creates the stable periodic orbit, solutions that pass close to the locus of the periodic orbit will spend a long time, proportional to $|\mu - \mu_c|^{-1/2}$, close to the points where the periodic orbit will eventually be created, before moving away. If there is some reinjection mechanism due to global properties of the map, then after moving away the solution may find its way back into the laminar region and the process repeats. The SNIC is a special case in which the reinjection is always at the same point. This sequence of long laminar regions interspersed by bursts is generalized by the idea of mixed-mode oscillations, where the laminar region may be replaced by much more complicated but localized behavior.

7.3 Hamiltonian Flows

If the defining differential equation can be derived from a Hamiltonian, so the phase space can be divided into two sets of variables $(q, p) \in \mathbb{R}^n \times \mathbb{R}^n$ with a function $H(q, p)$ such that

$$\dot{q}_i = \frac{\partial H}{\partial p_i}, \quad \dot{p}_i = -\frac{\partial H}{\partial q_i}, \quad i = 1, \dots, n,$$

then this special structure (and generalizations of it) implies that the dynamics has very special features. These equations are important because they include many Newtonian models where friction is ignored. The equations of motion imply that H is constant on solutions, so solutions lie on level sets of the function H . This in turn implies that features that are special (that is, have codimension one) in generic systems are robust in Hamiltonian systems. A good example is the existence of homoclinic orbits, so the global bifurcations of Hamiltonian systems are very different from those of the more general systems described in section 4. (Note that the global bifurcation theorems given above assumed that the homoclinic orbits exist on codimension-one surfaces in parameter space.) Even local bifurcations are special: a stationary point of a two-dimensional Hamiltonian system is typically either a saddle or a center, and this means that the saddle-node bifurcation involves the creation of a center and a saddle, with a set of periodic motions around the center, bounded by a robust homoclinic orbit! The

differential equation with Hamiltonian

$$H(q, p) = \frac{1}{2}p^2 + \mu q - \frac{1}{3}q^3$$

has just such a transition as μ passes through zero.

7.4 Homoclinic Snaking

Since the existence of homoclinic orbits can be persistent with changing parameters in Hamiltonian systems, homoclinic orbits may be continued in parameter space in the same way that periodic orbits can be continued in more general systems. One interesting feature that is observed is *homoclinic snaking*, where the curve of homoclinic orbits oscillates as some measure (such as a norm) increases with parameters. Models of pattern formation such as the SWIFT-HOENBERG EQUATIONS [IV.27 §2] exhibit this snaking if the time-dependent solutions are considered in one spatial dimension. Localized solutions (solitary waves) can be found that tend to zero at large spatial amplitudes but that have more and more complicated oscillations between these limits. In this case, the continuations of these solutions oscillate in parameter space, gaining an extra spatial maximum or minimum on each monotonic branch, in a pattern that is reminiscent of the oscillation of the periodic solution near the Shilnikov homoclinic orbits of figure 3, except that the oscillations have a bounded amplitude in parameter space rather than decreasing amplitude as in the figure.

7.5 Piecewise-Smooth Systems

Many applications in mechanics (friction and impacts, for example), biology (gene switching), and control (threshold control) are modeled by piecewise-smooth systems, where the dynamics evolves continuously until some switching surface is reached, and then there is a transition to a different (but still smooth) dynamics, possibly with a reset to another part of phase space. These are examples of HYBRID SYSTEMS [II.18]. The evolution is therefore a sequence of behaviors determined by smooth dynamical systems that are stitched together across the switching surfaces. New bifurcations occur when a periodic orbit intersects a switching surface tangentially, introducing a new segment to the dynamics, or if a fixed point or periodic orbit of a map intersects the switching surface. In the example of impacting systems, a standard model return map has a square root singularity:

$$x_{n+1} = \begin{cases} \mu - \sqrt{x_n}, & x_n > 0, \\ \mu + ax_n, & x_n < 0. \end{cases} \quad (4)$$

The maps obtained in these situations have much in common with the Lorenz maps discussed earlier with $\delta < 1$ as the derivative is unbounded as x tends to zero from above, but they are also continuous unimodal maps and so general theorems such as Sharkovskii's theorem (which describes how the existence of a periodic orbit of a given period implies the existence of other periodic orbits in continuous maps) hold (see LOGISTIC EQUATION [III.19]). When applied to the special case of unimodal maps this restricts the order in which periodic orbits are created. However, while the logistic map has many windows of stable periodic orbits, each with its own period-doubling cascade and associated chaotic motion, the *stable* periodic orbits of the square root map (4) are much more constrained. For example, if $0 < \alpha < \frac{1}{4}$, the stable periodic orbits form a period-adding sequence as μ decreases through zero. There is a parameter interval on which a period- n orbit is the only attractor, followed by a bifurcation creating a stable period-($n+1$) orbit so that the two stable orbits of period n and period ($n+1$) coexist. Then there is a further bifurcation at which the period- n orbit loses stability and the stable period-($n+1$) orbit is the only attractor. This sequence of behavior is repeated with n tending to infinity as μ tends to zero.

8 Afterview

Bifurcation theory provides insights into why certain types of dynamics occur and how they arise. In cases such as period-doubling cascades it provides a framework in which to understand the changes in complexity of dynamics even if the behavior at a single parameter value might appear nonrepeatable. The number of different cases that may need to be considered can proliferate, and there is currently a nonuniformity of nomenclature that means that it is hard to tell whether a particular case has been studied previously in the literature. Given that the techniques are useful in any discipline that uses dynamic modeling, this aspect is unfortunate and leads to many reinventions of the same result. However, this only underlines the central role played by bifurcation theory in understanding the dynamics of mathematical models wherever they occur.

IV.22 Symmetry in Applied Mathematics

Ian Stewart

We tend to think of the applied mathematical toolkit as a collection of specific techniques for precise calculations, each intended for a particular kind of problem, solving a system of algebraic or differential equations numerically, for example. But some of the most powerful ideas in mathematics are so broad that at first sight they seem too vague and nebulous to have practical implications. Among them are probability, continuity, and symmetry.

Probability started out as a way to capture uncertainty in gambling games, but it quickly developed into a vitally important collection of mathematical techniques used throughout applied science, economics, sociology—even for formulating government policy.

Continuity proved such an elusive concept that it was used intuitively for centuries before it could be defined rigorously; now it underpins calculus, perhaps the most widely used mathematical tool of them all, especially in the form of ordinary and partial differential equations. But continuity is also fundamental to topology, a relative newcomer from pure mathematics that is starting to demonstrate its worth in the design of efficient trajectories for spacecraft, improved methods for forecasting the weather, frontier investigations in quantum mechanics, and the structure of biologically important molecules, especially deoxyribonucleic acid (DNA).

Symmetry, the topic of this article, was initially a rather ill-defined feeling that certain parts of shapes or structures were much the same as other parts of those shapes or structures. It has since become a vital method for understanding pattern formation throughout the scientific world, with applications that range from architecture to zoology. Symmetry, it turns out, underlies many of the deepest aspects of the natural world. Our universe behaves the way it does because of its symmetries—of space, time, and matter. Both relativity and particle physics are based on symmetry principles. Symmetry methods shed light on difficult problems by revealing general principles that can help us find solutions. Symmetry can be static, dynamic, even

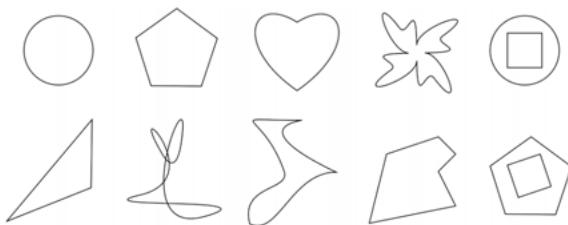

Figure 1 Which shapes are symmetric?

chaotic. It is a concept of great generality and deep abstraction, where beauty and power go hand in hand.

1 What Is Symmetry?

Symmetry is most easily understood in a geometric setting. Figure 1 shows a variety of plane figures, some symmetric, some not. Which are which?

The short answer is that the top row consists of symmetric shapes and the bottom row consists of asymmetric shapes. But there is more. Not only can shapes be symmetric, or not—they can have different *kinds* of symmetry. The heart (the middle of the top row) has the most familiar symmetry, one we encounter every time we look at ourselves in a mirror: *bilateral* symmetry. The left-hand side of the figure is an exact copy of the right-hand side, but flipped over. Three other shapes in the figure are bilaterally symmetric: the circle, the pentagon, and the circle with a square hole. The pentagon with a tilted square hole is not; if you flip it left-right, the pentagonal outline does not change but the square hole does because of the way it is tilted.

However, the circle has more than just bilateral symmetry. It would look the same if it were reflected in any mirror that runs through its center. The pentagon would look the same if it were reflected in any mirror that runs through its center and passes through a vertex.

What about the fourth shape in the top row, the flowery thing? If you reflect it in a mirror, it looks different, no matter where the mirror is placed. However, if you rotate it through a right angle about its center, it looks exactly the same as it did to start with. So this shape has *rotational* symmetry for a right-angle rotation. Thus primed, we notice that the pentagon also has rotational symmetry, for a rotation of 72° , and the circle has rotational symmetry for any angle whatsoever.

Most of the shapes on the bottom row look completely asymmetric. No significant part of any of them looks much like some other part of the same shape. The

possible exception is the pentagon with a square hole. The pentagon is symmetric, as we have just seen, and so is the square. Surely combining symmetric shapes should lead to a symmetric shape? On the other hand, it does look a bit lopsided, which is not what we would expect from symmetry. With the current definition of symmetry, this shape is asymmetric, even though some pieces of it are symmetric.

In the middle of the nineteenth century mathematicians finally managed to define symmetry, for geometric shapes, by abstracting the common idea that unifies all of the above discussion. The background involves the idea of a *transformation* (or function or map). Some of the most common transformations, in this context, are rigid motions of the plane. These are rules for moving the entire plane so that the distances between points do not change. There are three basic types.

Translations. Slide the plane in a fixed direction so that every point moves the same distance.

Rotations. Choose a point, keep this fixed, and spin the entire plane around it through some angle.

Reflections. Choose a line, think of it as a mirror, and reflect every point in it.

These transformations do not exhaust the rigid motions of the plane, but every rigid motion can be obtained by combining them. One of the new transformations produced in this way is the *glide reflection*; reflect the plane in a line and then translate it along the direction of that line.

Having defined rigid motions, we can now define what a symmetry is. Given some shape in the plane, a symmetry of that shape is a rigid motion of the plane that leaves the shape *as a whole* unchanged. Individual points in the shape may move, but the end result looks exactly the same as it did to start with—not just in terms of shape, but also location.

For example, if we reflect the pentagon about a line through its center and a vertex, then points not on the line flip over to the other side. But they swap places in pairs, each landing where the other one started from, so the final position of the pentagon fits precisely on top of the initial position. This is false for the pentagon with a square hole, and this is the reason why that shape is not considered to possess symmetry.

The shapes in figure 1 are all of finite size, so they cannot possess translational symmetry. Translational symmetries require infinite patterns. A typical example is a square tiling of the entire plane, like bathroom tiles

but continued indefinitely. If this pattern is translated sideways by the width of one tile, it remains unchanged. The same is true if it is translated upward by the width of one tile. It follows that, if the tiling is translated an integer number of widths in either of these two directions, it again remains unchanged. The symmetry group of translations is a *lattice*, consisting of integer combinations of two basic translations. The square tiling also has rotational symmetries, through multiples of 90° about the center of a tile or a corner where four tiles meet. Another type of rotational symmetry is rotation through 180° about the center of the edge of a tile. The square tiling pattern also has various reflectional symmetries.

Lattices in the plane can be interpreted as wallpaper patterns. In 1891 the pioneer of mathematical crystallography Yevgraf Fyodorov proved that there are exactly 17 different symmetry classes of wallpaper patterns. George Pólya obtained the same result independently in 1924. Lattice symmetries, often in combination with rotations and reflections, are of crucial importance in crystallography, but now the “tiling” is the regular atomic structure of the crystal, and it repeats in three-dimensional space along integer combinations of three independent directions. Again there may also be rotations and reflections. The physics of a crystal is strongly influenced by the symmetries of its atomic lattice. In the 1890s Fyodorov, Arthur Shönflies, and William Barlow proved that there are 230 symmetry types of lattice, or 219 if certain mirror-image pairs are considered to be the same.

Of course, no physical crystal can be of infinite extent. However, the idealization to infinite lattices can be a very accurate model for a real crystal because the size of the crystal is typically much larger than the lattice spacing. Real crystals differ from this ideal model in many ways: dislocations, where the lattice fails to repeat exactly; grain boundaries, where local lattices pointing in different directions meet; and so on. All applied mathematics involves a modeling step, representing the physical system by a simplified and idealized mathematical model. What matters is the extent to which the model provides useful insights. Its failure to include certain features of reality is not, of itself, a valid criticism. In fact, such a failure can be a virtue if it makes the analysis simpler without losing anything important.

Symmetries need not be rigid motions. Another geometric symmetry is dilation—change of scale. A logarithmic spiral, found in nature as a nautilus shell,

remains unchanged if it is dilated by some fixed amount and also rotated through an appropriate angle.

Symmetry does not apply only to shapes; it is equally evident in mathematical formulas. For example, $x + y + z$ treats the three variables x , y , and z in exactly the same manner. But the expression $x^3 + y - 2z^2$ does not. The first formula is symmetric in x , y , and z ; the second is not. This time the transformations concerned are *permutations* of the three symbols—ways to swap them around. However we permute them, $x + y + z$ stays the same. For instance, if we swap x and y but leave z the same, the expression becomes $y + x + z$. By the laws of algebra, this equals $x + y + z$. But the same permutation applied to the other expression yields $y^3 + x - 2z^2$, which is clearly different.

Symmetry thereby becomes a very general concept. Given any mathematical structure, and some class of transformations that can act on the structure, we define a symmetry to be any transformation that preserves the structure—that is, leaves it unchanged.

If a physical system has symmetry, then most sensible mathematical models of that system will have corresponding symmetries. (I say “most” because, for example, numerical methods cannot always incorporate all symmetries exactly. No computer model of a circle can be unchanged by all rotations. This inability of numerical methods to capture all symmetries can sometimes cause trouble.) The precise formulation of symmetry for a given model depends on the kind of model being used and its relation to reality.

2 Symmetry Groups

The above definition tells us that a symmetry of some structure (shape, equation, process) is not a thing but a transformation. However, it also tells us something deeper: structures may have several different symmetries. Indeed, some structures, such as the circle, have infinitely many symmetries. So there is a shift of emphasis from symmetry to symmetries, not symmetry as an abstract property of a structure but the *set of all symmetries* of the structure.

This set of transformations has a simple but vital feature. Transformations can be combined by performing them in turn. If two symmetries of some structure are combined in this way, the result is always a symmetry of that structure. It is not hard to see why: if you do not change something, and then you *again* do not change it... you do not change it. This feature is known as the

“group property,” and the set of all symmetry transformations, together with this operation of composition, is the *symmetry group* of the structure.

The shapes in figure 1 illustrate several common kinds of symmetry group. The rotations of the circle form the *circle group* or *special orthogonal group in the plane*, denoted by S^1 or $SO(2)$. The reflections and rotations of the circle form the *orthogonal group in the plane*, denoted by $O(2)$. The rotations of the pentagon form the *cyclic group* Z_5 of order 5 (the order of a group is the number of transformations that it contains). The rotations of the flower shape form the cyclic group Z_4 of order 4. There is an analogous cyclic group Z_n whose order is any positive integer n ; it can be defined as the group of rotational symmetries of a regular n -sided polygon. If we also include the five reflectional symmetries of the pentagon, we obtain the *dihedral group* D_5 , which has order 10. There is an analogous dihedral group D_n of order $2n$ for any positive integer n : the rotations and reflections of a regular n -sided polygon. Finally, we mention the *symmetric group* S_n of all permutations of a set with n elements, such as $\{1, 2, 3, \dots, n\}$. This has order $n!$, that is, $n(n - 1)(n - 2) \cdots 3 \cdot 2 \cdot 1$.

Even asymmetric shapes have some symmetry; the identity transformation “leave everything as it is.” The symmetry group contains only this trivial but useful transformation, and it is symbolized by **1**.

We mention one useful piece of terminology. Often one group sits inside a bigger one. For example, $SO(2)$ is contained in $O(2)$, and Z_n is contained in D_n . In such cases, we say that the smaller group is a *subgroup* of the bigger one. (They may also be equal, a trivial but sensible convention.)

The study of groups has led to a huge area of mathematics known as *group theory*. Some of it is part of abstract algebra, especially when the group is finite—that is, contains a finite number of transformations. Examples are the cyclic, dihedral, and symmetric groups. Another area, involving analysis and topology, is the theory of *Lie groups*, such as the circle group, the orthogonal group, and their analogues in spaces of any dimension. Here the main emphasis is on continuous families of symmetry transformations, which correspond to all choices of some real number. For example, a circle can be rotated through any real angle. Yet another important area is *representation theory*, which studies all the possible ways to construct a given group using matrices, linear transformations of some vector space.

One of the early triumphs of group theory in applied mathematics was Noether’s theorem, proved by Emmy Noether in 1918. This applies to a special type of differential equation known as a Hamiltonian system, which arises in models of classical mechanics in the absence of frictional forces. Celestial mechanics—the motion of the planets—is a significant example. The theorem states that whenever a Hamiltonian system has a continuous family of symmetries, there is an associated conserved quantity. “Conserved” means that this quantity remains unchanged as the system moves.

The laws of nature are the same at all times: if you translate time from t to $t + \theta$, the laws do not look any different. These transformations form a continuous family of symmetries, and the corresponding conserved quantity is energy. Translational symmetry in space (the laws are the same at every location) corresponds to conservation of momentum. Rotations about some axis in three-dimensional space provide another continuous family of symmetries; here the conserved quantity is angular momentum about that axis. All of the conservation laws of classical mechanics are consequences of symmetry.

3 Pattern Formation

Symmetry methods come into their own, and nowadays are almost mandatory, in problems about pattern formation. Often the most striking feature of some natural or experimental system is the occurrence of patterns. Rainbows are colored circular arcs of light. Ripples caused by a stone thrown into a pond are expanding circles. Sand dunes, ocean waves, and the stripes on a tiger or an angelfish are all patterns that can be modeled using repeating parallel features. Crystal lattices are repeating patterns of atoms. Galaxies form vast spirals, which rotate without (significantly) changing shape—a group of symmetries combining time translation with spatial rotation.

Many of these patterns arise through a general mechanism called “symmetry breaking.” This is applicable whenever the equations that model a physical system have symmetry. I say “equations” here, even though I have already insisted that the symmetries of the system should appear in the equations, because it is not unusual for the model equations to have *more* symmetry than the pattern under consideration. Our theories of symmetry breaking and pattern formation rest on the structure of the symmetry group and its implications for mathematical models of symmetric systems.

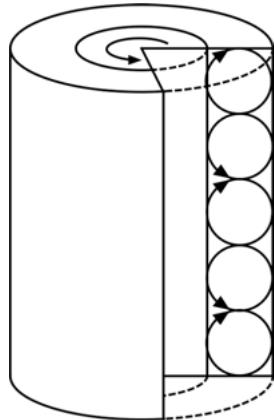

Figure 2 Taylor-Couette apparatus, showing flow pattern for Taylor vortices.

A classic example is Taylor-Couette flow, in which fluid is confined between two rotating cylinders (figure 2). In experiments this system exhibits a bewildering variety of patterns, depending on the angular velocities of the cylinders and the relative size of the gap between them. The experiment is named after Maurice Couette, who used a fixed outer cylinder and a rotating inner one to measure the viscosity of fluids. At the low velocities he employed, the flow is featureless, as in figure 3(a). In 1923 Geoffrey Ingram Taylor noted that when the angular velocity of the inner cylinder exceeds a critical threshold, the uniform pattern of Couette flow becomes unstable and instead a stack of vortices appears; see figures 2 and 3(b). The vortices spiral round the cylinder, and alternate vortices spin the opposite way in cross section (small circles with arrows). Taylor calculated this critical velocity and used it to test the NAVIER-STOKES EQUATIONS [III.23] for fluid flow.

Further experimental and theoretical work followed, and the apparatus was modified to allow the outer cylinder to rotate as well. This can make a difference because, in a rotating frame of reference, the fluid is subject to additional centrifugal forces. In these more general experiments, many other patterns were observed. Figure 3 shows a selection of them.

The most obvious symmetries of the Taylor-Couette system are rotations about the common axis of the cylinders. These preserve the structure of the apparatus. But notice that not all patterns have full rotational symmetry. In figure 3 only the first two—Couette flow and Taylor vortices—are symmetric under all rotations. Another family of symmetries arises if the system is

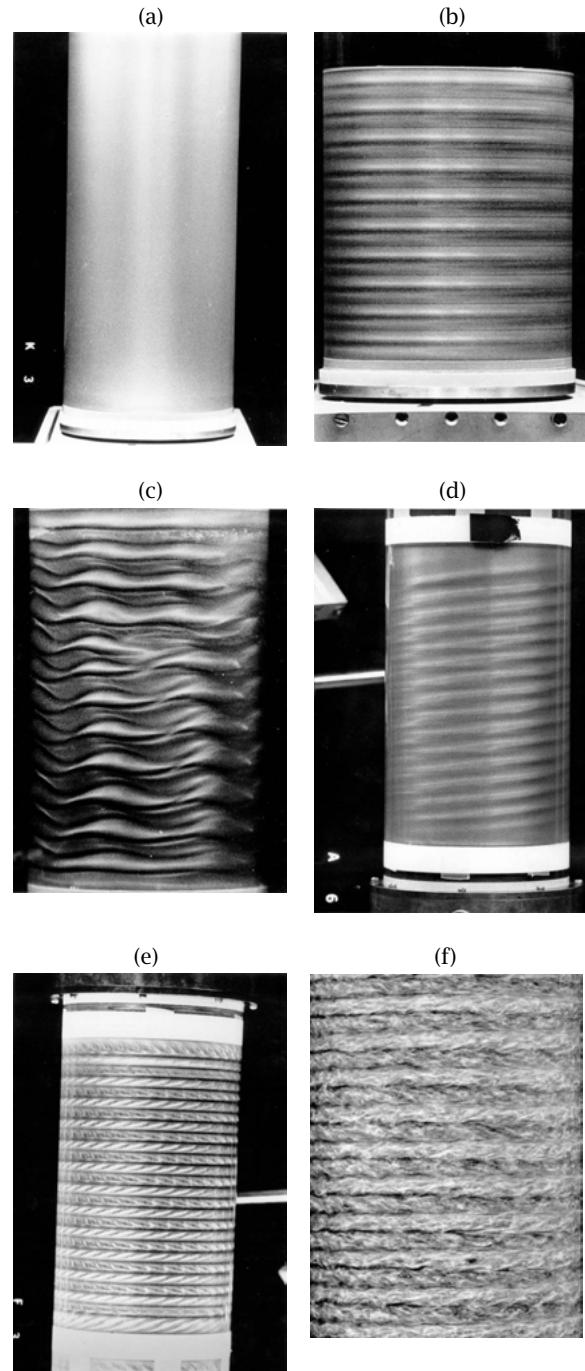

Figure 3 Some of the numerous flow patterns in the Taylor-Couette system: (a) Couette flow; (b) Taylor vortices; (c) wavy vortices; (d) spiral vortices; (e) twisted vortices; and (f) turbulent vortices. Source: Andereck et al. (1986).

modeled (as is common for some purposes) by two infinitely long cylinders but restricted to patterns that repeat periodically along their lengths. In effect, this wraps the top of the cylinder round and identifies it with the bottom. Mathematically, this trick employs a modeling assumption: “periodic boundary conditions” that require the flow near the top to join smoothly to the flow near the bottom. With periodic boundary conditions, the equations are symmetric under all vertical translations. But again, not all patterns have full translational symmetry. In fact, the only one that does is Couette flow. So all patterns except Couette flow break at least some of the symmetries of the system.

On the other hand, most of the patterns retain some of the symmetries of the system. Taylor vortices are unchanged by vertical translations through distances equal to the width of a vortex pair (see figure 2). The same is true of wavy vortices, spirals, and twisted vortices. We will see in section 7 how each pattern in the figure can be characterized by its symmetry group.

There are at least two different ways to try to understand pattern formation in the Taylor-Couette system. One is to solve the Navier-Stokes equations numerically. The computations are difficult and become infeasible for more complex patterns. They also provide little insight into the patterns beyond showing that they are (rather mysterious) consequences of the Navier-Stokes equations. The other is to seek theoretical understanding, and here the symmetry of the apparatus is of vital importance, explaining most of the observed patterns.

4 Symmetry of Equations

To understand the patterns that arise in the Taylor-Couette system, we begin with a simpler example and abstract its general features. We then explain what these features imply for the dynamics of the system. In a later section we return to the Taylor-Couette system and show how the general theory of dynamics with symmetry classifies the patterns and shows how they arise. This theory is based on a mathematical consequence of the symmetry of the system being modeled; the differential equations used to set up the model have the same symmetries as the system. A symmetry of an equation is defined to be a transformation of the variables that sends solutions of the equation to (usually different) solutions.

The appropriate formulation of symmetry for an ordinary differential equation is called equivariance.

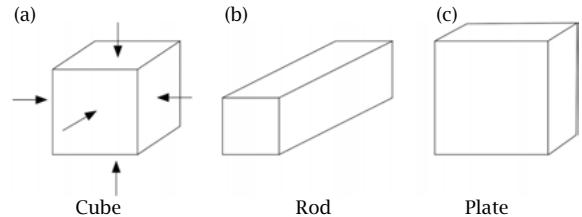

Figure 4 (a) Cube under compression (force at back not shown). (b) Rod solution. (c) Plate solution.

Suppose that Γ is a group of symmetries acting on the variables $x = (x_1, \dots, x_m)$ in the equation

$$\frac{dx}{dt} = F(x).$$

Then F is *equivariant* if

$$F(yx) = yF(x) \quad \text{for all symmetries } y \text{ in } \Gamma.$$

It follows immediately that, if $x(t)$ is any solution of the system, so is $yx(t)$ for any symmetry y . In fact, this condition is logically equivalent to equivariance. In simple terms, solutions always occur in symmetrically related sets. We will see an example of this phenomenon below.

A central concept in symmetric dynamics is **BIFURCATION** [IV.21], for which the context is a family of differential equations—an equation that contains one or more parameters. These are variables that are assumed to remain constant when solving the equation but can take arbitrary values. In a problem about the motion of a planet, for example, the mass of the planet may appear as a parameter. Such a family undergoes a *bifurcation* at certain parameter values if the solutions change in a qualitative manner near those values. For example, the number of equilibria might change, or an equilibrium might become a time-periodic oscillation. Bifurcations have a stronger effect than, say, moving an equilibrium continuously or slightly changing the shape and period of an oscillation. They provide a technique for proving the existence of interesting solutions by working out when simpler solutions become unstable and what happens when they do.

To show how symmetries behave at a bifurcation point, we consider a simple model of the deformation of an elastic cube when it is compressed by six equal forces acting at right angles to its faces (figure 4(a)). We consider deformations into any cuboid shape with sides (a, b, c) . When the forces are zero, the shape of the body is a cube, with $a = b = c$. The symmetry group consists of the permutations of the coordinate

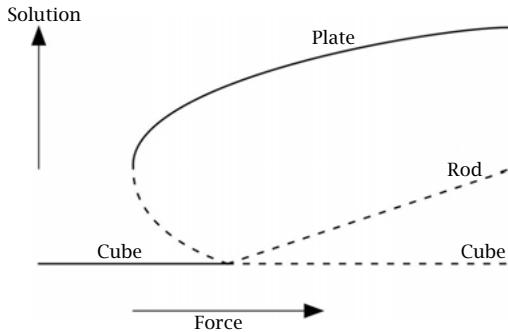

Figure 5 Bifurcation diagram (solid lines, stable; dashed lines, unstable).

axes, changing (a, b, c) to (a, c, b) , (b, c, a) , and so on. Physically, these rotate or reflect the shape, and they constitute the symmetric group S_3 .

As the forces increase, always remaining equal, the cube becomes smaller. Initially, the sides remain equal, but analysis of a simplified but reasonable model shows that, when the forces become sufficiently large, the fully symmetric “cube” state becomes unstable. Two alternative shapes then arise: a *rod* shape (a, b, c) with two sides equal and smaller than the third, and a *plate* shape (a, b, c) with two sides equal and larger than the third (figure 4). The *bifurcation diagram* in figure 5 is a schematic plot of the shape of the deformed cube, plotted vertically, against the forces, plotted horizontally. The diagram shows how the existence and stability of the deformed states relate to the force. In this model only the plate solutions are stable.

In principle there might be a third shape, in which all three sides are of different lengths; however, such a solution does not occur (even unstably) in the model concerned.

Earlier, I remarked that solutions of symmetric equations occur in symmetrically related sets. Here, rod solutions occur in three symmetrically related forms, with the longer side of the rod pointing in any of the three coordinate directions. Algebraically, these solutions satisfy the symmetrically related conditions $a = b < c$, $a = c < b$, and $b = c < a$. The same goes for plate solutions.

5 Symmetry Breaking

The symmetry group for the buckling cube model contains six transformations:

$$I: (a, b, c) \rightarrow (a, b, c),$$

$$X: (a, b, c) \rightarrow (a, c, b),$$

$$Y: (a, b, c) \rightarrow (c, b, a),$$

$$Z: (a, b, c) \rightarrow (b, a, c),$$

$$R: (a, b, c) \rightarrow (b, c, a),$$

$$S: (a, b, c) \rightarrow (c, a, b).$$

We can consider the symmetries of the possible states, that is, the transformations that leave the shape of the buckled cube unchanged. Rods and plates have square cross section, and the two lengths in those directions are equal. If we interchange those two axes, the shape remains the same. Only the cube state has all six symmetries S_3 . The rod with $a = b < c$ is symmetric under the permutations that leave z fixed, namely $\{I, Z\}$. The rod with $a = c < b$ is symmetric under the permutations that leave y fixed, namely $\{I, Y\}$. The rod with $b = c < a$ is symmetric under the permutations that leave x fixed, namely $\{I, X\}$. The same holds for the plates. If a solution existed in which all three sides had different lengths, its symmetry group would consist of just $\{I\}$. All of these groups are subgroups of S_3 .

Notice that the subgroups $\{I, X\}$, $\{I, Y\}$, $\{I, Z\}$ are themselves related by symmetry. For example, a solution (a, b, c) with $a = b < c$ becomes (b, c, a) with $b = c < a$ when the coordinate axes are permuted using R . In the terminology of group theory, these three subgroups are *conjugate* in the symmetry group.

The buckling cube is typical of many symmetric systems. Solutions need not have all of the symmetries of the system itself. Instead, some solutions may have smaller groups of symmetries—subgroups of the full symmetry group. Such solutions are said to *break* symmetry. For an equivariant system of ordinary differential equations, fully symmetric solutions may exist, but these may be unstable. If they are unstable, the system will find a stable solution (if it can), and this typically breaks the symmetry.

In general, the symmetry group of a solution is a subgroup of the symmetry group of the differential equation. Some subgroups may not occur here. Those that do are known as *isotropy subgroups*. For the buckling cube, the group S_3 has the five isotropy subgroups listed above. One subgroup is missing from that list, namely $\{I, R, S\}$. This is not an isotropy subgroup because a shape with these symmetries must satisfy the condition $(a, b, c) = (b, c, a)$, which forces $a = b = c$. This shape is the cube, which has additional symmetries X , Y , and Z . This situation is typical of subgroups that are not isotropy subgroups; the symmetries of such a subgroup force additional symmetries that are not in the subgroup.

A first step toward classifying the possible symmetry-breaking solutions of a differential equation with a known symmetry group is to use group theory to list the isotropy subgroups. Techniques then exist to find solutions with a given isotropy subgroup. Only one isotropy subgroup from each conjugacy class need be considered because solutions come in symmetrically related sets.

There are general theorems that guarantee the existence of solutions with certain types of isotropy subgroup, but they are too technical to state here. Roughly speaking, symmetry-breaking solutions often occur for large isotropy subgroups (but ones smaller than the full symmetry group). The theorems make this statement precise. In particular, they explain why rod and plate solutions occur for the buckling cube. Other general theorems help to determine whether a solution is stable or unstable.

6 Time-Periodic Solutions

A famous example of pattern formation is the Belousov-Zhabotinskii (or BZ) chemical reaction. This involves three chemicals together with an indicator that changes color from red to blue depending on whether the reaction is oxidizing or reducing. The chemicals are mixed together and placed in a shallow circular dish. They turn blue and then red. For a few minutes nothing seems to be happening; then tiny blue spots appear, which expand and turn into rings. As each ring grows, a new blue dot appears at its center. Soon the dish contains several expanding “target patterns” of rings. Unlike water waves, the patterns do not overlap and superpose. Instead, they meet to form angular junctions (figure 6(a)). Different target patterns expand at different rates, giving rings with differing thicknesses. However, each set of rings has a specific uniform speed of expansion, and the rings in that set all have the same width.

Another pattern can be created by breaking up a ring—by dragging a paperclip across it, for example. This new pattern curls up into a spiral (close to an Archimedean spiral with equally spaced turns), and the spiral slowly rotates about its center, winding more and more turns as it does so.

Neither pattern is an equilibrium, so the theorems alluded to above are not applicable. Instead, we can employ a different but related series of techniques. These apply to *time-periodic* solutions, which repeat their form at fixed intervals of time.

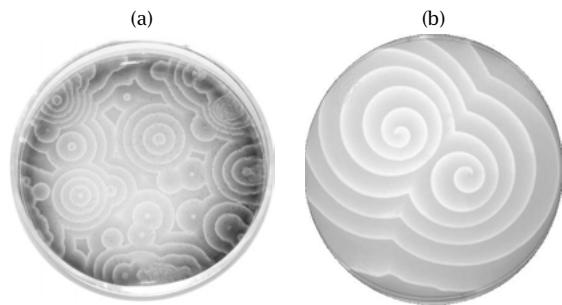

Figure 6 Patterns in the BZ reaction: (a) snapshot of several coexisting target patterns; (b) snapshot of two coexisting spirals.

There are two main types of bifurcation in which the fully symmetric steady state loses stability as a parameter is varied, with new solutions appearing nearby. One is a steady-state bifurcation (which we met above), for which these new solutions are equilibria. The other is HOPF BIFURCATION [IV.21 §2], for which the new solutions are time-periodic oscillations. Hopf bifurcation can occur for equations without symmetry, but there is a generalization to symmetric systems. The main new ingredient is that symmetries can now occur not just in space (the shape of the pattern) and time (integer multiples of the period make no difference), but in a combination of both.

A single target pattern in the BZ reaction has a purely spatial symmetry: at any instant in time it is unchanged under all rotations about its center. It also has a purely temporal symmetry: in an ideal version where the pattern fills the whole plane, it looks identical after a time that is any integer multiple of the period.

A single spiral, occupying the entire plane, has no nontrivial spatial symmetry, but it has the same purely temporal symmetry as a target pattern. However, it has a further *spatiotemporal symmetry* that combines both. As time passes, the spiral slowly rotates without changing form. That is, an arbitrary translation of time, combined with a rotation through an appropriate angle, leaves the spiral pattern (and how it develops over time) unchanged.

For symmetric equations there is a version of the Hopf bifurcation theorem that applies to spatiotemporal symmetries when there is a suitable symmetry-breaking bifurcation. Again, its statement is too technical to give here, but it helps to explain the BZ patterns. In conjunction with the theory for steady-state bifurcation, it can be used to understand pattern formation in many physical systems.

7 Taylor-Couette Revisited

The Taylor-Couette system is a good example of the symmetry-breaking approach. A standard model, derived from the Navier-Stokes equations for fluid flow, involves three types of symmetry.

Spatial: rotation about the common axis of the cylinders through any angle.

Temporal: shift time by an integer multiple of the period.

Model: translation along the common axis of the cylinders through any distance (a consequence of the assumption of periodic boundary conditions).

Using bifurcation theory and a few properties of the Navier-Stokes equations, the dynamics of this model for the Taylor-Couette system can be reduced to an ordinary differential equation (the so-called center manifold reduction) in six variables. Two of these variables correspond to a steady-state bifurcation from Couette flow to Taylor vortices. This is steady in the sense that the fluid *velocity* at any point remains constant. The other four variables correspond to a Hopf bifurcation from Couette flow to spirals. These are the two basic “modes” of the system, and their combination is called a mode interaction.

Symmetric bifurcation theory’s general theorems now prove the existence of numerous flow patterns, each with a specific isotropy subgroup. For example, if the rotational symmetry remains unbroken, but the group of translational symmetries breaks, a typical solution will have a specific translational symmetry, through some fraction of the length of the cylinder. All integer multiples of this translation are also symmetries of that solution. This combination of symmetries corresponds precisely to Taylor vortices; it leads to a discrete, repetitive pattern vertically, with no change in the horizontal direction.

A further breaking of the rotational symmetry produces a discrete set of rotational symmetries; these characterize wavy vortices. Symmetry under any rotation, if combined with a vertical translation through a corresponding distance, characterizes spiral vortices, and so on.

The only pattern in figure 3 that is not explained in this manner is the final one: turbulent vortices. This pattern turns out to be an example of symmetric chaos, chaotic dynamics that possesses “symmetry

on average.” At each instant the turbulent vortex state has no symmetry. But if the fluid velocity at each point is averaged over time, the result has the same symmetry as Taylor vortices. This is why the picture looks like Taylor vortices with random disturbances. A general theory of symmetric chaos also exists.

8 Conclusion

The symmetries of physical systems appear in the equations that model them. The symmetry affects the solutions of the equations, but it also provides systematic ways to solve them. One general area of application is pattern formation, and here the methods of symmetric bifurcation theory have been widely used. Topics include animal locomotion, speciation, hallucination patterns, the balance-sensing abilities of the inner ear, astrophysics, liquid crystals, fluid flow, coupled oscillators, elastic buckling, and convection.

In addition to a large number of specific applications, there are many other ways to exploit symmetry in applied mathematics. This article has barely scratched the surface.

IV.23 Quantum Mechanics

David Griffiths

Quantum mechanics makes use of a wide variety of tools and techniques from applied mathematics—linear algebra, complex variables, differential equations, Fourier analysis, group representations—but the mathematical core of the subject is the theory of eigenvectors and eigenvalues of self-adjoint operators in Hilbert space.

1 A Single Particle in One Dimension

Let us begin with the simplest mechanical system: a particle (which is physicists' jargon for an object so small, compared with other relevant distances, that it can be considered to reside at a single point) of mass m , constrained to move in one dimension (say, along the x -axis) under the influence of a specified force F (which may depend on position and time). The program of CLASSICAL MECHANICS [IV.19] is to determine the location of the particle at time t : $x(t)$. How do you calculate it? By applying Newton's second law of motion, $F = ma$ (or $d^2x/dt^2 = F/m$). If the force is conservative (nonconservative forces, such as friction, do not occur at a fundamental level), it can be expressed as the negative gradient of the *potential energy*, $V(x, t)$, and Newton's law becomes $d^2x/dt^2 = -m^{-1}\partial V/\partial x$. Together with appropriate initial conditions (typically, x and dx/dt at $t = 0$), this determines $x(t)$. From there it is easy to obtain the velocity ($v(t) \equiv dx/dt$), momentum ($p \equiv mv$), kinetic energy ($T \equiv \frac{1}{2}mv^2$), or any other dynamical quantity.

The program of quantum mechanics is quite different. Instead of $x(t)$, we seek the *wave function*, $\Psi(x, t)$, which we obtain by solving SCHRÖDINGER'S EQUATION [III.26],

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \frac{\partial^2 \Psi}{\partial x^2} + V(x, t)\Psi, \quad (1)$$

where $\hbar \equiv 1.05457 \times 10^{-34}$ J s is *Planck's constant*, the fingerprint of all quantum phenomena. Together with appropriate initial conditions (typically, $\Psi(x, 0)$) this determines $\Psi(x, t)$.

But what is this wave function, and how can it be said to describe the state of the particle? After all, as its name suggests, $\Psi(x, t)$ is spread out in space, whereas a particle, by its nature, is localized at a point. The answer is provided by Born's statistical interpretation of the wave function: $\Psi(x, t)$ tells you the *probability*

of finding the particle at the point x if you conduct a (competent) measurement at time t . More precisely, $\int_a^b |\Psi(x, t)|^2 dx$ is the probability of finding the particle between point a and point b . Evidently, the wave function must be *normalized*: $\int_{-\infty}^{\infty} |\Psi(x, t)|^2 dx = 1$ (the particle has got to be *somewhere*). Once normalized, at $t = 0$, Ψ remains normalized for all time.

The statistical interpretation introduces a kind of *indeterminacy* into the theory, in the sense that even if you know everything quantum mechanics has to tell you about the particle (to wit: its wave function), you still cannot predict with certainty the outcome of a measurement to determine its position—all quantum mechanics has to offer is *statistical* information about the results from an ensemble of identically prepared systems (each in the state Ψ).

The average, or *expectation value*, of x can be written in the form

$$\langle x \rangle = \int_{-\infty}^{\infty} \Psi(x, t)^* x \Psi(x, t) dx;$$

similarly, the expectation value of *momentum* is

$$\langle p \rangle = \int_{-\infty}^{\infty} \Psi(x, t)^* \left[-i\hbar \frac{\partial}{\partial x} \right] \Psi(x, t) dx.$$

This is a consequence of de Broglie's formula relating momentum to the wavelength (λ) of Ψ : $\lambda = 2\pi\hbar/p$. We say that the observables x and p are “represented” by the operators

$$\hat{x} \equiv x, \quad \hat{p} \equiv -i\hbar \frac{\partial}{\partial x}. \quad (2)$$

In general, a classical dynamical quantity $Q(x, p)$ is represented by the quantum operator

$$\hat{Q} \equiv Q(x, -i\hbar(\partial/\partial x))$$

(simply replace every p by \hat{p}), and its expectation value (in the state Ψ) is obtained by “sandwiching” \hat{Q} between Ψ and its conjugate Ψ^* , and integrating:

$$\langle Q \rangle = \int_{-\infty}^{\infty} \Psi(x, t)^* \hat{Q} \Psi(x, t) dx.$$

Thus, for example, kinetic energy $T = \frac{1}{2}mv^2 = p^2/2m$ is represented by the operator

$$\hat{T} = -\frac{\hbar^2}{2m} \frac{\partial^2}{\partial x^2},$$

and the Schrödinger equation can be written

$$i\hbar \frac{\partial \Psi}{\partial t} = \hat{H}\Psi,$$

where $\hat{H} = \hat{T} + \hat{V}$ is the *Hamiltonian operator*, representing the total energy.

If the potential energy is independent of time, the Schrödinger equation can be solved by separation of

variables: $\Psi(x, t) = e^{-iEt/\hbar}\psi(x)$, where E is the separation constant and $\psi(x)$ satisfies the *time-independent Schrödinger equation*:

$$\hat{H}\psi = -\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + V\psi = E\psi. \quad (3)$$

The expectation value of the total energy is

$$\begin{aligned} \langle H \rangle &= \int_{-\infty}^{\infty} \Psi(x, t)^* \hat{H} \Psi(x, t) dx \\ &= \int_{-\infty}^{\infty} \Psi(x, t)^* E \Psi(x, t) dx \\ &= E, \end{aligned}$$

hence the choice of the letter E .

Suppose, for example, the particle is attached to a spring of force constant k . Classically, this would be a simple harmonic oscillator, with potential energy $V(x) = \frac{1}{2}kx^2$, and the (time-independent) Schrödinger equation reads

$$-\frac{\hbar^2}{2m} \frac{d^2\psi}{dx^2} + \frac{1}{2}kx^2\psi = E\psi. \quad (4)$$

The normalized solutions have energies $E_n = (n + \frac{1}{2})\hbar\omega$ ($n = 0, 1, 2, \dots$) and are given by

$$\psi_n(x) = \frac{1}{\sqrt{2^n n! a \sqrt{\pi}}} e^{-x^2/2a^2} H_n(x/a),$$

where $\omega \equiv \sqrt{k/m}$ is the classical (angular) frequency of oscillation, $a \equiv \sqrt{\hbar/m\omega}$, and H_n is the n th HERMITE POLYNOMIAL [II.29]. (As a second-order ordinary differential equation, (4) admits two linearly independent solutions for every value of E , but all the other solutions are not normalizable, so they do not represent possible physical states.) The separable solutions of the time-dependent Schrödinger equation in this case are $\Psi_n(x, t) = e^{-iE_nt/\hbar}\psi_n(x)$. For instance, if the particle happens to be in the state $n = 0$, the probability of finding it outside the classical range ($\pm\sqrt{2E/k}$) is

$$2 \int_a^{\infty} |\Psi_0(x, t)|^2 dx = 1 - \text{erf}(1) = 0.1573,$$

where $\text{erf}(x) \equiv (2/\sqrt{\pi}) \int_0^x e^{-t^2} dt$ is the standard error function.

Of course, not all solutions to the Schrödinger equation are separable, but the separable solutions do constitute a complete set, in the sense that the most general (normalizable) solution can be expressed as a linear combination of them, $\Psi(x, t) = \sum_{n=0}^{\infty} c_n \Psi_n(x, t)$. Furthermore, they are orthonormal,

$$\int_{-\infty}^{\infty} \Psi_n(x, t)^* \Psi_m(x, t) dx = \delta_{nm},$$

where δ_{nm} is the KRONECKER DELTA [I.2 §2, table 3], so the expansion coefficients can be determined from the

initial wave function in the usual way:

$$c_n = \int_{-\infty}^{\infty} \Psi_n(x)^* \Psi(x, 0) dx.$$

2 States and Observables

Formally, the state of a system is represented, in quantum mechanics, by a vector in HILBERT SPACE [I.2 §19.4]. In *Dirac notation*, vectors are denoted by *kets* $|s\rangle$ and their duals by *bras* $\langle s|$; the inner product of $|s_a\rangle$ and $|s_b\rangle$ is written as a “bra(c)ket” $\langle s_a | s_b \rangle = \langle s_b | s_a \rangle^*$. For instance, the wave function $\Psi(x, t)$ resides in the (infinite-dimensional) space L^2 of square-integrable functions $f(x)$ on $-\infty < x < \infty$, with the inner product

$$\langle f_a | f_b \rangle \equiv \int_{-\infty}^{\infty} f_a(x)^* f_b(x) dx.$$

But there exist much simpler quantum systems in which the vector space is finite dimensional, and it pays to explore the general theory in this context first.

In an n -dimensional space a vector is conveniently represented by the column of its components (with respect to a specified orthonormal basis): $|s\rangle = (c_1, c_2, \dots, c_n)$ (as a column), $\langle s|$ is its conjugate transpose (a row), and $\langle s_a | s_b \rangle = \sum_{i=1}^n (c_a)_i^* (c_b)_i$ is their matrix product. *Observables* (measurable dynamical quantities) are represented by linear operators; for the system considered in section 1 they involve multiplication and differentiation, but in the finite-dimensional case they are matrices, $\hat{Q} \in \mathbb{C}^{n \times n}$ (with respect to a specified basis). In its most general form, the statistical interpretation reads as follows.

If you measure observable Q , on a system in the state $|s\rangle$, you will get one of the eigenvalues of \hat{Q} ; the probability of getting the particular eigenvalue λ_i is $|\langle v_i | s \rangle|^2$, where $|v_i\rangle$ is the corresponding normalized eigenvector, $\hat{Q}|v_i\rangle = \lambda_i|v_i\rangle$, with $\langle v_i | v_i \rangle = 1$. In the act of measurement the state “collapses” to the eigenvector, $|s\rangle \rightarrow |v_i\rangle$. (This ensures that an immediately repeated measurement—on the same particle—will return the same value.)

Of course, the outcome of a measurement must be a real number, and the probabilities must add up to 1. This is guaranteed if we stipulate that the operators representing observables be self-adjoint, i.e., $\langle s_a | \hat{Q} s_b \rangle = \langle \hat{Q} s_a | s_b \rangle$ for all vectors $|s_a\rangle$ and $|s_b\rangle$, which is to say that the matrix \hat{Q} is *Hermitian* (equal to its transpose conjugate). (Physicists’ notation is sloppy but harmless: technically, “ s ” is just the *name* of the

vector, and you cannot multiply a matrix by a name. But $|\hat{Q}s\rangle$ means $\hat{Q}|s\rangle$, of course, and $\langle\hat{Q}s|$ is its dual.)

The expectation value of Q , for a system in the state $|s\rangle$, is $\langle Q \rangle = \langle s | \hat{Q} | s \rangle$, and the *standard deviation* σ_Q —known informally as the *uncertainty* in Q , and sometimes written ΔQ —is given by

$$\sigma_Q^2 \equiv \langle (\hat{Q} - \langle Q \rangle)^2 \rangle = \langle \hat{Q}^2 \rangle - \langle Q \rangle^2.$$

It is zero if and only if $|s\rangle$ is an eigenvector of \hat{Q} (in which case a measurement is certain to return the corresponding eigenvalue). Because noncommuting operators do not admit common eigenvectors, it is not possible, in general, to construct states with definite values of two different observables (say, A and B). This is expressed quantitatively in the *uncertainty principle*:

$$\sigma_A \sigma_B \geq \frac{1}{2} |\langle [\hat{A}, \hat{B}] \rangle|, \quad (5)$$

where square brackets denote the *commutator*,

$$[\hat{A}, \hat{B}] \equiv \hat{A}\hat{B} - \hat{B}\hat{A}.$$

Consider, for example, a two-dimensional space in which the state is represented by a (normalized) *spinor*, $|s\rangle = (c_1, c_2)$, such that $|c_1|^2 + |c_2|^2 = 1$. The most general 2×2 Hermitian matrix has the form

$$\hat{Q} = \begin{pmatrix} a_0 + a_3 & a_1 - ia_2 \\ a_1 + ia_2 & a_0 - a_3 \end{pmatrix} = \sum_{i=0}^3 a_i \sigma_i,$$

where the a_i s are real numbers, σ_0 is the unit matrix, and the other three σ_i s are the *Pauli spin matrices*:

$$\sigma_1 \equiv \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \quad \sigma_2 \equiv \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \quad \sigma_3 \equiv \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}. \quad (6)$$

The Pauli matrices constitute a basis for the Lie algebra of $SU(2)$, the group of “special” (unimodular) unitary 2×2 matrices.

Suppose we measure the observable represented by σ_3 . According to the statistical interpretation, the outcome could be $+1$ with probability $P_+ = |c_1|^2$ or -1 with probability $P_- = |c_2|^2$, since the eigenvalues and eigenvectors in this case are obviously $\lambda_+ = +1$, with $|s_+\rangle = (1, 0)$, and $\lambda_- = -1$, with $|s_-\rangle = (0, 1)$. But what if we chose instead to measure σ_1 ? The eigenvalues are again ± 1 , but the (normalized) eigenvectors are now $|s_+\rangle = \frac{1}{\sqrt{2}}(1, 1)$ and $|s_-\rangle = \frac{1}{\sqrt{2}}(1, -1)$. The *possible* outcomes are the same as for σ_3 , but the *probabilities* are quite different: $P_+ = \frac{1}{2}|c_1 + c_2|^2$ and $P_- = \frac{1}{2}|c_1 - c_2|^2$. Clearly, a system cannot simultaneously be in an eigenstate of σ_3 and of σ_1 , and hence it cannot have definite values of both observables at the same time. What if I measure σ_3 and get (say) $+1$, and then you measure σ_1 and get (say) -1 . Does this

not mean that the system has definite values of both? No, because each measurement altered (collapsed) the state: $(c_1, c_2) \rightarrow (1, 0) \rightarrow \frac{1}{\sqrt{2}}(1, -1)$. If I now repeat my measurement of σ_3 , I am just as likely to get -1 as $+1$. It is not that I am *ignorant*—I know the state of the system precisely—but it simply does not *have* a definite value of σ_3 if it is in an eigenstate of σ_1 . Indeed, since $[\sigma_3, \sigma_1] = 2i\sigma_2$, the uncertainty principle says that $\Delta_1 \Delta_3 \geq |\langle \sigma_2 \rangle|$.

3 Continuous Spectra

In a *finite*-dimensional vector space every Hermitian matrix has a complete set of orthonormal eigenvectors, and implementation of the statistical interpretation is straightforward. But in an *infinite*-dimensional Hilbert space some or all of the eigenvectors may reside outside the space. For example, the eigenvectors of the position operator (2) are DIRAC DELTA FUNCTIONS [III.7]

$$x f_\lambda(x) = \lambda f_\lambda(x) \Rightarrow f_\lambda(x) = A \delta(x - \lambda), \quad (7)$$

which are not square integrable, so they do not live in L^2 and cannot represent physically realizable states. The same goes for momentum,

$$-i\hbar \frac{\partial f_\lambda}{\partial x} = \lambda f_\lambda \Rightarrow f_\lambda = A' e^{i\lambda x/\hbar}. \quad (8)$$

Evidently, a particle simply cannot have a definite position or momentum in quantum mechanics. Moreover, since \hat{x} and \hat{p} do not commute ($[\hat{x}, \hat{p}] = i\hbar$), (5) says that $\sigma_x \sigma_p \geq \frac{1}{2}\hbar$, which is the original *Heisenberg uncertainty principle*.

Even though the eigenfunctions of \hat{x} and \hat{p} are not possible physical states, they are complete and orthogonal; the wave function can be expanded as a linear combination of them, and the (absolute) square of the coefficient represents the probability density for a measurement outcome. Note that nonnormalizable eigenfunctions are associated with a continuous spectrum of eigenvalues; probabilities become probability densities, and discrete sums are replaced by integrals. Adopting the convenient Dirac convention $\langle f_\lambda | f'_\lambda \rangle = \delta(\lambda - \lambda')$ (so that $A = 1$ in (7) and $A' = 1/\sqrt{2\pi\hbar}$ in (8)), we have

$$\Psi(x, t) = \int c_\lambda f_\lambda(x) d\lambda$$

$$\Leftrightarrow c_\lambda = \int f_\lambda(x)^* \Psi(x, t) dx.$$

For eigenfunctions of position we get

$$c_\lambda = \int_{-\infty}^{\infty} \delta(x - \lambda) \Psi(x, t) dx = \Psi(\lambda, t),$$

which is to say that the expansion coefficient is precisely the wave function itself (and we recover Born's

original statistical interpretation). For eigenfunctions of momentum,

$$c_\lambda = \frac{1}{\sqrt{2\pi\hbar}} \int_{-\infty}^{\infty} e^{-i\lambda x/\hbar} \Psi(x, t) dx \equiv \Phi(\lambda, t),$$

which is the so-called *momentum space* wave function (mathematically, the Fourier transform of the position space wave function Ψ). Of course, Ψ and Φ describe the same state vector, referred to two different bases.

In general, $E \geq \min\{V(x)\}$; in the case of a free particle ($V = 0$) of energy $E \geq 0$, we have, from (3),

$$\frac{-\hbar^2}{2m} \frac{d^2\Psi}{dx^2} = E\Psi \Rightarrow \Psi(x) = Ae^{ikx},$$

so $\Psi(x, t) = Ae^{i(kx-Et/\hbar)}$, where $k^2 \equiv 2mE/\hbar^2$. If k is positive, Ψ is a wave propagating in the $+x$ direction (if k is negative, it travels in the $-x$ direction). However, Ψ is not normalizable, so it does not represent a possible physical state—there is *no such thing* as a free particle with precisely determined energy. But we can construct a normalizable *linear combination* of these states:

$$\Psi(x, t) = \int_{-\infty}^{\infty} c(k) e^{i(kx-k^2\hbar t/2m)} dk.$$

For instance, we might start with a *Gaussian wave packet* of width σ_0 :

$$\Psi(x, 0) = \frac{1}{(2\pi\sigma_0^2)^{1/4}} e^{-(x/2\sigma_0)^2} e^{ilx}.$$

Then $c(k) = (8\pi\sigma_0^2)^{1/4} e^{-[\sigma_0(k-l)]^2}$, so

$$\begin{aligned} \Psi(x, t) &= \frac{e^{-l^2\sigma_0^2}}{(2\pi\sigma_0^2)^{1/4}\sqrt{1+i\hbar t/2m\sigma_0^2}} \\ &\quad \times \exp\left\{\frac{[(ix+2l\sigma_0^2)/2\sigma_0]^2}{1+i\hbar t/2m\sigma_0^2}\right\}, \end{aligned}$$

and hence

$$|\Psi(x, t)|^2 = (2\pi\sigma^2)^{-1/2} \exp\{-2[(x-l\hbar t/m)/2\sigma]^2\},$$

where $\sigma(t) \equiv \sigma_0\sqrt{1+(\hbar t/2m\sigma_0^2)^2}$. The wave packet travels at speed $l\hbar/m$, spreading out as it goes. This is the quantum description of a free particle in motion.

Some Hamiltonians (e.g., the harmonic oscillator) have a discrete spectrum, with normalizable eigenstates; some (e.g., the free particle, $V = 0$) have a continuous spectrum and nonnormalizable eigenstates. Many systems have some of each. For example, the delta-function well, $V(x) = -\alpha\delta(x)$ (for some positive constant α), admits a single normalizable state $\psi(x) = (\sqrt{m\alpha}/\hbar)e^{-m\alpha|x|/\hbar^2}$ with energy $E = -m\alpha^2/2\hbar^2$. This represents a *bound state*: the particle is “stuck” in the well. If (as here) $V(x) \rightarrow 0$ as $|x| \rightarrow \infty$, a bound state is typically characterized by a negative energy. But the

delta-function well also admits *scattering states*, which have the form

$$\psi(x) = \begin{cases} Ae^{ikx} + Be^{-ikx}, & x \leq 0, \\ Fe^{ikx} + Ge^{-ikx}, & x \geq 0, \end{cases}$$

where $k \equiv \sqrt{2mE}/\hbar$ with $E > 0$. Here A is the amplitude of an incoming wave from the left, and G is the amplitude of an incoming wave from the right; B is an outgoing wave to the left, and F an outgoing wave to the right (remember, ψ is to be combined with the time-dependent factor $\exp(-iEt/\hbar)$). The outgoing amplitudes are determined from the incoming amplitudes by the boundary conditions at $x = 0$:

$$\Delta\psi = 0, \quad \Delta\left(\frac{d\psi}{dx}\right) = -\frac{2m\alpha}{\hbar^2}\psi(0).$$

In the typical case of a particle incident from the left, $G = 0$, and the *reflection coefficient* (the probability of reflection back to the left) is

$$R = \frac{|B|^2}{|A|^2} = \frac{1}{1 + (2\hbar^2E/m\alpha^2)},$$

while the *transmission coefficient* (the probability of transmission through to the right) is

$$T = \frac{|F|^2}{|A|^2} = \frac{1}{1 + (m\alpha^2/2\hbar^2E)}.$$

Naturally, $R + T = 1$. Of course, these scattering states are not normalizable, and to represent an actual particle we should, in principle, form normalizable linear combinations of them.

4 Three Dimensions

Quantum mechanics extends to three dimensions in the obvious way: $\partial^2/\partial x^2 \rightarrow \nabla^2$ (the three-dimensional Laplacian), and the time-independent Schrödinger equation becomes

$$-\frac{\hbar^2}{2m} \nabla^2 \psi + V\psi = E\psi.$$

We will use spherical coordinates (r, θ, ϕ) , where θ is the polar angle, measured down from the z -axis ($0 \leq \theta \leq \pi$), and ϕ is the azimuthal angle around from the x -axis ($0 \leq \phi < 2\pi$). In the typical case where V is a function only of r , we solve by separation of variables; $\psi(r, \theta, \phi) = (1/r)u(r)Y_l^m(\theta, \phi)$, where

$$Y_l^m(\theta, \phi) = (-1)^m \sqrt{\frac{(2l+1)}{4\pi} \frac{(l-m)!}{(l+m)!}} e^{im\phi} P_l^m(\cos \theta) \tag{9}$$

is a *spherical harmonic* ($l = 0, 1, 2, \dots$, $m = -l, \dots, l$), and P_l^m is an associated Legendre function. (Equation (9) applies for $m \geq 0$; for negative values, $Y_l^{-m} =$

$(-1)^m(Y_l^m)^*$.) Meanwhile, $u(r)$ satisfies the *radial equation*

$$-\frac{\hbar^2}{2m} \frac{d^2u}{dr^2} + \left[V + \frac{\hbar^2}{2m} \frac{l(l+1)}{r^2} \right] u = Eu, \quad (10)$$

which is identical to the one-dimensional Schrödinger equation, except that the effective potential energy carries an extra centrifugal term.

The spherical harmonics are eigenfunctions of the angular momentum operator, $\hat{L} \equiv \hat{\mathbf{r}} \times \hat{\mathbf{p}}$ ($\hat{L}_z = -i\hbar(x\partial/\partial y - y\partial/\partial x)$, and cyclic permutations thereof). The components of angular momentum do not commute,

$$[\hat{L}_i, \hat{L}_j] = i\hbar\hat{L}_k \text{ with } (ijk) = (xyz), \text{ etc.,} \quad (11)$$

so it would be futile to look for simultaneous eigenstates of all three. However, each component does commute with the square of the total angular momentum, $\hat{L}^2 \equiv \hat{L}_x^2 + \hat{L}_y^2 + \hat{L}_z^2$, so it is possible to construct simultaneous eigenfunctions of \hat{L}^2 and (say) \hat{L}_z . In spherical coordinates, \hat{L}^2 is $-\hbar^2$ times the Laplacian restricted to the unit sphere ($r = 1$), $\hat{L}_z = -i\hbar\partial/\partial\phi$, and spherical harmonics are their eigenstates:

$$\hat{L}^2 Y_l^m = \hbar^2 l(l+1) Y_l^m, \quad \hat{L}_z Y_l^m = \hbar m Y_l^m. \quad (12)$$

In addition to its orbital angular momentum, L , every particle carries an intrinsic *spin* angular momentum, S (distantly analogous to the daily rotation of the Earth on its axis, while the orbital angular momentum corresponds to its annual revolution about the sun). The components of \hat{S} satisfy the same fundamental commutation relations as \hat{L} , namely, $[\hat{S}_x, \hat{S}_y] = i\hbar\hat{S}_z$ (and its cyclic permutations), and admit the same eigenvalues (with s and m_s in place of l and m), $\hat{S}^2 |sm_s\rangle = \hbar^2 s(s+1) |sm_s\rangle$, and $\hat{S}_z |sm_s\rangle = \hbar m_s |sm_s\rangle$. However, whereas l can only be an integer, s can be an integer or a half-integer; it is a fixed number, for a given type of particle (0 for π mesons, $\frac{1}{2}$ for protons and electrons, 1 for photons, $\frac{3}{2}$ for the Ω^- , and so on); we call it the *spin* of the particle. In the case of spin $\frac{1}{2}$, there are just two possible values for m_s : $\frac{1}{2}$ ("spin up") and $-\frac{1}{2}$ ("spin down"), and the resulting two-dimensional state space is precisely the one we studied in section 2, with the association $\hat{S}_x = \frac{1}{2}\hbar\sigma_1$, $\hat{S}_y = \frac{1}{2}\hbar\sigma_2$, $\hat{S}_z = \frac{1}{2}\hbar\sigma_3$.

Hydrogen is the simplest atom, consisting of a single electron bound to a single proton by the electrical attraction of opposite charges. The proton is almost 2000 times heavier than the electron, so it remains essentially at rest, and the potential energy of the electron is given by Coulomb's law, $V(r) = -e^2/(4\pi\epsilon_0 r)$, where $e = 1.602 \times 10^{-19}$ C is the charge of the proton

($-e$ is the charge of the electron). The radial equation (10) reads

$$-\frac{\hbar^2}{2m} \frac{d^2u}{dr^2} + \left[-\frac{1}{4\pi\epsilon_0} \frac{e^2}{r} + \frac{\hbar^2}{2m} \frac{l(l+1)}{r^2} \right] u = Eu.$$

It admits a discrete set of bound states, with energies

$$E_n = \frac{E_1}{n^2}, \quad E_1 = -\frac{me^4}{2(4\pi\epsilon_0)^2\hbar^2} = -13.606 \text{ eV} \quad (13)$$

for $n = 1, 2, 3, \dots$ (as well as a continuum of scattering states with $E > 0$). The normalized wave functions are

$$\psi_{nlm} = \sqrt{\left(\frac{2}{na}\right)^3 \frac{(n-l-1)!}{2n[(n+l)!]^3}} \times e^{-r/na} \left(\frac{2r}{na}\right)^l \left[L_{n-l-1}^{2l+1}\left(\frac{2r}{na}\right)\right] Y_l^m, \quad (14)$$

where $L_q^p(x)$ is an associated LAGUERRE POLYNOMIAL [II.29], and $a \equiv 4\pi\epsilon_0\hbar^2/me^2 = 0.5292 \times 10^{-10}$ m is the Bohr radius.

The *principal quantum number*, n , tells you the energy of the state (13); the (misnamed) *azimuthal quantum number* l , which ranges from 0 to $n-1$, specifies the magnitude of the orbital angular momentum, and m gives its z component (12). Since $s = \frac{1}{2}$ for the electron, there are two linearly independent orientations for its spin. All told, the *degeneracy* of E_n (that is, the number of distinct states sharing this energy) is $2n^2$.

If the atom makes a transition, or "quantum jump," to a state with lower energy, a photon (quantum of light) is emitted, carrying the energy released. (With the absorption of a photon it could make a transition in the other direction.) The energy of a photon is related to its frequency ν by the Planck equation $E = 2\pi\hbar\nu$, so the *spectrum* of hydrogen is given by

$$\lambda^{-1} = R(n_{\text{final}}^{-2} - n_{\text{initial}}^{-2}), \quad (15)$$

with

$$R \equiv \frac{m}{4\pi c \hbar^3} \left(\frac{e^2}{4\pi\epsilon_0} \right)^2 = 1.097 \times 10^7 \text{ m}^{-1}, \quad (16)$$

where $\lambda = c/\nu$ is the wavelength (color) of the light. The *Rydberg formula* (15), with R as an empirical constant, was discovered experimentally in the nineteenth century; Bohr derived it (and obtained the expression for R) in 1913, using a serendipitous mixture of inapplicable classical physics and primitive quantum theory. Schrödinger put it on a rigorous theoretical footing in 1924.

5 Composite Structures

The theory generalizes easily to systems with more than one particle. For example, two particles in one dimension would be described by the wave function $\Psi(x_1, x_2, t)$, where

$$\int_{x_1=a_1}^{b_1} \int_{x_2=a_2}^{b_2} |\Psi(x_1, x_2, t)|^2 dx_1 dx_2$$

is the probability of finding particle 1 between a_1 and b_1 and particle 2 between a_2 and b_2 , if a measurement is made at time t .

But here quantum mechanics introduces a new twist: suppose the two particles are absolutely identical, so there is no way of knowing which is #1 and which #2. In classical physics such indistinguishability is unthinkable—you could always stamp a serial number on each particle. But you cannot put labels on electrons; they simply do not possess independent identities—the theory must treat the two particles on an equal footing. There are essentially two possibilities (others occur in special geometries): under interchange, Ψ can be symmetric, $\Psi(x_2, x_1) = \Psi(x_1, x_2)$ (*bosons*), or antisymmetric, $\Psi(x_2, x_1) = -\Psi(x_1, x_2)$ (*fermions*). Some elementary particles (electrons and quarks, for example) are fermions; others (photons and pions, for instance) are bosons. The distinction is related to the spin of the particle: particles of integer spin are bosons, whereas particles of half-integer spin are fermions. (This “connection between spin and statistics” can be proved using relativistic quantum mechanics, but in the nonrelativistic theory it is simply an empirical fact.)

Suppose we have two particles, one in state $\psi_a(x)$ and the other in state $\psi_b(x)$. If the particles are distinguishable (an electron and a proton, say) and the first is in state ψ_a , then the composite wave function is $\psi(x_1, x_2) = \psi_a(x_1)\psi_b(x_2)$. But if they are identical bosons (two pions, say), we must use the symmetric combination,

$$\psi(x_1, x_2) = \frac{1}{\sqrt{2}}[\psi_a(x_1)\psi_b(x_2) + \psi_a(x_2)\psi_b(x_1)],$$

and for identical fermions (two electrons, say),

$$\psi(x_1, x_2) = \frac{1}{\sqrt{2}}[\psi_a(x_1)\psi_b(x_2) - \psi_a(x_2)\psi_b(x_1)].$$

(The normalization factor $1/\sqrt{2}$ assumes that ψ_a and ψ_b are orthonormal.)

For example, we might calculate the expectation value of the square of the separation distance between the two particles. If they are distinguishable, then

$$\langle (x_1 - x_2)^2 \rangle = \langle x^2 \rangle_a + \langle x^2 \rangle_b - 2\langle x \rangle_a \langle x \rangle_b \equiv \Delta^2,$$

where $\langle x \rangle_a$ is the expectation value of x for a particle in the state ψ_a , and so on. If, however, the particles are identical bosons, then there is an extra term $\langle (x_1 - x_2)^2 \rangle = \Delta^2 - 2|\langle x \rangle_{ab}|^2$, and if they are identical fermions, then $\langle (x_1 - x_2)^2 \rangle = \Delta^2 + 2|\langle x \rangle_{ab}|^2$, where

$$\langle x \rangle_{ab} \equiv \int x \psi_a(x)^* \psi_b(x) dx.$$

Thus bosons tend to be closer together, and fermions farther apart, than distinguishable particles in the same two states. It is as if there were an attractive force between identical bosons and a repulsive force between identical fermions. We call these *exchange forces*, though there is no actual force involved—it is just an artifact of the (anti)symmetrization requirement. Exchange forces are responsible for ferromagnetism, and they contribute to *covalent bonding*. (If you include spin, it is the *total* wave function that must be antisymmetrized; if the spin part is antisymmetric, then the position wave function must actually be symmetric (for fermions), and the exchange force is attractive. Covalent bonding occurs when shared electrons cluster in the region between two nuclei, tending to pull them together.)

The (anti)symmetrization requirement gives rise to very different statistical mechanics for bosons and fermions. In particular, two identical fermions cannot occupy the same state, since if $\psi_a = \psi_b$ the composite wave function $\psi(x_1, x_2)$ vanishes. This is the famous *Pauli exclusion principle*. There is no such rule for bosons, and at extremely low temperatures identical bosons tend to congregate in the ground state, forming a *Bose-Einstein condensate*. In a large sample at (absolute) temperature T , the most probable number of particles in a (one-particle) state with energy E is

$$n(E) = \begin{cases} e^{-(E-\mu)/kT}, & \text{Maxwell-Boltzmann,} \\ \frac{1}{e^{(E-\mu)/kT} + 1}, & \text{Fermi-Dirac,} \\ \frac{1}{e^{(E-\mu)/kT} - 1}, & \text{Bose-Einstein.} \end{cases}$$

Here, $k = 1.3807 \times 10^{-23}$ J K⁻¹ is Boltzmann's constant, and μ is the *chemical potential*—it is a function of temperature and depends on the nature of the particles. The Maxwell-Boltzmann distribution (the classical result) applies to distinguishable particles, the Fermi-Dirac distribution is for identical fermions, and the Bose-Einstein distribution is for identical bosons.

The Pauli principle is crucial in accounting for the periodic table of the elements. Atoms are labeled by their atomic number Z , the number of protons in the nucleus, which is also the number of electrons in orbit

(the number of neutrons distinguishes different *isotopes*). Since the nucleus remains essentially at rest, only the behavior of the electrons is at issue in atomic physics. Hydrogen has one electron, helium has two (and two protons in the nucleus), lithium three, and so on. Ordinarily, each electron will settle into the lowest-energy accessible state. But the Pauli principle forbids any given state from being occupied by more than one electron, so they fill up the allowed states in succession, and this means that the outermost (valence) electrons (which are responsible for chemical behavior) are differently situated for different elements.

The Hamiltonian for an atom with atomic number Z is

$$\hat{H} = \sum_{j=1}^Z \left\{ -\frac{\hbar^2}{2m} \nabla_j^2 - \frac{1}{4\pi\epsilon_0} \frac{Ze^2}{r_j} \right\} + \frac{e^2}{8\pi\epsilon_0} \sum_{k \neq j}^Z \frac{1}{|\mathbf{r}_j - \mathbf{r}_k|},$$

where \mathbf{r}_j is the position of the j th electron, $r_j = |\mathbf{r}_j|$, and ∇_j^2 is the Laplacian with respect to \mathbf{r}_j . The term in curly brackets represents the kinetic and potential energy of the j th electron in the electric field of the nucleus, and the other term is the potential energy associated with the mutual repulsion of the electrons. (A tiny relativistic correction and magnetic coupling between the spin of the electron and the orbital motion account for *fine structure*, while an even smaller magnetic coupling between the spin of the electron and the spin of the nucleus leads to *hyperfine structure*.)

If we ignore the electron-electron repulsion altogether, we simply have Z independent electrons, each in the field of a nucleus of charge Ze ; we simply copy the results for hydrogen, replacing e^2 by Ze^2 . The first two electrons would occupy the *orbital*, $n = 1$, $l = 0$, $m = 0$, the next eight fill out the $n = 2$ orbitals, and so on. This simple scheme explains the first two rows of the periodic table (up through neon). One would anticipate a third row of eighteen, but after argon the electron-electron repulsion finally catches up, and potassium skips to $n = 4$, $l = 0$ for the next electron, in preference to $n = 3$, $l = 2$. The details get complicated and are handled by sophisticated approximation schemes (hydrogen is the only atom for which the Schrödinger equation can be solved analytically).

The addition of angular momenta is an interesting problem in quantum mechanics. Suppose I want to combine $|l_1 m_1\rangle$ with $|l_2 m_2\rangle$; what is the resulting combined state, $|lm\rangle$? For instance, the electron in a hydrogen atom has orbital angular momentum and spin angular momentum; what is its total angular momentum? (I will use l as the generic letter for the angular

momentum quantum number—it could be orbital, or spin, or total, as the case may be.) Because $\mathbf{L} = \mathbf{L}_1 + \mathbf{L}_2$, the z components add: $m = m_1 + m_2$. But the total angular momentum quantum number l depends on the relative orientation of \mathbf{L}_1 and \mathbf{L}_2 , and it can range from $|l_1 - l_2|$ (roughly speaking, when they are antiparallel) to $l_1 + l_2$ (parallel), in integer steps:

$$l = -|l_1 - l_2|, -|l_1 - l_2| + 1, \dots, l_1 + l_2 - 1, l_1 + l_2.$$

Specifically,

$$|l_1 m_1\rangle |l_2 m_2\rangle = \sum_{l=|l_1-l_2|}^{l_1+l_2} C_{m_1 m_2 m}^{l_1 l_2 l} |lm\rangle,$$

where $C_{m_1 m_2 m}^{l_1 l_2 l}$ are the so-called *Clebsch-Gordan coefficients*, which are tabulated in many handbooks. Mathematically, what we are doing is decomposing the direct product of two irreducible representations of $SU(2)$ (the covering group for $SO(3)$, the rotation group in three dimensions) into a direct sum of irreducible representations. For instance,

$$|2 1\rangle | \frac{1}{2} \frac{1}{2} \rangle = \sqrt{\frac{4}{5}} | \frac{5}{2} \frac{3}{2} \rangle - \sqrt{\frac{1}{5}} | \frac{3}{2} \frac{3}{2} \rangle.$$

If you had a hydrogen atom in the state Y_1^2 , and the electron had spin up ($m_s = \frac{1}{2}$), the probability is $\frac{4}{5}$ that a measurement of the total \hat{l} would return the value $\frac{5}{2}$ and $\frac{1}{5}$ that it would yield $\frac{3}{2}$ (a measurement of m would be certain to give $\frac{3}{2}$). The Clebsch-Gordan coefficients work the other way, too. If I have a system in the angular momentum state $|lm\rangle$, composed of two particles with l_1 and l_2 , and I want to know the possible values of m_1 and m_2 , I would use

$$|lm\rangle = \sum_{m_1=-l_1}^{l_1} \sum_{m_2=-l_2}^{l_2} C_{m_1 m_2 m}^{l_1 l_2 l} |l_1 m_1\rangle |l_2 m_2\rangle,$$

where the sum is over all combinations of m_1 and m_2 such that $m_1 + m_2 = m$.

6 Implications, Applications, Extensions

In quantum mechanics the state of a system is represented by a (normalized) vector ($|s\rangle$) in Hilbert space; observables are represented by (self-adjoint) operators acting on vectors in this space. The theory rests on three pillars: the Schrödinger equation, which in its most general form tells you how the state vector $|s\rangle$ evolves in time,

$$i\hbar \frac{\partial}{\partial t} |s\rangle = \hat{H} |s\rangle; \quad (17)$$

the statistical interpretation, which tells you how $|s\rangle$ determines the outcome of a measurement; and the (anti)symmetrization requirement, which tells you how

to construct $|s\rangle$ for a collection of identical particles. Although the calculational procedures are unambiguous and the results are in spectacular agreement with experiment, the physical interpretation of quantum mechanics (the story we tell ourselves about what we are doing) has always been controversial. Some of the major issues are listed below.

Indeterminacy. Einstein argued—most persuasively in the famous *EPR* (Einstein–Podolsky–Rosen) *paradox*—that quantum indeterminacy means the theory is *incomplete*; other information (so-called *hidden variables*) must supplement the state vector to provide a full description of physical reality. By contrast, Bohr’s *Copenhagen interpretation* holds that systems simply do not have definite properties (such as position or angular momentum) prior to measurement.

Nonlocality. The EPR argument is predicated on an assumption of *locality*: no influence can propagate faster than light. But in quantum mechanics, two particles can be *entangled* such that a measurement on one determines the state of the other and, if they are far apart, then that “influence” (the collapse of the wave function) is instantaneous. In 1964 John Bell proved that no local deterministic (hidden-variable) theory can be compatible with quantum mechanics. In subsequent experiments the quantum mechanical predictions were sustained. Evidently, nonlocality is a fact of nature, though the “influences” in question are not strictly causal—they produce no effects that can be discerned by examining the second particle alone. (A *causal* nonlocal influence would be incompatible with special relativity.)

Measurement. It has never been clear what constitutes a “measurement,” as the word is used in the statistical interpretation. Why does a measurement force the system (which previously did not possess a determinate value of the observable in question) to “take a stand,” and how does it collapse the wave function? Does “measurement” mean something people in white coats do in the laboratory, or can it occur in a forest, when no one is looking? Does measurement require the leaving of a permanent record or the interaction of a microscopic system with a macroscopic device? Does it involve the intervention of human consciousness? Or does it perhaps split reality into many worlds? After nearly a century of debate, there is no consensus on these questions.

Decoherence. If an electron can have an indeterminate position, what about a baseball? Could a baseball be

in a linear combination of Seattle and San Francisco (until, I guess, the batters swing, and there is a home run in Seattle and nothing at all in San Francisco)? There is something absurd about the very idea of a macroscopic object being in two places at once (or an animal—in Schrödinger’s famous *cat paradox*—being both alive and dead). Why do macroscopic objects obey the familiar classical laws, while microscopic objects are subject to the bizarre rules of quantum mechanics? Presumably if you *could* put a baseball into a state that stretched from Seattle to San Francisco, its wave function would very rapidly *decohere* into a state localized at some specific place. By what mechanism? Maybe multiple interactions with random impinging particles (photons left over from the Big Bang, perhaps) constitute a succession of “measurements” and collapse the wave function. But the details remain frustratingly elusive.

I have mentioned two kinds of solutions to the Schrödinger equation, for time-independent potentials: (normalizable) bound states, at discrete negative energies, and (nonnormalizable) scattering states, at a continuum of positive energies. There is a third important case, which occurs for periodic potentials, $V(x + a) = V(x)$, as in a crystal lattice. For these the spectrum forms *bands*, with continua of allowed energies separated by forbidden gaps. This band structure is crucial in accounting for the behavior of solids and underlies most of modern electronics.

Very few quantum problems can be solved exactly, so a number of powerful approximation methods have been developed. Here are some examples.

The variational principle. The lowest eigenvalue of a Hamiltonian \hat{H} is less than or equal to the expectation value of \hat{H} in *any* normalized state $|s\rangle$:

$$E_0 \leq \langle s | \hat{H} | s \rangle. \quad (18)$$

To get an upper bound on the ground-state energy of a system, then, you simply pick any (normalized) vector $|s\rangle$ and calculate $\langle s | \hat{H} | s \rangle$ in that state. Ordinarily, you will get a tighter bound if your “trial state” bears some resemblance to the actual ground state. In a typical application the trial state carries a number of adjustable parameters, which are then chosen so as to minimize $\langle \hat{H} \rangle$. The binding energy of helium, for example, has been calculated in this way and is consistent with the measured value to better than eight significant digits.

Time-independent perturbation theory. Suppose you know the eigenstates $\{|n\rangle\}$ and eigenvalues $\{E_n\}$ of some (time-independent) Hamiltonian H . Now you perturb that Hamiltonian slightly, $H \rightarrow H + H'$. The resulting change in the n th eigenvalue is approximately equal to the expectation value of \hat{H}' in the unperturbed state $|n\rangle$:

$$\Delta(E_n) \approx \langle n | \hat{H}' | n \rangle. \quad (19)$$

For example, the fine structure of hydrogen can be calculated very accurately in this way, starting with the wave functions in (14).

Time-dependent perturbation theory. Again, suppose you know the eigenstates and eigenvalues of some time-independent Hamiltonian, and now you (briefly) turn on a small time-dependent perturbation, $H'(t)$. What is the transition rate (probability per unit time) to go from state $|n\rangle$ to state $|m\rangle$? The answer is given by

$$R_{n \rightarrow m} = \frac{2\pi}{\hbar} |H'_{mn}|^2 \rho(E_m),$$

where $H'_{mn} \equiv \langle m | \hat{H}' | n \rangle$ is the so-called *matrix element* for the transition, and ρ is the *density of states*—the number of states per unit energy. Fermi called this the *golden rule*. It is used, for example, to calculate the lifetime of an excited state.

In two important respects quantum mechanics is obviously not the end of the story. First of all, the Schrödinger equation as it stands is inconsistent with special relativity—as a differential equation it is second order in x but first order in t , whereas relativity requires that they be treated on an equal footing. Dirac introduced the eponymous relativistic equation for particles of spin $\frac{1}{2}$ (the DIRAC EQUATION [III.9]) and others followed (Klein-Gordon for spin 0, Proca for spin 1, and so on). Second, while the *particles* have been treated quantum mechanically, the *fields* have not. In the hydrogen atom, for example, the electric potential energy was taken from classical electrostatics. In a fully consistent theory the fields, too, must be quantized. The quantum of the electromagnetic field is the photon, but although I have used this word once or twice, it has no place in quantum mechanics; it belongs instead to quantum field theory (specifically *quantum electrodynamics*). In the *standard model* of elementary particles, all known interactions save gravity are successfully handled by relativistic quantum field theory. But a fully consistent union of quantum mechanics and GENERAL RELATIVITY [IV.40] (Einstein's theory of gravity) still does not exist.

IV.24 Random-Matrix Theory

Jonathan Peter Keating

1 Introduction

Linear algebra and the analysis of systems of linear equations play a central role in applied mathematics; for example, QUANTUM MECHANICS [IV.23] is a linear wave theory in which observables are represented by linear operators; linear models are fundamental in electromagnetism, acoustics, and water waves; and linearization is important in stability analysis. When a linear system is intrinsically complex, either by virtue of external stochastic forcing or because of an underlying, persistent self-generated instability, it is natural to model it statistically by assuming that the elements of the matrices that appear in its mathematical description are in some sense random. This is similar, philosophically, to the way in which statistical features of long trajectories in complex dynamical systems are modeled statistically via notions of ergodicity and mixing. An example is when classical dynamics is modeled by statistical mechanics, that is, where one deduces statistical properties of the solutions of systems of equations, in this case Newton's equations of motion, by analyzing ensembles of similar trajectories and invoking notions of ergodicity (that time averages equal ensemble averages in the appropriate limit).

This is one significant motivation for exploring the properties of random matrices. There are, however, many others: linear algebra and probabilistic models both play a foundational role in mathematics, and it is therefore not surprising that they combine in a wide range of applications, including mathematical biology, financial mathematics, high-energy physics, condensed matter physics, numerical analysis, neuroscience, statistics, and wireless communications.

In many of the examples listed above, one has a system of linear equations that can be written in matrix

form. One might then be interested in the eigenvalues or eigenvectors of the matrix in question, if it is square. For example, one might want to know the range of the spectrum, its density within that range, and the nature of fluctuations/correlations in the positions of the eigenvalues. Alternatively, one might want an estimate of the condition number of the matrix or the values taken by its characteristic polynomial.

If the matrix possesses no special features—that is, if its entries do not obey simple rules—it is natural to consider whether it behaves like one that is a “typical” member of some appropriate class of matrices. This again motivates the study of random matrices, that is, matrices whose entries are random variables.

The basic formulation of random-matrix theory is that one has a space of matrices X endowed with a probability measure $P(X)$. This is termed a matrix *ensemble*. We shall here focus on square matrices of dimension N . One can then seek to determine the probability distribution of the eigenvalues and eigenvectors, and of other related quantities of interest. The motivation is that in many cases one can prove that spectral averages for a given matrix coincide, with probability 1, with ensemble averages, when $N \rightarrow \infty$.

The following are examples of such matrix ensembles.

- Let X be an $N \times N$ matrix with real or complex-valued entries X_{mn} satisfying $X_{mn} = \bar{X}_{nm}$ (so the matrix is either real symmetric or complex Hermitian). Take the entries X_{nm} , $n < m$, to be independent zero-mean real or complex-valued random variables, and the entries X_{nn} to be independent, identically distributed, centered real-valued random variables, so $P(X)$ factorizes as $P(X) = \prod_{m \leq n} P_{mn}(X_{mn})$. This defines the ensemble of *Wigner random matrices*.
- Let X be an $N \times N$ real symmetric matrix. When the probability measure is invariant under all orthogonal transformations of X , i.e., when $P(OXO^T) = P(X)$ for all orthogonal ($OO^T = I$) matrices O , then the ensemble is called *orthogonal invariant*.
- Let X be an $N \times N$ complex Hermitian matrix. When the probability measure is invariant under all unitary transformations of X , i.e., when $P(UXU^\dagger) = P(X)$ for all unitary ($UU^\dagger = I$) matrices U , then the ensemble is called *unitary invariant*.
- The *Gaussian orthogonal ensemble* (GOE) is the (unique) orthogonal invariant ensemble of Wigner random matrices. It has $P(X) \propto \exp(-\frac{1}{4} \text{Tr } X^2)$.

Similarly, the *Gaussian unitary ensemble* (GUE) is the (unique) unitary invariant ensemble of Wigner random matrices. It has $P(X) \propto \exp(-\frac{1}{2} \text{Tr } X^2)$.

- The most general class of random $N \times N$ matrices corresponds to taking the matrix elements X_{mn} to be real or complex-valued independent identically distributed random variables with, for example, zero mean and unit variance. When these random variables have a Gaussian distribution, the matrices form what is known as the *Ginibre ensemble*.
- The *circular ensembles* correspond to $N \times N$ unitary matrices with probability measures that are invariant under all orthogonal (COE) or unitary (CUE) transformations. Matrices in the COE are unitary and symmetric. Alternatively, one can consider ensembles corresponding to the Haar measure on the classical compact groups (i.e., the measure that is invariant under the group action): for example, the orthogonal group $O(N)$, comprising $N \times N$ orthogonal matrices, or the unitary group $U(N)$, which coincides with the CUE, or the symplectic group $\text{Sp}(2N)$.
- Let X be an $N \times k$ matrix, each row of which is drawn independently from a k -variate normal distribution with zero mean. The *Wishart ensemble* corresponds to the matrices $X^T X$.

These are far from being the only examples that are important—one can also define random matrices whose elements are quaternionic, or which have additional structure (i.e., invariance under additional symmetries)—but they will suffice to illustrate a number of general questions and themes.

For any of the above ensembles of random matrices, one can first ask where the eigenvalues typically lie, and what their mean density is. In ensembles where the eigenvalues are real, for example, how many can one expect to find in a given interval on average? One can, in particular, ask whether there is a limiting density when the matrix size tends to infinity.

Second, one can seek to understand fluctuations about the mean in the eigenvalue distribution. For example, in an interval of length such that the expected number of eigenvalues is k , what is the distribution of the actual numbers in the interval for different matrices in the ensemble? Again, is there a limiting distribution when the matrix size tends to infinity? Or, similarly, how do the gaps between adjacent eigenvalues fluctuate around their mean? How, if at all, are eigenvalues

Figure 1 The spectrum of a randomly chosen complex Hermitian (GUE) matrix of dimension $N = 20$.

correlated on the scale of their mean spacing? How are other functions over the ensemble distributed? For example, the values of the characteristic polynomials of the matrices, their traces, their condition numbers, the sizes of the largest and smallest eigenvalues?

Third, how do the answers to these questions depend on the particular choice of probability measure intrinsic to the definition of a given ensemble, and on the symmetries (if any) of the matrices involved? If they depend on the choice of the probability measure, then how do they? Is there a class of probability measures for which they can be said to be *universal* in an appropriate limit? Are there choices of probability measure that are in some sense exactly solvable?

Fourth, given answers to questions such as these, how can they be used to shed light on applications?

Our aim here is to give an introductory overview of some of these issues.

In order to motivate and illustrate the theory, it may be helpful to anticipate it with the results of some numerical computations. Figure 1 shows the spectrum of a complex Hermitian matrix of dimension $N = 20$, picked at random from the GUE by generating normal random variables to fill the independent matrix entries. One sees that the spectrum is denser at the center than at the edges and that the eigenvalues do not often lie close to each other.
